$$\begin{aligned} & \begin{bmatrix} \langle a, 1|\psi \rangle \\ \langle a, 2|\psi \rangle \\ \langle a, 3|\psi \rangle \\ \vdots \\ \langle a, n|\psi \rangle \end{bmatrix} \\ &= \begin{bmatrix} \langle a, 1|b, 1 \rangle & \langle a, 1|b, 2 \rangle & \langle a, 1|b, 3 \rangle & \dots & \langle a, 1|b, n \rangle \\ \langle a, 2|b, 1 \rangle & \langle a, 2|b, 2 \rangle & \langle a, 2|b, 3 \rangle & \dots & \langle a, 2|b, n \rangle \\ \langle a, 3|b, 1 \rangle & \langle a, 3|b, 2 \rangle & \langle a, 3|b, 3 \rangle & \dots & \langle a, 3|b, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle a, n|b, 1 \rangle & \langle a, n|b, 2 \rangle & \langle a, n|b, 3 \rangle & \dots & \langle a, n|b, n \rangle \end{bmatrix} \\ &\quad \times \begin{bmatrix} \langle b, 1|\psi \rangle \\ \langle b, 2|\psi \rangle \\ \langle b, 3|\psi \rangle \\ \vdots \\ \langle b, n|\psi \rangle \end{bmatrix} \end{aligned} \quad (22a)$$

$$\begin{aligned} & [\langle \psi|a, 1 \rangle \quad \langle \psi|a, 2 \rangle \quad \langle \psi|a, 3 \rangle \quad \dots \quad \langle \psi|a, n \rangle] \\ &= [\langle \psi|b, 1 \rangle \quad \langle \psi|b, 2 \rangle \quad \langle \psi|b, 3 \rangle \quad \dots \quad \langle \psi|b, n \rangle] \\ &\quad \times \begin{bmatrix} \langle b, 1|a, 1 \rangle & \langle b, 1|a, 2 \rangle & \langle b, 1|a, 3 \rangle & \dots & \langle b, 1|a, n \rangle \\ \langle b, 2|a, 1 \rangle & \langle b, 2|a, 2 \rangle & \langle b, 2|a, 3 \rangle & \dots & \langle b, 2|a, n \rangle \\ \langle b, 3|a, 1 \rangle & \langle b, 3|a, 2 \rangle & \langle b, 3|a, 3 \rangle & \dots & \langle b, 3|a, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle b, n|a, 1 \rangle & \langle b, n|a, 2 \rangle & \langle b, n|a, 3 \rangle & \dots & \langle b, n|a, n \rangle \end{bmatrix} \end{aligned} \quad (22b)$$

Note that the columns of the first transformation matrix are merely the representation of the b basis kets in the a basis, while the rows are the representation of the a bras in the b basis. The second transformation matrix is the adjoint (complex conjugate transpose) of the first. If the two matrices are multiplied in either order, the result is a unit matrix, because the basis states are normalized. But this is just the definition of a unitary matrix. In compact matrix notation, we have

$$\psi_a = \mathbf{T}\psi_b, \quad \psi_a^\dagger = \psi_b^\dagger \mathbf{T}^\dagger \quad (23)$$

The unitary nature of the transformation is expressed as

$$\mathbf{T}\mathbf{T}^\dagger = \mathbf{T}^\dagger\mathbf{T} = \mathbf{E} = \mathbf{T}\mathbf{T}^{-1} = \mathbf{T}^{-1}\mathbf{T} \quad (24)$$

From these two equations, it is evident that the normalization of the state is preserved, regardless of the representation used:

$$\psi_a^\dagger \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b^\dagger \psi_b \quad (25)$$

The inverse transformation can easily be derived. If $\psi_a = \mathbf{T}\psi_b$ then we have

$$\mathbf{T}^{-1}\mathbf{T}\psi_b = \mathbf{T}^{-1}\psi_a, \quad \psi_b = \mathbf{T}^{-1}\psi_a \quad (26)$$

But the inverse transformation is

$$\begin{aligned} |\psi\rangle &= \sum_{i=1}^n \langle a, i|\psi\rangle |a, i\rangle \\ &= \sum_{i=1}^n \langle a, i|\psi\rangle \sum_{j=1}^n \langle b, j|a, i\rangle |b, j\rangle \\ &= \sum_{i,j=1}^n \langle b, j|a, i\rangle \langle a, i|\psi\rangle |b, j\rangle \end{aligned} \quad (27)$$

Comparing equations (21a) and (27), the relationship between the a to b and b to a transforms is found to be

$$T_{ji}^* = \langle b, i|a, j\rangle^* = \langle a, j|b, i\rangle = T_{ij}^\dagger \quad (28)$$

which shows that the inverse transformation matrix $\mathbf{T}^{-1}$ is just the adjoint of the original matrix—but this is again just the definition of a unitary matrix. Examining equations (22a) and (22b), it is clear that the complex conjugate transpose of the transformation matrix is, indeed, the desired inverse transformation. This may be shown more easily by noting from equation (24) that $\mathbf{T}^\dagger = \mathbf{T}^{-1}$. Then, from equation (23), we have

$$\left. \begin{aligned} \mathbf{T}^\dagger \psi_a &= \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b \\ \psi_a^\dagger \mathbf{T} &= \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} = \psi_b^\dagger \end{aligned} \right\} \quad (29)$$

We now turn to some relationships involving operators. Suppose one has some arbitrary operator $\hat{O}$. Using equation (19), we can write

$$\begin{aligned} \hat{O} &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) \hat{O} \left(\sum_{j=1}^n |j\rangle \langle j| \right) \\ &= \sum_{i,j=1}^n |i\rangle \langle i| \hat{O} |j\rangle \langle j| \\ &= \sum_{i,j=1}^n \langle i| \hat{O} |j\rangle |i\rangle \langle j| \\ &= \sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \end{aligned} \quad (30)$$

A unit operator can be inserted anywhere without affecting the equality. This equation is a prescription for writing any operator as a sum of operators $|i\rangle \langle j|$. Clearly, if there are n basis states $|i\rangle$ then there are n^2 basis operators $|i\rangle \langle j|$. If we multiply this equation from the left and right by a basis state, the result is a prescription for the coefficients c_{ij} :

$$\begin{aligned} \langle k| \hat{O} |l\rangle &= \langle k| \left(\sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \right) |l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \langle k|i\rangle \langle j|l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \delta_{ki} \delta_{jl} = c_{kl} \end{aligned} \quad (31)$$

These coefficients are commonly called the *matrix elements* of the operator, and can be arranged in a matrix to form a Hilbert space representation of the operator:

$$\hat{O} \xrightarrow{|i\rangle} \mathbf{O} = \begin{bmatrix} \langle 1|\hat{O}|1\rangle & \langle 1|\hat{O}|2\rangle & \langle 1|\hat{O}|3\rangle & \dots & \langle 1|\hat{O}|n\rangle \\ \langle 2|\hat{O}|1\rangle & \langle 2|\hat{O}|2\rangle & \langle 2|\hat{O}|3\rangle & \dots & \langle 2|\hat{O}|n\rangle \\ \langle 3|\hat{O}|1\rangle & \langle 3|\hat{O}|2\rangle & \langle 3|\hat{O}|3\rangle & \dots & \langle 3|\hat{O}|n\rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|\hat{O}|1\rangle & \langle n|\hat{O}|2\rangle & \langle n|\hat{O}|3\rangle & \dots & \langle n|\hat{O}|n\rangle \end{bmatrix} \quad (32)$$

Proceeding as in equation (25), we can write

$$\psi_a^\dagger \mathbf{O}_a \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \psi_b = \psi_b^\dagger \mathbf{O}_b \psi_b \quad (33)$$

where we have defined the operator in the b basis as

$$\mathbf{O}_b = \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \quad (34)$$

Analogously, the basis operators themselves can be represented as follows to yield a matrix of all zero elements except the ij th:

$$\begin{aligned} |i\rangle\langle j| \xrightarrow{|i\rangle} & \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 & \dots & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 & \dots & 0 \end{bmatrix} \end{aligned} \quad (35)$$

This result can also be obtained from equations (17a) and (17b) by writing

$$\begin{aligned} & \begin{bmatrix} \langle 1|i\rangle \\ \langle 2|i\rangle \\ \vdots \\ \langle j|i\rangle \\ \vdots \\ \langle n|i\rangle \end{bmatrix} [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ &= \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \end{aligned} \quad (36)$$

The basis operators are orthogonal, just as the basis states are; however, the inner product exemplified by equation (11) must

be replaced by the trace operation:

$$\begin{aligned} \text{Tr}(|j\rangle\langle k|l\rangle\langle m|) &= \sum_{i=1}^n \langle i|j\rangle\langle k|l\rangle\langle m|i\rangle \\ &= \langle k|l\rangle\langle m|j\rangle \\ &= \delta_{kl}\delta_{mj} \end{aligned} \quad (37)$$

In equation (37), the right-hand side will be nonzero if and only if $j = m$ and $k = l$; then

$$|j\rangle\langle k|k\rangle\langle j| = |j\rangle\langle k|(|j\rangle\langle k|)^\dagger \quad (38)$$

In order to simplify notation, we now make a mapping of the indices j and k of $|j\rangle\langle k|$ onto a single index i of $\hat{U}_i$. This is simply a relabeling of the basis operators. The exact nature of the mapping is arbitrary, except that there must be a one-to-one correspondence between the pair of indices j, k and the index i . The expression corresponding to equation (37) is then

$$\text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \delta_{ij} \quad (39)$$

This equation is the normalization condition for basis operators analogous to equation (11). Note that if the basis states used in equation (37) are normalized then these basis operators will also be normalized.

If we expand the generic operator $\hat{O}$ in terms of this basis set, the result is

$$\hat{O} = \sum_{i=1}^{n^2} c_i \hat{U}_i \quad (40)$$

Now, if this equation is multiplied by $\hat{U}_j^\dagger$ and the trace taken, a prescription is obtained for the expansion coefficients c_i :

$$\begin{aligned} \text{Tr}(\hat{O} \hat{U}_j^\dagger) &= \text{Tr}\left(\sum_{i=1}^{n^2} c_i \hat{U}_i \hat{U}_j^\dagger\right) \\ &= \sum_{i=1}^{n^2} c_i \text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \sum_{i=1}^{n^2} c_i \delta_{ij} = c_j \end{aligned} \quad (41)$$

Equation (40) may then be rewritten as

$$\hat{O} = \sum_{i=1}^{n^2} \text{Tr}(\hat{O} \hat{U}_i^\dagger) \hat{U}_i \quad (42)$$

The coefficients in this equation can be arranged in a vector to form the Liouville space representation of the operator:

$$\hat{O} \xrightarrow{\hat{U}_i} \begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \quad (43)$$

Note that this space is n^2 -dimensional.

As was done with basis states, it is possible to transform among alternative sets of basis operators. Consider a new operator basis $\{\hat{V}_i, i = 1, 2, 3, \dots, n^2\}$. These operators can be expressed in the original basis as

$$\hat{V}_i = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_i \hat{U}_j^\dagger) \hat{U}_j \quad (44)$$

Equation (42) can be written in terms of the $\hat{V}_i$; then equation (44) can be substituted:

$$\begin{aligned} \hat{O} &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{V}_j \\ &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \sum_{i=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \hat{U}_i \\ &= \sum_{i,j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{U}_i \end{aligned} \quad (45)$$

Comparing equations (42) and (45), it is evident that the conversion of operator bases is accomplished as follows:

$$\text{Tr}(\hat{O} \hat{U}_i^\dagger) = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \quad (46)$$

In terms of the Liouville space representation, this can be written as

$$\begin{aligned} &\begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &= \begin{bmatrix} \text{Tr}(\hat{V}_1 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_1^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_2^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_3^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_3^\dagger) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \text{Tr}(\hat{V}_1 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_{n^2}^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &\quad \times \begin{bmatrix} \text{Tr}(\hat{O} \hat{V}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{V}_{n^2}^\dagger) \end{bmatrix} \end{aligned} \quad (47)$$

2.3 Direct Product Bases

It is quite common that one is able to derive a basis for two or more parts of a system using the techniques described in the previous section, but it is then desired to represent the whole

system so that interactions among the parts can be considered. For example, a molecule might contain two spins, say a ^{13}C nucleus and a ^1H nucleus. For this purpose, we introduce the *direct* or *outer product* of the subspaces to form the space appropriate for the whole system. One can form the direct products in either Hilbert space or Liouville space. The only new definitions needed are as follows. For vectors (states),

$$|\psi_1\rangle|\psi_2\rangle = |\psi\rangle \quad (48a)$$

$$\begin{bmatrix} \langle 1, 1|\psi_1\rangle \\ \langle 1, 2|\psi_1\rangle \\ \langle 1, 3|\psi_1\rangle \\ \vdots \\ \langle 1, n|\psi_1\rangle \end{bmatrix} \otimes \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} = \begin{bmatrix} \langle 1, 1|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 2|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 3|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \vdots \\ \langle 1, n|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \end{bmatrix} \quad (48b)$$

A slightly more condensed notation is required to make the corresponding definition for matrices (operators) manageable:

$$\hat{O} = \hat{O}^{(1)} \otimes \hat{O}^{(2)} \quad (49a)$$

$$\mathbf{O} = \begin{bmatrix} O_{1,1}^{(1)} \mathbf{O}^{(2)} & O_{1,2}^{(1)} \mathbf{O}^{(2)} & O_{1,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{1,n}^{(1)} \mathbf{O}^{(2)} \\ O_{2,1}^{(1)} \mathbf{O}^{(2)} & O_{2,2}^{(1)} \mathbf{O}^{(2)} & O_{2,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{2,n}^{(1)} \mathbf{O}^{(2)} \\ O_{3,1}^{(1)} \mathbf{O}^{(2)} & O_{3,2}^{(1)} \mathbf{O}^{(2)} & O_{3,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{3,n}^{(1)} \mathbf{O}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{n,1}^{(1)} \mathbf{O}^{(2)} & O_{n,2}^{(1)} \mathbf{O}^{(2)} & O_{n,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{n,n}^{(1)} \mathbf{O}^{(2)} \end{bmatrix} \quad (49b)$$

$$\mathbf{O}^{(2)} = \begin{bmatrix} O_{1,1}^{(2)} & O_{1,2}^{(2)} & O_{1,3}^{(2)} & \dots & O_{1,m}^{(2)} \\ O_{2,1}^{(2)} & O_{2,2}^{(2)} & O_{2,3}^{(2)} & \dots & O_{2,m}^{(2)} \\ O_{3,1}^{(2)} & O_{3,2}^{(2)} & O_{3,3}^{(2)} & \dots & O_{3,m}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{m,1}^{(2)} & O_{m,2}^{(2)} & O_{m,3}^{(2)} & \dots & O_{m,m}^{(2)} \end{bmatrix} \quad (49c)$$

Note that the dimension of the product space is always the product of the dimensions of the subspaces.

In equation (43) the Liouville space was introduced. With the introduction of the concept of direct products, it is possible to give a more satisfying explanation of the mapping from Hilbert space to Liouville space. The Hilbert space operators $|i\rangle\langle j|$ can be mapped onto a Liouville space with the following basis states:

$$|i\rangle\langle j| = |ij\rangle \quad (50)$$

Clearly, a one-to-one mapping is possible. In Section 5, the use of Liouville space representations will be explored further with the introduction of superoperators.

It is common in the NMR literature to have implied direct products. For example, one might write $\hat{I}_z^{(1)} + \hat{I}_z^{(2)}$, where (1) and (2) refer to different spins. This is meant to imply $\hat{I}_z^{(1)} \otimes \hat{E}^{(2)} + \hat{E}^{(1)} \otimes \hat{I}_z^{(2)}$. Alternatively, one might encounter $\hat{I}_z \hat{I}_+$, where no direct product is implied, or $\hat{I}_+^{(1)} \hat{I}_-^{(2)}$, where we are to understand that this means $\hat{I}_+^{(1)} \otimes \hat{I}_-^{(2)}$. It is necessary to understand from the context and notation what is really meant.

3 SOME COMMONLY USED BASES

Next let us consider some examples of bases commonly used in NMR, using simple spin systems to illustrate how this formalism can be applied to nuclear spins.

3.1 The Single Spin Eigenstate Basis

A single isolated spin- $\frac{1}{2}$ nucleus has two energy eigenstates. They are commonly represented as $|\alpha\rangle$ and $|\beta\rangle$; however, since this notation is applicable only for spin- $\frac{1}{2}$, we shall also use the notation $|\frac{1}{2}\rangle$ and $|\frac{-1}{2}\rangle$, respectively, where each state is labelled by its $\hat{I}_z$ eigenvalue (this will be discussed in more detail below). It is assumed that these states are orthonormal. Using equation (17a), we can write the Hilbert space representation of the basis states as

$$\left. \begin{aligned} |\alpha\rangle = |\frac{1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\alpha\rangle \\ \langle\beta|\alpha\rangle \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ |\beta\rangle = |\frac{-1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\beta\rangle \\ \langle\beta|\beta\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (51)$$

The corresponding Hilbert space representation of the basis operators can be obtained most easily using equation (36) to write

$$\left. \begin{aligned} \hat{U}_1 = |\alpha\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_2 = |\alpha\rangle\langle\beta| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_3 = |\beta\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 = |\beta\rangle\langle\beta| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (52)$$

It is easily verified that these matrices satisfy the orthonormality conditions by comparing with equation (39) for all pairs.

For spins with a higher angular momentum quantum number, the bases are similar but with higher dimension. For example, a spin-1 nucleus, like ^2H , has three eigenstates

and nine basis operators. Representations of basis states and operators for any nucleus can be obtained just as above knowing only the number of eigenstates and assuming that they are orthonormal.

3.2 The Basis Derived from Direct Products of Single Spin Bases

When the system of interest includes more than one spin, a direct product of single spin bases described in the previous section (one set corresponding to the correct spin for each nucleus) yields a basis for the combined system. The first state and the first operator for two spin- $\frac{1}{2}$ nuclei, for example, would be

$$\left. \begin{aligned} |\alpha\rangle \otimes |\alpha\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \otimes \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} 1 \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ 0 \begin{bmatrix} 1 \\ 0 \end{bmatrix} \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ \hat{U}_1 \otimes \hat{V}_1 &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \otimes \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} 1 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} & 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} & 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix} \\ &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \right\} \quad (53)$$

The other 3 basis states and 15 operators are composed in the same fashion using all the pairs of single spin matrices.

3.3 The Basis Derived from the Eigenstates of the Hamiltonian

The states given in equation (51) for a single spin $\frac{1}{2}$ are the eigenstates of the Hamiltonian, but for two identical spin- $\frac{1}{2}$ nuclei (an A_2 spin system), the eigenstates are

$$\left. \begin{aligned} |A_2, 1\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ |A_2, 2\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 3\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ -\sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 4\rangle = |\beta\beta\rangle &\rightarrow \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (54)$$

These equations show a representation of the eigenstates in the basis of the spin product states. Assembling these vectors into a unitary matrix according to equation (22a) gives the following transformation matrix from the spin product basis to the eigenbasis:

$$\mathbf{U} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} & 0 \\ 0 & \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (55)$$

It is easily verified that $\mathbf{U}\mathbf{U}^\dagger = \mathbf{U}\mathbf{U}^{-1} = \mathbf{E}$. Applying this transformation to the spin product states or operators yields the desired eigenstate basis for the Hilbert space representation or the Liouville space representation, respectively.

3.4 The Angular Momentum Operator Basis

For a single spin- $\frac{1}{2}$ nucleus, the components of the angular momentum vector operator $\hat{\mathbf{I}} = \{\hat{I}_x, \hat{I}_y, \hat{I}_z\}$ augmented by the identity operator $\hat{E}$ are a complete basis. For a development of the angular momentum operators from first principles, the reader is referred to the standard texts.^{6,7,10} We shall be content to define them according to their effect on the basis states as in equation (5). For any spin- I nucleus there are $2I + 1$ quantum states $|m\rangle$ such that

$$\left. \begin{aligned} \hat{I}_x|m\rangle &= \frac{1}{2} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad + [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_y|m\rangle &= \frac{1}{2i} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad - [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_z|m\rangle &= m|m\rangle \end{aligned} \right\} \quad (56)$$

The eigenvalue m ranges in integer steps such that $-I \leq m \leq I$. For spin- $\frac{1}{2}$, using the $\{|\frac{1}{2}\rangle, |-\frac{1}{2}\rangle\}$ basis, the angular momentum operators and their representations are

$$\begin{aligned} \hat{I}_x &\rightarrow \frac{1}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \quad (57)$$

It is easily verified that these operators are orthogonal but not normalized using equation (39). Normalization can easily be achieved by multiplying by the appropriate constants to satisfy equation (39); this yields the desired basis for spin- $\frac{1}{2}$:

$$\left. \begin{aligned} \hat{U}_1 &= \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \sqrt{2} \hat{I}_x \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 &= \sqrt{2} \hat{I}_y \rightarrow \frac{\sqrt{2}}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (58)$$

For a spin-1 nucleus, using equation (56), the angular momentum operators are

$$\left. \begin{aligned} \hat{I}_x &\rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{i\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (59)$$

However, since nine basis operators are required for spin 1, augmenting this set with $\hat{E}$ would clearly not be sufficient to produce a complete basis. However, we shall defer enumerating the other members of this basis until the next section, because the task becomes much easier once the spherical tensor operators have been introduced.

3.5 The Spherical Tensor Operator Basis

Examination of equation (56) rapidly leads one to conclude that a simpler basis might be composed including the following operators:

$$\left. \begin{aligned} \hat{I}_+|m\rangle &= [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ \hat{I}_-|m\rangle &= [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \end{aligned} \right\} \quad (60)$$

These operators are commonly called the *raising* or *step-up* and *lowering* or *step-down* operators, because they convert a given eigenket of $\hat{I}_z$ into one with the eigenvalue increased or decreased, respectively, by one. In terms of these operators, we have

$$\hat{I}_x = \frac{1}{2}(\hat{I}_+ + \hat{I}_-), \quad \hat{I}_y = \frac{1}{2i}(\hat{I}_+ - \hat{I}_-) \quad (61)$$

The inverse relationship is

$$\hat{I}_+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}_- = \hat{I}_x - i\hat{I}_y \quad (62)$$

Applying these relations to equation (57) leads to a new basis:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, & \hat{I}_- &\rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (63)$$

The orthonormal basis corresponding to equation (58) is given by

$$\left. \begin{aligned} \hat{U}_1 &= \hat{T}_{0,0}^{(0)} = \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \hat{T}_{0,0}^{(1)} = \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \hat{T}_{1,0}^{(1)} = -\hat{I}_+ \rightarrow \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_4 &= \hat{T}_{-1,0}^{(1)} = \hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (64)$$

The $\hat{T}_{q,j}^{(k)}$ designation for these operators is that characterizing the *irreducible spherical tensor operators*. There will be

$2k + 1$ members in a set of operators of rank k with projection q ranging from $-k$ to k in integer steps. Note that the index j is not needed here, but will come into play when more complicated spin systems are considered with more than one set of operators of a given k . In what follows, the index j will be suppressed when it is not needed. It is easily verified that this basis is orthonormal. The minus sign associated with $\hat{U}_3$ does not affect the orthonormality of the set. It is common practice to choose this ‘phase factor’ to correspond to that of the spherical harmonic functions, i.e., such that

$$\hat{T}_q^{(k)\dagger} = (-1)^q \hat{T}_{-q}^{(k)} \quad (65)$$

The operators then satisfy equation (39) in the form

$$\text{Tr}(\hat{T}_q^{(k)} \hat{T}_{q'}^{(k)\dagger}) = (-1)^q \text{Tr}(\hat{T}_q^{(k)} \hat{T}_{-q'}^{(k)}) = \delta_{kk'} \delta_{q-q'} \quad (66)$$

The defining characteristic of the irreducible spherical tensor operators is that when they are subjected to a rotation of the coordinate system, they behave like the spherical harmonic functions, i.e., they transform to linear combinations of the set such that operators of differing k or j never mix:

$$\hat{R}(\phi, \theta, \chi) \hat{T}_{q,j}^{(k)} \hat{R}^{-1}(\phi, \theta, \chi) = \sum_{q'=-k}^k D_{q'q}^{(k)}(\phi, \theta, \chi) \hat{T}_{q',j}^{(k)} \quad (67)$$

The rotation operator $\hat{R}(\phi, \theta, \chi)$ and its inverse (defined by equation (68)) transform any operator from the original coordinate system $\{x, y, z\}$ into a new one $\{x', y', z'\}$:

$$\left. \begin{aligned} \hat{R}(\phi, \theta, \chi) &= \exp(-i\phi \hat{I}_z) \exp(-i\theta \hat{I}_y) \exp(-i\chi \hat{I}_z) \\ \hat{R}^{-1}(\phi, \theta, \chi) &= \exp(i\phi \hat{I}_z) \exp(i\theta \hat{I}_y) \exp(i\chi \hat{I}_z) \end{aligned} \right\} \quad (68)$$

The Euler angles $\{\phi, \theta, \chi\}$ define rotations about the z , then y , then z again axes of the original coordinate system, which rotations carry the original coordinate system to coincide with the new one. The $D_{q'q}^{(k)}(\phi, \theta, \chi)$ are called the *Wigner rotation matrix elements*. The definition of these coefficients is rather involved, and will not be given here. They are defined and tabulated in numerous texts, such as the excellent one by Zare.¹⁰ Exponential operators like those in equation (68) as generators of rotations play a central role in the theoretical development of NMR. They, too, are discussed in great detail in Zare’s text.

It was noted in Section 2.1 that operators do not necessarily commute. A special shorthand notation is commonly used for *commutators* of operators, defined as follows:

$$\hat{A}\hat{B} - \hat{B}\hat{A} \equiv [\hat{A}, \hat{B}] \quad (69)$$

Using this notation, an equivalent, though perhaps less intuitive, definition of irreducible spherical tensor operators is provided by the following commutation relations:

$$\left. \begin{aligned} [\hat{I}_{\pm}, \hat{T}_{q,j}^{(k)}] &= \{(k \mp q)(k \pm q + 1)\}^{1/2} \hat{T}_{q \pm 1, j}^{(k)} \\ [\hat{I}_z, \hat{T}_{q,j}^{(k)}] &= q \hat{T}_{q,j}^{(k)} \end{aligned} \right\} \quad (70)$$

Note that one is free to choose either the positive or the negative square root in the coefficient in equation (70), and the result will still satisfy both commutation relations. Thus, we choose the one that satisfies equation (65). The following commutators are easily verified for spin- $\frac{1}{2}$ from equation (63):

$$[\hat{I}_z, \hat{I}_{\pm}] = \pm \hat{I}_{\pm}, \quad [\hat{I}_{\pm}, \hat{I}_{\mp}] = \pm 2\hat{I}_z \quad (71)$$

From equation (59), using equation (62), one can generate the following operators and verify that equation (71) holds for spin 1 also:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \sqrt{2} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \hat{I}_- \rightarrow \sqrt{2} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (72)$$

It can be shown⁶ that these commutation relations are true in general. These three matrices represent an irreducible spherical tensor operator of rank one just as was the case for spin- $\frac{1}{2}$ in equation (64), and the zeroth-order operator can be written as well. Note, however, that the required normalization factors are different:

$$\left. \begin{aligned} \hat{T}_0^{(0)} &= \frac{1}{\sqrt{3}} \hat{E} \rightarrow \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \\ \hat{T}_1^{(1)} &= -\frac{1}{2} \hat{I}_+ \rightarrow -\frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \\ \hat{T}_{-1}^{(1)} &= \frac{1}{2} \hat{I}_- \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{T}_0^{(1)} &= \frac{1}{\sqrt{2}} \hat{I}_z \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (73)$$

It is easily verified that these operators are orthonormal and satisfy equation (70).

Using these four operators as a starting point, the problem of finding the other five basis operators for spin 1 can now be addressed. The required operators must be mutually orthogonal and orthogonal to the four already proposed. A logical extension of what has been done so far would be the five elements of an irreducible spherical tensor operator of rank two. For spin 1, the step-up operator can be applied twice to the eigenstate $|-1\rangle$ to produce first the $|0\rangle$ then the $|1\rangle$ eigenstate. The corresponding second-rank operator is $\hat{I}_+ \hat{I}_+$. The representation of this operator can be obtained in several ways according to what we have learned so far. Perhaps the easiest way is to square the matrix given in equation (72) and normalize the result to give

$$\hat{T}_2^{(2)} = \frac{1}{2} \hat{I}_+ \hat{I}_+ \rightarrow \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (74)$$

which is easily shown to satisfy equation (70). Equation (70) can now be used to successively generate the other members of the set as follows:

$$[\hat{I}_-, \hat{T}_2^{(2)}] = \{(2+2)(2-2+1)\}^{1/2} \hat{T}_1^{(2)} = -2\hat{T}_1^{(2)} \quad (75)$$

The negative square root is chosen so as to satisfy equation (65). Hence, we have

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{2}[\hat{I}_-, \frac{1}{2}\hat{I}_+\hat{I}_+] = -\frac{1}{4}[\hat{I}_-, \hat{I}_+\hat{I}_+] \\ &= -\frac{1}{4}(\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+\hat{I}_+\hat{I}_-) \end{aligned} \quad (76)$$

Then substituting from equation (71) yields

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{4}\{\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+(2\hat{I}_z + \hat{I}_-\hat{I}_+)\} \\ &= -\frac{1}{4}\{(\hat{I}_-\hat{I}_+ - \hat{I}_+\hat{I}_-)\hat{I}_+ - 2\hat{I}_+\hat{I}_z\} \\ &= -\frac{1}{4}\{(-[\hat{I}_+, \hat{I}_-]\hat{I}_+ - 2\hat{I}_+\hat{I}_z) \end{aligned} \quad (77)$$

Using equation (71) again gives the desired operator, and substitution from equation (72), gives the representation:

$$\hat{T}_1^{(2)} = \frac{1}{2}(\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{bmatrix} \quad (78)$$

Applying the same procedure successively generates the other three operators. The $q = 0$ component is

$$\begin{aligned}\hat{T}_0^{(2)} &= -\sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_1^{(2)}] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}[\hat{I}_-, (\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z)] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_-\hat{I}_z\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z - \hat{I}_+\hat{I}_z\hat{I}_-) \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}\{(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z \\ &\quad - \hat{I}_+(-\hat{I}_- + \hat{I}_-\hat{I}_z)\} \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+ + \hat{I}_z[\hat{I}_-, \hat{I}_+] + [\hat{I}_-, \hat{I}_+]\hat{I}_z) \\ &= \sqrt{\frac{1}{6}}\{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\} \rightarrow \frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \end{aligned} \quad (79)$$

In this case, the negative phase is chosen arbitrarily, because equation (65) places no constraint on the phase of this operator. The $q = -1$ component is

$$\begin{aligned}\hat{T}_{-1}^{(2)} &= \sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_0^{(2)}] \\ &= \frac{1}{6}[\hat{I}_-, \{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\}] \\ &= \frac{1}{6}(2\hat{I}_-\hat{I}_z^2 - 2\hat{I}_z^2\hat{I}_- + \frac{1}{2}\hat{I}_+\hat{I}_-\hat{I}_- - \frac{1}{2}\hat{I}_-\hat{I}_-\hat{I}_+) \\ &= \frac{1}{6}\{2(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_z - 2\hat{I}_z(-\hat{I}_- + \hat{I}_-\hat{I}_z) \\ &\quad + \frac{1}{2}(2\hat{I}_z + \hat{I}_-\hat{I}_+)\hat{I}_- - \frac{1}{2}\hat{I}_-(-2\hat{I}_z + \hat{I}_+\hat{I}_-)\} \\ &= \frac{1}{2}(\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \end{bmatrix} \end{aligned} \quad (80)$$

Here the positive phase has been chosen to satisfy equation (65). The $q = -2$ component is

$$\begin{aligned}\hat{T}_{-2}^{(2)} &= \frac{1}{2}[\hat{I}_-, \hat{T}_{-1}^{(2)}] \\ &= \frac{1}{4}[\hat{I}_-, (\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z)] \\ &= \frac{1}{4}(-\hat{I}_z\hat{I}_-\hat{I}_- + \hat{I}_-\hat{I}_-\hat{I}_z) \\ &= \frac{1}{4}\{-(\hat{I}_- + \hat{I}_-\hat{I}_z)\hat{I}_- + \hat{I}_-(\hat{I}_- + \hat{I}_z\hat{I}_-)\} \\ &= \frac{1}{2}\hat{I}_-\hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix} \end{aligned} \quad (81)$$

The positive phase has been chosen here, again arbitrarily. The same result could also be obtained by starting from $T_{-2}^{(2)}$ and stepping it up with I_+ . These nine operators given by equations (73), (74), and (78)–(81) form a complete basis set for spin 1. Of course, higher spin bases can be constructed in the same way; spin I will require irreducible spherical tensors of rank $k = 0, 1, 2, \dots, 2I$.

4 THE DENSITY OPERATOR

It is a familiar concept⁷ that an experimental measurement will yield a value corresponding to the bracket of the state of the system under study with the operator corresponding to the observable:

$$\langle \hat{O}(t) \rangle = \langle \psi(t) | \hat{O} | \psi(t) \rangle \quad (82)$$

The notation on the left-hand side carries some connotation that the operator is time-dependent, which need not be the case; the time dependence in this case is carried entirely in the state. Some authors use the notation $\langle \hat{O} \rangle(t)$ or some other variant to avoid possible ambiguity. We shall retain the notation of equation (82), trusting the reader to realize the subtle difference implied. This leads to a discussion of Schrödinger versus Heisenberg versus interaction pictures of quantum mechanics, which will be addressed in Section 4.1. Of course, this result is independent of the ‘picture’ employed or the basis chosen. Inserting twice the sum on projection operators for some basis as in equation (19) and rearranging yields

$$\begin{aligned}\langle \hat{O}(t) \rangle &= \langle \psi(t) | \sum_{i=1}^n |i\rangle \langle i| \hat{O} \sum_{j=1}^n |j\rangle \langle j| \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \langle j | \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \end{aligned} \quad (83)$$

As in equation (9), the quantity $|\psi(t)\rangle \langle \psi(t)|$ can be regarded as an operator, which is known as the density operator $\hat{\rho}(t)$:

$$\hat{\rho}(t) = |\psi(t)\rangle \langle \psi(t)| \quad (84)$$

Continuing from equation (83), we can write

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \sum_{i,j=1}^n \langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle \\
 &= \sum_{j=1}^n \langle j | \hat{\rho}(t) \hat{O} | j \rangle \\
 &= \text{Tr}(\hat{\rho}(t) \hat{O})
 \end{aligned} \tag{85}$$

This is an important relationship showing that the expected value of any operator can be computed by taking the trace of its product with the density operator. This form is completely equivalent to equation (82), and is the form commonly used for discussion of magnetic resonance phenomena. Just as the state $|\psi(t)\rangle$ contains all that can be known about the state of a system, so does the density operator.

According to equation (42), using an appropriate operator basis, we can write

$$\begin{aligned}
 \hat{\rho}(t) &= \sum_{i=1}^{n^2} \text{Tr}[\hat{\rho}(t) \hat{U}_i^\dagger] \hat{U}_i \\
 &= \sum_{i=1}^{n^2} \langle \hat{U}_i^\dagger(t) \rangle \hat{U}_i
 \end{aligned} \tag{86}$$

Thus, the expected values of all the basis operators provide the coefficients needed to represent the density operator in any basis, and these values provide a Liouville space representation of the density operator according to equation (43). Extensive use of this concept will be made later in developing the equations needed to explain spin relaxation.

The development so far has implied that the system of interest can be characterized by a state $|\psi(t)\rangle$. Liquid samples can never be so characterized, but can often be viewed as an ensemble of such isolated systems. Thus, it is desirable to take an ensemble average of equation (84). Since all the variation among the members of the ensemble resides in the operator $|\psi(t)\rangle\langle\psi(t)|$, the averaging process commutes with the sums over basis states, and we can write

$$\begin{aligned}
 \overline{\langle \hat{O}(t) \rangle} &= \sum_{i,j=1}^n \overline{\langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{i,j=1}^n \overline{\langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{j=1}^n \langle j | \bar{\hat{\rho}}(t) \hat{O} | j \rangle \\
 &= \text{Tr}\{\bar{\hat{\rho}}(t) \hat{O}\}
 \end{aligned} \tag{87}$$

Clearly, $\hat{\rho}(t)$ can be replaced by $\bar{\hat{\rho}}(t)$ in the above equations, leaving the form of the equations the same. In what follows, we shall not retain the overbar notation, but the density operator should be assumed to be averaged over an ensemble.

4.1 Time Evolution of the Density Operator

The time-dependent Schrödinger equation

$$i\hbar \frac{d}{dt} |\psi(t)\rangle = \hat{\mathcal{H}}(t) |\psi(t)\rangle \tag{88}$$

can easily be converted to our density operator formalism. Beginning from equation (84) and using equation (88) and its complex conjugate obtained using equations (2) and (7), we can write

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \frac{d}{dt} \{ |\psi(t)\rangle \langle \psi(t)| \} \\
 &= \frac{d}{dt} \{ |\psi(t)\rangle \} \langle \psi(t)| + |\psi(t)\rangle \frac{d}{dt} \{ \langle \psi(t)| \} \\
 &= -\frac{i}{\hbar} \hat{\mathcal{H}}(t) |\psi(t)\rangle \langle \psi(t)| + \frac{i}{\hbar} |\psi(t)\rangle \langle \psi(t)| \hat{\mathcal{H}}(t) \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}}(t) \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}}(t) \} \\
 &= -\frac{i}{\hbar} [\hat{\mathcal{H}}(t), \hat{\rho}(t)]
 \end{aligned} \tag{89}$$

Note that the Hamiltonian is Hermitian. The commutator of the Hamiltonian with the density operator determines the time development of the density operator. This relation is referred to as the *Liouville-von Neuman equation*, and will play a central role in what follows. Our goal, generally stated, will be to find solutions of this equation using a Hamiltonian corresponding to various experimental situations. The density operator at some particular time will generally be known—at least parametrically—and equation (89) must then be integrated to obtain the time development of the density operator.

The solution of this equation of motion is fairly simple if the Hamiltonian is not time-dependent. If we suppose that the density operator has the value $\hat{\rho}(0)$ at $t = 0$ then

$$\hat{\rho}(t) = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \tag{90}$$

is a solution, as can be verified by differentiation:

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \left(-\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &\quad + \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \left(\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &= -\frac{i}{\hbar} \left\{ \hat{\mathcal{H}} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right. \\
 &\quad \left. - \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\mathcal{H}} \right\} \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}} \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}} \} = -\frac{i}{\hbar} [\hat{\mathcal{H}}, \hat{\rho}(t)]
 \end{aligned} \tag{91}$$

We have used the fact that an operator commutes with a function of itself.

Now let us examine the expected value of a generic operator with this solution. Substituting equation (90) into equation (87) yields

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \text{Tr}\{\hat{\rho}(t) \hat{O}\} = \text{Tr}\left\{ \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \right\} \\
 &= \text{Tr}\left\{ \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right\} \\
 &= \text{Tr}\{\hat{\rho}(0) \hat{O}(t)\}
 \end{aligned} \tag{92}$$

The fact that the trace operation is invariant under cyclic permutation of the factors has been used, and the time-dependent operator $\hat{O}(t)$ has been introduced according to

$$\hat{O}(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \hat{O} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \quad (93)$$

Equation (87) expresses the Schrödinger picture of quantum mechanics, whereas equation (92) transforms into the Heisenberg picture. Clearly, the two forms are equivalent.

Differentiating equation (93) yields the equation of motion for the time-dependent operators of the Heisenberg picture, corresponding to equation (89) for the Schrödinger picture:

$$\frac{d\hat{O}(t)}{dt} = \frac{i}{\hbar}[\hat{\mathcal{H}}, \hat{O}(t)] \quad (94)$$

The derivation proceeds like that of equation (91). The equations for the Schrödinger and the Heisenberg pictures are similar in form, but the sign differences in the various terms should be noted.

When the Hamiltonian is time-dependent, the situation is considerably more complex, and no attempt will be made here to discuss this case in general terms. However, suppose the Hamiltonian can be separated into a term that is time-dependent and another that is not:

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t) \quad (95)$$

Equation (89) may then be rewritten as

$$\begin{aligned} \frac{d\hat{\rho}(t)}{dt} &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t), \hat{\rho}(t)] \\ &= -\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)] + [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\} \end{aligned} \quad (96)$$

If $\hat{\mathcal{H}}_1(t) = 0$ then the solution is as in equation (90). By analogy with equation (90), let us define the transformed operators

$$\hat{\rho}'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (97)$$

$$\hat{\mathcal{H}}_1'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\mathcal{H}}_1(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (98)$$

Differentiating equation (97) and substituting from equations (96) and (98) then gives

$$\begin{aligned} \frac{d\hat{\rho}'(t)}{dt} &= \frac{i}{\hbar}\hat{\mathcal{H}}_0 \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \frac{d\hat{\rho}(t)}{dt} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0\right) \\ &= \frac{i}{\hbar}[\hat{\mathcal{H}}_0, \hat{\rho}'(t)] + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)]\right. \\ &\quad \left.+ [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\}\right) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_1'(t), \hat{\rho}'(t)] \end{aligned} \quad (99)$$

Thus, in this ‘interaction picture’, part of the time dependence is placed in the operators and part remains in the density operator. The effect of $\hat{\mathcal{H}}_0$ appears only implicitly in the exponential transformation operator. Of course, this is not a solution of the equation of motion, but it will prove to be a useful technique to be applied later on.

4.2 The Reduced Density Operator

In NMR experiments, it is usually the case that the nuclear spins interact weakly with the other degrees of freedom of the sample of interest. For the moment, let us assume that they do not interact at all. The state of the system can be written as a direct product, as in equation (48a), of a ket corresponding to the spin degrees of freedom with one corresponding to the rest of the system, the lattice:

$$|S\rangle|L\rangle = |SL\rangle \quad (100)$$

The number of degrees of freedom, i.e., the number of basis states, necessary to span the spins is modest, while that necessary to span the lattice is very large—effectively infinite.

Consider the expected value of an operator that acts only on the spin degrees of freedom. If $\{|s\rangle\}$ is a basis set spanning both the spins and the lattice, we can write

$$\begin{aligned} \langle\hat{O}\rangle &= \text{Tr}(\hat{\rho}\hat{O}) = \text{Tr}(|SL\rangle\langle SL|\hat{O}) \\ &= \sum_{sl} \langle sl|SL\rangle\langle SL|\hat{O}|sl\rangle \end{aligned} \quad (101)$$

Since $\hat{O}$ commutes with the lattice operators, this can be rearranged to yield

$$\begin{aligned} \langle\hat{O}\rangle &= \sum_s \langle s|S\rangle\langle S|\hat{O}|s\rangle \sum_l \langle l|L\rangle\langle L|l\rangle \\ &= \sum_s \langle s|S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S|\hat{O}|s\rangle \end{aligned} \quad (102)$$

We can now define the reduced density operator by

$$\hat{\sigma} = |S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S| = \text{Tr}_l(\hat{\rho}) \quad (103)$$

The expected value of $\hat{O}$ can then be written as

$$\langle\hat{O}\rangle = \text{Tr}_s(\hat{\sigma}\hat{O}) \quad (104)$$

Thus, observing experimental quantities corresponding to spin operators requires only a knowledge of this reduced density operator, and the problem has, at least in principle, only the small dimensionality of the spin degrees of freedom and not the very large dimensionality of the spins and the lattice. In particular, the Liouville equation, equation (99), can be cast in this form. However, if there were, indeed, no interaction of the spins with the lattice, as was assumed above, there would be no relaxation. Of course, this is observed not to be the case, but the interaction is sufficiently weak that it can be treated by perturbation methods, and the very large number of

degrees of freedom in the lattice permits treating the lattice classically to achieve excellent correspondence of theory to experiment. In what follows, then, solutions will be sought of the Liouville–von Neuman equation for the reduced density operator:

$$\frac{d\hat{\sigma}(t)}{dt} = -\frac{i}{\hbar}[\hat{\mathcal{H}}(t), \hat{\sigma}(t)] \quad (105)$$

5 SUPEROPERATORS

The representation of operators in Liouville space has been discussed in Section 2.2. In this section, we shall introduce superoperators that act on operators in Liouville space in much the same way as operators act on states in Hilbert space, i.e., superoperators transform one operator into another.

Consider the operator product

$$\hat{C} = \hat{B}_1 \hat{A} \hat{B}_2 \quad (106)$$

Let us attempt to cast $\hat{A}$ in a Liouville space representation and then find a superoperator $\hat{B}$ such that $|\hat{C}\rangle = \hat{B}|\hat{A}\rangle$. The operator product can be written as follows and rearranged as shown by applying equations (7) and (15):

$$\begin{aligned} \langle i|\hat{C}|j\rangle &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle k|\hat{A}|l\rangle \langle l|\hat{B}_2|j\rangle \\ &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \langle k|\hat{A}|l\rangle \end{aligned} \quad (107)$$

The superoperator matrix elements can now be defined by

$$\langle ij|\hat{B}|kl\rangle = \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \quad (108)$$

This expression can be viewed as the matrix elements of a direct product in a space with basis $|i\rangle|j\rangle = |ij\rangle$, the direct product of two identical Hilbert space bases as in equation (50):

$$\hat{B} = \hat{B}_1 \otimes \hat{B}_2^\dagger \quad (109)$$

The matrix elements of $\hat{A}$ may be mapped into a vector in this same space just as in equation (43). In fact, the operator basis $\{\hat{U}_i\}$ introduced in equation (43) is equivalent to the basis $\{|ij\rangle\}$. The matrix elements of $\hat{A}$ may be written as

$$\langle ij|\hat{A}\rangle = \langle i|\hat{A}|j\rangle \quad (110)$$

Then equation (107) can be written as

$$|\hat{C}\rangle = \hat{B}|\hat{A}\rangle \quad (111)$$

The utility of this formalism is evident from several examples.

5.1 Unitary Transformations

Unitary transformations like $\hat{U}\hat{A}\hat{U}^\dagger$ in Hilbert space can easily be translated to Liouville space using equation (109) to define the relevant superoperator

$$\hat{\hat{U}} = \hat{U} \otimes \hat{U} \quad (112)$$

Note that $(\hat{U}^\dagger)^\dagger = \hat{U}$. Then the unitary transformation becomes

$$\hat{\hat{U}}|\hat{A}\rangle \quad (113)$$

The superoperator $\hat{\hat{U}}$ is unitary. To show this, we can write

$$\hat{A} = \hat{U}^\dagger \hat{U} \hat{A} \hat{U}^\dagger \hat{U} \quad (114)$$

But this implies

$$|\hat{A}\rangle = (\hat{U}^\dagger \otimes \hat{U}^\dagger)(\hat{U} \otimes \hat{U})|\hat{A}\rangle = \hat{\hat{U}}^\dagger \hat{\hat{U}}|\hat{A}\rangle \quad (115)$$

where the second equality in equation (115) follows immediately by considering the adjoint of equation (108). Thus, it must be that

$$\hat{\hat{U}}^\dagger \hat{\hat{U}} = \hat{E} \quad (116)$$

5.2 Commutators

Consider the commutator $[\hat{A}, \hat{B}]$ as the action of something denoted by $[\hat{A},]$ on the operator $\hat{B}$ to produce a new operator $\hat{C}$. This relationship can be written as

$$[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A} = \hat{A}\hat{B}\hat{E} - \hat{E}\hat{B}\hat{A} \quad (117)$$

Applying equation (109) then yields

$$\hat{\hat{A}} = \hat{A} \otimes \hat{E} - \hat{E} \otimes \hat{A}^\dagger \quad (118)$$

5.3 The Liouvillian

Using equation (118), the equation of motion for the density operator equation (89) can be re-written as

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar}\hat{\hat{\mathcal{L}}}(t)|\hat{\rho}(t)\rangle \quad (119)$$

The Liouvillian superoperator corresponding to the commutator with the Hamiltonian is defined as

$$\hat{\hat{\mathcal{L}}}(t) = \hat{\mathcal{H}}(t) \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}}(t) \quad (120)$$

Note that the Hamiltonian is Hermitian, so that $\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}(t)^\dagger$.

1 INTRODUCTION

The nuclear Overhauser effect is defined as the change in the overall intensity of one resonance that occurs when another resonance is saturated. Generally it is expressed as the fractional enhancement:

$$f_I\{S\} = \frac{I - I^0}{I^0} \quad (1)$$

where I is the intensity of the observed resonance when the spin S is saturated and I^0 is the equilibrium intensity of the I resonance. Conventionally, the observed spin is called I and the saturated spin is called S . However, particularly for heteronuclear cases, the NOE is often also expressed as the enhancement ratio:

$$\eta = \frac{I}{I^0} = f_I\{S\} + 1 \quad (2)$$

Detection of an appreciable NOE between two spins indicates that there is a relatively short internuclear distance between them, generally less than about 4 or 5 Å. It is this through-space dependence, which is completely independent of the nature of the covalent bonding network between the two interacting spins, that makes the NOE extremely powerful for characterizing molecular stereochemistry and conformation. However, the dependence on the internuclear separation between I and S is complicated by a dependence on several other factors, particularly the rates of molecular motions. For this reason, a truly quantitative interpretation of NOE enhancements is difficult, and the effect is usually interpreted at a semiquantitative level when deriving structural information, as will be discussed below.

The original prediction by Overhauser concerning the enhancement of nuclear spin polarization in metals upon saturation of the electron spins was published in 1953,¹ and the nuclear analog was described by Solomon in 1955.² The first applications to structure determination were by Anet and Bourne in 1965,³ and for 10 years or so the method

found applications mainly in organic chemistry.⁴ Detection of NOE enhancements using repeated integration of CW-detected one-dimensional spectra imposed a detection limit in the region of 5%, but the introduction of new measurement techniques together with high-field, computer-assisted Fourier transform NMR spectrometers in the mid-1970s revolutionized the whole area. Now two experiments in particular, NOE difference spectroscopy and NOESY, have greatly improved sensitivity and allow very much more extensive use to be made of the NOE in structure determination than was possible previously. The technique is very widely used to determine stereo- and regiochemical isomerism in small and medium-sized natural and synthetic molecules, and more recently it has become the basis for a whole area of NMR, namely the structure determination of biological macromolecules, particularly proteins, in solution.⁵

2 CROSS RELAXATION AND THE ORIGIN OF THE NOE

The origin of the NOE lies in population changes caused by a particular form of longitudinal relaxation, namely dipole–dipole cross relaxation (see also *Relaxation Processes in Coupled-Spin Systems*). Longitudinal relaxation involves energy exchange events between the nuclear spin states and the ‘lattice’, which term is used to depict the continuum of translational and rotational energy levels of the system as a whole. If the population of the high-energy state of a particular nuclear spin transition is larger than its equilibrium value, it will relax back towards equilibrium through events in which individual nuclei flip from high-energy to low-energy spin state while the lattice accepts the energy released, for instance by accelerating either the overall rotation or some internal motion of the molecule in which the nuclear spin transition occurred. Similarly, if the population of the high-energy state were smaller than its equilibrium value, then corresponding decelerations of molecular motions would provide energy to promote spins to the high-energy state.

However, such relaxation events can only occur if there exists a mechanism to couple the motions of the molecule to the nuclear spin states. In practice this means that the motion must itself cause a varying transverse magnetic field at the site of the nucleus it is to relax, and that this magnetic field variation must have an appreciable frequency component corresponding to the frequency of the nuclear spin transition. In the case of dipole–dipole relaxation, this ‘local field’ originates from the magnetic dipoles of other neighboring spins. Because in this case the local field itself originates from a spin, this opens the possibility for cooperative relaxation events in which *both* spins simultaneously flip, while the lattice accepts or provides energy corresponding to the net change. This is dipole–dipole cross relaxation. The various possible transitions for the simplest case of a two-spin system are summarized in Figure 1.

Two types of cross relaxation event are possible. In one, characterized by the transition probability W_2 , both spins flip in the same sense, and the energy change accommodated by the lattice corresponds to the *sum* of the energies of the individual spin transitions. For these ‘ W_2 transitions’ to occur, the local field resulting from lattice motions must contain fluctuations

Figure 1 Energy level for a two-spin system, showing the definitions of transition probabilities (W_0 , W_1 , and W_2) and spin states ($\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, and $\beta\beta$). Spin states are written with the state of I first and that of S second, i.e. $\alpha\beta$ means spin I is in the α state, and spin S in the β

at the sum frequency ($\omega_I + \omega_S$). In the other type of transition, characterized by the transition probability W_0 , the spins flip in opposite senses. In the homonuclear case, this implies that a very much smaller energy change is accommodated by the lattice, corresponding to the *difference* between the energies of the individual transitions. For ' W_0 transitions', the local field must contain fluctuations at the difference frequency ($\omega_I - \omega_S$).

These two types of cross relaxation event are crucially different in their influence on the NOE. Suppose that spin S is saturated, thereby equalizing the populations of states $\alpha\alpha$ and $\alpha\beta$, and (separately) equalizing the populations of the states $\beta\alpha$ and $\beta\beta$. For all of the relaxation transitions involving S there will now be an excess of downward transitions (i.e. high $\rightarrow$ low energy), since there are more spins in the high-energy state than would be the case at equilibrium. The excess of downward single spin flips of S (W_1 transitions) has no effect on the intensity of I . However, if spin S flips downwards during a W_2 transition, spin I also flips downwards, thereby *increasing* the population difference across the I spin transition. Thus when W_2 transitions predominate over W_0 transitions, saturation of S causes the intensity of I to increase, which corresponds to a positive NOE enhancement. Conversely, for a W_0 transition, if spin S flips downwards then spin I must flip upwards, thereby *decreasing* the population difference across the I spin transitions. Therefore if W_0 transitions predominate over W_2 transitions, saturation of S causes the intensity of I to decrease, implying a negative NOE enhancement. If there are equal numbers of W_2 and W_0 transitions, the opposing effects cancel and there is no NOE at all.

2.1 The NOE for an Isolated Two-Spin System

These points may be expressed more formally using the Solomon equations, which form the basis for the theory of the NOE. For a system of two isolated spins $\frac{1}{2}$, the equation of

motion for the longitudinal component of I spin magnetization is given by^{2,6}

$$\frac{dI_z}{dt} = -(I_z - I_z^0)(W_{0IS} + 2W_{1I} + W_{2IS}) - (S_z - S_z^0)(W_{2IS} - W_{0IS}) \quad (3)$$

If S is saturated until steady state is reached, then dI_z/dt and S_z may both be set to zero, whereupon rearrangement and substituting $I_z^0 = (\gamma_I/\gamma_S)S_z^0$ gives

$$f_I\{S\} = \frac{I_z - I_z^0}{I_z} = \frac{\gamma_S}{\gamma_I} \frac{W_{2IS} - W_{0IS}}{W_{0IS} + 2W_{1I} + W_{2IS}} \quad (\text{two-spin}) \quad (4)$$

where $f_I\{S\}$ is the fractional steady state NOE enhancement measured at I upon completely saturating S . For the case of two spins $\frac{1}{2}$ relaxing exclusively via their mutual dipole-dipole interaction, the values of the various transition probabilities can be shown to be⁷

$$\left. \begin{aligned} W_{0IS} &= \frac{1}{20} K^2 J(\omega_I - \omega_S) \\ W_{1I} &= \frac{3}{40} K^2 J(\omega_I) \\ W_{2IS} &= \frac{3}{10} K^2 J(\omega_I + \omega_S) \end{aligned} \right\} \left(\begin{array}{l} \text{dipole} \\ \text{only,} \\ \text{extreme} \\ \text{narrowing} \end{array} \right) \quad (5)$$

where $K = (\mu_0/4\pi)\hbar\gamma_I\gamma_S r_{IS}^{-3}$. Given that K always appears as its square, this shows that all of these intramolecular dipole-dipole transition probabilities depend linearly on the minus sixth power of the internuclear distance r_{IS} . The various spectral density functions $J(\omega_x)$ each describe the power available at the corresponding frequency ω_x from molecular motions to stimulate relaxation. These spectral density functions provide the vital link between transition probabilities and molecular tumbling properties. If it is assumed that molecular tumbling is isotropic, and that it can be described by a correlation function that is a simple exponential decay with a rate constant τ_c , then the spectral density functions are given by

$$J(\omega_x) = \frac{2\tau_c}{(1 + \omega_x^2 \tau_c^2)} \quad (6)$$

For small molecules molecular tumbling is very rapid, τ_c is very short and $\omega_x \tau_c < 1$. This is called the 'extreme narrowing' condition, and in this limit the denominators of the various spectral density expressions can all be set to unity, leading to much simpler expressions for the transition probabilities in equation (5). When these are substituted into equation (4), we have

$$\begin{aligned} f_I\{S\} &= \frac{\gamma_S}{\gamma_I} \frac{\frac{3}{5} K^2 \tau_c - \frac{1}{10} K^2 \tau_c}{\frac{1}{10} K^2 \tau_c + \frac{3}{10} K^2 \tau_c + \frac{3}{5} K^2 \tau_c} \\ &= \frac{\gamma_S}{2\gamma_I} \left(\begin{array}{l} \text{two-spin} \\ \text{dipole only,} \\ \text{extreme} \\ \text{narrowing} \end{array} \right) \end{aligned} \quad (7)$$

which, in the homonuclear case, is just +50%.

As molecular weight increases and tumbling becomes slower, the spectrum of rates of molecular motions becomes

more and more concentrated at low frequencies. The spectral densities $J(\omega_I + \omega_S)$ and $J(\omega_I)$ thus become progressively smaller until they cease to make any significant contribution to relaxation; in other words, the local field produced by motions of neighboring dipoles in large molecules has no frequency component high enough to stimulate W_2 or W_1 transitions. In heteronuclear systems, the same fate eventually overtakes $J(\omega_I - \omega_S)$ also [indeed, if γ_S and γ_I have opposite signs, $J(\omega_I + \omega_S)$ will diminish before $J(\omega_I - \omega_S)$, and for $S = {}^1\text{H}$, ω_I is generally smaller than $(\omega_I - \omega_S)$ or $(\omega_I + \omega_S)$], but in homonuclear cases the difference frequency $(\omega_I - \omega_S)$ is so low (being just a difference of chemical shifts in this case) that $J(\omega_I - \omega_S)$ always remains large.

Thus, although in the extreme narrowing limit there are six times as many W_2 transitions as W_0 transitions, where $\omega\tau_c \approx 1$ (for a homonuclear system) the numbers of W_2 and W_0 transitions are nearly equal, resulting in small or zero NOE enhancements irrespective of the internuclear distances involved. For homonuclear systems in still larger molecules where $\omega\tau_c \gg 1$, all the spectral densities other than $J(\omega_I - \omega_S)$ become insignificant, dipolar relaxation is completely dominated by W_0 transitions and NOE enhancements are all negative. This limit is known as the ‘spin diffusion’ limit, for reasons that will become apparent shortly.

The overall dependence of the NOE on $\omega_I\tau_c$ for an ideal two-spin system relaxing exclusively through mutual dipole–dipole interactions can be calculated from equations (4)–(6). This function, often called $\eta_{\max}$, is actually *independent* of the internuclear distance r , since all of the terms in equation (4) have an identical dependence on r^{-6} that cancels out. Conceptually, $\eta_{\max}$ represents the theoretical maximum NOE enhancement observable between two spins in the absence of other spins and external relaxation. Figure 2 shows $\eta_{\max}$ for a homonuclear system.

To simplify later equations, it is convenient to introduce here the cross-relaxation rate σ_{IS} and the direct relaxation rate ρ_{IS} , defined by

$$\sigma_{IS} = W_{2IS} - W_{0IS}; \quad \rho_{IS} = W_{0IS} + 2W_{1I} + W_{2IS} \quad (8)$$

Figure 2 Maximum theoretical homonuclear NOE enhancement ($\eta_{\max}$) for a two-spin system relaxing exclusively via dipolar interaction, as a function of $\omega\tau_c$. For small rapidly tumbling molecules where $\omega\tau_c \ll 1$, the maximum NOE enhancement is +50%, while for large, slowly tumbling molecules where $\omega\tau_c \gg 1$, the maximum enhancement is –100%

In this way, $\eta_{\max}$ can be reexpressed as

$$\eta_{\max} = \frac{\gamma_S}{\gamma_I} \frac{\sigma_{IS}}{\rho_{IS}} \quad (9)$$

2.2 Competition from Other Relaxation Mechanisms

Of course, in real situations, there will be relaxation mechanisms other than intramolecular dipole–dipole operating, and there will generally be more than two spins in the system. Almost without exception, other relaxation mechanisms do not contribute to cross relaxation at all, so their only influence is to dilute the contribution of dipolar relaxation to the whole. Such additional relaxation is often referred to as ‘leakage’, and in the equations the ‘leakage rate’ ρ^*_I is introduced as a *purely empirical* correction factor to allow for it; the subscript I is required since, in principle, every spin could have a different leakage rate.

$$f_I\{S\} = \frac{\gamma_S}{\gamma_I} \frac{\sigma_{IS}}{\rho_{IS} + \rho^*_I} \quad (\text{two-spin}) \quad (10)$$

Significantly, for most systems leakage is much more important for small molecules than for large. This is because dipolar relaxation becomes steadily more efficient as tumbling rates diminish, whereas the leakage rate is often not greatly affected by solute tumbling rate. For instance, in many cases the dominant source of leakage is intermolecular dipole–dipole interactions between spins on the solute and unpaired electrons of dissolved oxygen molecules (see also **Paramagnetic Relaxation in Solution**). This interaction is likely to be largely independent of solute tumbling rate, since the relative positions of the electron and nuclear spins will always vary rapidly as the oxygen molecule tumbles. Figure 3 shows how the ideal homonuclear two-spin NOE $\eta_{\max}$ is reduced more severely for small molecules than for large, assuming various constant leakage rates.

For spin systems involving nuclei with $I > \frac{1}{2}$, efficient quadrupolar relaxation usually leads to very high leakage rates,

Figure 3 Reduction in $\eta_{\max}$ resulting from leakage, e.g. due to intermolecular relaxation by dissolved oxygen. The different curves are calculated according to equation (10) using the indicated values for ρ^*_I , assumed to remain constant as a function of solute tumbling rate, and taking an internuclear distance r_{IS} of 2 Å and a spectrometer frequency of 300 MHz

so that little or no NOE is detectable (see also *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*).

3 MULTISPIN SYSTEMS

In multispin systems, two further points need to be considered. Firstly, spin I will be relaxed not only by spin S but also potentially by all the other spins in the system (here collectively denoted X), depending on their distances from I . This adds further terms to the direct relaxation rate of I , diluting the NOE in much the same way as does ρ_I^* . Thus, the total relaxation rate of I becomes

$$R_I = \rho_{IS} + \sum_X \rho_{IX} + \rho_I^* \quad (11)$$

Note that there is an implicit assumption made in equation (11) and in all the theory for multispin NOE enhancements that follows, namely that the total relaxation behavior of the system can be obtained by a simple summation over all possible pairwise interactions. This amounts to neglecting the cross correlation that must exist between the random motions of one spin pair and another within the same molecule. This assumption is almost universally made throughout applications of the NOE, and various authors have shown that it actually introduces little error into conventional interpretations (see also *Relaxation Processes: Cross Correlation and Interference Terms*).⁸

Note also that the inclusion of ρ_I^* in this definition implies that R_I corresponds to the reciprocal of the *experimentally measured* selective T_1 . In all the equations involving R_I that follow, one may in principle either include or exclude ρ_I^* . If it is included, the equations relate directly to measured results, but they require that measured values or at least estimates of leakage rates are available. If ρ_I^* is excluded, the equations relate to a hypothetical spin system with no leakage, allowing idealized NOE properties to be calculated provided only that the relevant internuclear distances are known.

The second important point for the NOE in multispin systems is the possibility of indirect enhancements. Once spins close to S have themselves received NOE enhancements, their own populations are no longer at equilibrium. This in turn disturbs the balance of their cross relaxation with their own neighboring spins, thereby creating additional NOE enhancements often called *indirect* enhancements. Such indirect enhancements can themselves cause further enhancements, and so on, until at steady state the original population disturbance at S may cause intensity changes to a greater or lesser extent throughout the spin system. For a multispin system, the relevant Solomon equation is

$$\begin{aligned} \frac{dI_z}{dt} = & -(I_z - I_z^0)(W_{0IS} + 2W_{1I} + W_{2IS}) - (S_z - S_z^0) \\ & \times (W_{2IS} - W_{0IS}) - \sum_X (X_z - X_z^0) \\ & \times (W_{2IX} - W_{0IX}) \end{aligned} \quad (12)$$

Setting dI_z/dt and S_z to zero as before, then rearranging and substituting $I_z^0 = (\gamma_I/\gamma_S)S_z^0 = (\gamma_I/\gamma_X)X_z^0$ gives the steady

state enhancement as

$$f_I\{S\} = \frac{\gamma_S}{\gamma_I} \frac{1}{R_I} \left[\sigma_{IS} - \sum_X \frac{\gamma_X}{\gamma_S} f_X\{S\} \sigma_{IX} \right] \quad (13)$$

where all the indirect contributions to $f_I\{S\}$ are represented by the summation over the other spins X . Thus, in general, the theoretical steady state enhancements (i.e. assuming no leakage) upon saturating S in an N -spin system where the distances are all known can be calculated from a set of $(N - 1)$ linear simultaneous equations of the form of equation (12).⁹ Note particularly that steady state enhancements are not controlled only by the internuclear distance between I and S , but are a function of many (potentially all) of the internuclear distances in the system. This crucially important point is all too often ignored in naïve interpretations of NOE experiments, particularly those involving small molecules.

The significance of indirect enhancements depends very much on the tumbling rate of the molecule under study, as will be illustrated in the following sections.

4 STEADY-STATE NOE EXPERIMENTS WITH SMALL MOLECULES

For homonuclear systems in small molecules, direct enhancements are positive, so that a directly enhanced signal can itself be thought of as being ‘negatively saturated’. Spins that are significantly closer to such a directly enhanced spin than they are to the saturated spin therefore receive a *negative* enhancement from the directly enhanced spin, often called a ‘three-spin effect’. However, at extreme narrowing, σ is significantly smaller than R_I , so that the transmission of enhancements down a chain of spins is a relatively inefficient process, even in the absence of leakage. In practice, efficient leakage reduces the transmission of indirect effects still further, and effects transmitted over more than one intermediate spin are almost never observed in small molecules. Given the sign distinction between direct and three-spin effects, this makes distinguishing indirect effects a relatively trivial matter.

Clearly, the geometry of a spin system is crucial in determining what effects will actually be seen. Substantial three-spin effects are generally associated with spins in a nearly linear arrangement, and it also follows that for some arrangements of spins, appreciable direct and indirect effects cancel leaving a small or zero net enhancement despite a short IS internuclear distance. These points are illustrated by the theoretical enhancements shown for some particular geometries in Figure 4.

4.1 NOE Difference Spectroscopy

The experiment that is now most widely used to measure steady state enhancements in small molecules is the NOE difference experiment, the pulse sequence for which is summarized in Figure 5. Two datasets are acquired, in one of which selective, low-power preirradiation is applied to the target resonance S . In the other experiment (the control), all details are identical to the first except that the preirradiation is applied in a blank area of the spectrum. Subtraction of

Figure 4 Theoretical NOE intensities ($\rho^*_I = 0$) for various simple multispin systems at the extreme narrowing limit ($\omega\tau_c \ll 1$). (a) Illustration of the transmission of a three-spin effect (here $f_X\{S\}$) in a linear spin system. (b) Illustration of how substantial direct and indirect contributions can cancel, leaving a very small net enhancement ($f_X\{S\}$) despite short distances. (c) Illustration as to how two direct effects corresponding to the same distance can differ drastically when one enhanced spin is rapidly relaxed by another near neighbor, and the other enhanced spin is not

Figure 5 Pulse sequence for the one-dimensional NOE difference experiment

the control spectrum from that in which S is preirradiated yields a difference spectrum containing only those signals that changed intensity upon preirradiation of S . Note that, since the saturating field is switched off during acquisition of the FID, no coherent decoupling effects are present to complicate the data, and (ideally) only population effects can contribute to the difference spectrum.

In order to minimize unwanted differences between the datasets arising from instrumental instabilities, acquisition of the two datasets is usually carried out in an interleaved manner. If, as is usual, a series of experiments is to be carried out, a list is constructed of frequencies corresponding to the various preirradiation targets. Since, in principle, the control data are identical for all the different preirradiation targets, generally only one or two control entries are included in this list. The spectrometer then cycles repeatedly through the whole list, typically acquiring two or four dummy scans followed by eight or 16 transients at each frequency on each pass, until the available experimental time has been filled. A separate dataset is maintained for each preirradiation frequency, and incoming data are always added to data acquired at the same frequency on previous cycles. Careful attention to temperature equilibration and stability are also crucial to obtaining high-quality data. Long preirradiation periods (5–10 s or more) are often useful in NOE difference experiments, since then informative three-spin effects are

allowed to become significant. However, when sensitivity for measuring relatively strong direct effects is the only issue, somewhat shorter preirradiation periods of $(1-3)T_1$ are often used in conjunction with an increased number of scans. Note also that there is no need whatsoever for a relaxation delay between acquisition and the start of the next preirradiation.

Preirradiation power is generally set extremely low, in order to avoid unwanted saturation of neighboring resonances. This can result in the target resonance being only partially saturated, which leads to NOE enhancements being only partially excited in direct proportion. However, this is of little real consequence since the absolute size of the enhancement rarely needs to be interpreted quantitatively in steady state experiments, the only real loss being one of sensitivity. Various techniques are available for saturating multiplets evenly without using high powers, for instance by cycling the preirradiation frequency around the multiplet components during each preirradiation period. These methods help to minimize the unwanted effects of selective population transfer (SPT) that arise at scalar coupling partners of the irradiated signal if the multiplet components of S are unevenly saturated (e.g. see Figure 6); these appear as intense antiphase signals at the coupled signals, and are completely unrelated to the NOE. Further suppression of SPT effects can be achieved by using a composite 90° pulse to excite the spectrum.

With care and long acquisition periods, enhancements well below the 1% level may now be quite routinely detected using

Figure 6 NOE difference and control spectra of a mixture of 4- and 9-methylcyclopenta[*b*]naphthalenes [compounds **1** and **2**], obtained by photolysis of 4a-methyl-4aH-fluorene followed by treatment with butyllithium in $CDCl_3$ solution, recorded at ambient temperature and 250 MHz (preirradiation period 5 s).¹¹ For each NOE difference trace, the preirradiation target is indicated on the left, and the relative vertical scaling on the right. The enhancements between the CH_2 and CH_3 signals in compound **1**, and the enhancements $H_9\{CH_2\}$ and $H_3\{CH_3\}$ in compound **2**, established the relative assignment of signals from the two isomers, thereby allowing compound **1** to be identified as the one that was initially formed in the photolysis step (the small peaks near 2.9 ppm and 3.9 ppm are due to impurities). This example also demonstrates the use of NOE difference experiments in analyzing mixtures in cases where spectral overlap is not too severe, and the appearance of SPT artifacts at coupling partners of the preirradiated signals (these spectra were recorded before the methods of SPT suppression referred to in the text had been introduced). Adapted with permission from Neuhaus¹¹

the NOE difference technique (but such experiments are a particularly demanding test of instrumental stability).¹⁰

4.2 Applications to Small Molecules

One-dimensional NOE difference spectroscopy has now become an essential and routine tool for the determination of regio- and stereochemical isomerism in small and medium-sized molecules. However, a major and unavoidable limitation to the approach is imposed by molecular flexibility. The NOE can only distinguish between two or more possible structures or conformations if there is some significant and *consistently maintained* difference between internuclear distances corresponding to measurable NOE enhancements in the various cases. In this context, it is largely irrelevant whether the formal difference between the possibilities is one of covalently bonded structure or one of noncovalently stabilized conformation, provided that the relative spatial arrangement of protons is preserved.

Some of the simplest applications of the NOE involve the determination of aromatic ring and olefinic double-bond substitution patterns. Interpretation of the NOE enhancements in these essentially flat molecules is particularly simple, since the differences between internuclear distances in various possible structures are usually extremely clear cut. Aromatic ring fusion patterns are also usually quite straightforward to establish, provided, as in the case of substitution patterns, that there are strategically located protons at or near the sites that differ between the structures needing be distinguished (e.g. on each side of ring junctions). A simple example is shown in Figure 6.

Saturated systems often require a somewhat more sophisticated analysis, since differences between internuclear distances in various structures may be more subtle, and the importance of relaxation from other nearby protons in determining the relative sizes of enhancements may be less obvious. Substitution positions and ring fusion patterns are more likely to be available from coupling connectivities in such cases, so it is more often *stereochemical* information that is required

from the interpretation of the NOE results. Applications to five-membered rings are perhaps more common than to six-membered rings, presumably due to the relative difficulty of using coupling constant magnitudes to distinguish whether protons are *cis* or *trans* in a five-membered ring. Rigidity is again crucial to the successful application of the technique, so applications to medium-sized or larger ring systems are more difficult, unless flexibility is limited, e.g. by fusion to another ring.

In larger systems, rigidity may be maintained in more complicated ways, e.g. by a specific, intramolecular network of hydrogen bonds that may, in effect, convert an acyclic portion of a molecule into a cyclic one. In combination with other NMR techniques, the NOE has been used to define largely or completely the stereochemistry and conformation of many complicated natural products, including steroids and other terpenoids, alkaloids, saccharides, small cyclic peptides, and various other types of natural macrocycles (see also *Carbohydrates and Glycoconjugates*).¹⁵

Applications to characterizing conformational equilibria have been much less common. Accurate quantitation and very careful analysis are essential, and several unavoidable assumptions render analysis of even the simplest systems extremely approximate. In particular, if averaged NOE data from a rapidly exchanging system are to be fitted to try to find the relative proportions of two or more conformers, then the r^{-6} dependence of enhancements implies that the fit will be critically dependent on having very accurate internuclear distances available from models of the contributing conformers. The outlook for improvement in this situation remains bleak.

A few representative examples of applications of the NOE to problems of structure determination in small and medium-sized molecules are summarized in Figure 7.

5 KINETIC NOE EXPERIMENTS WITH LARGE MOLECULES

In complete contrast to the situation for small molecules, for homonuclear experiments with large molecules direct and

Figure 7 A few representative examples of structural applications of the NOE in small molecules. Compound (3) is a petroporphyrin whose substitution pattern was determined by the NOE enhancements shown.¹² Compound (4) is a hydroxyhomocepham isolated during work on penicillin biosynthesis, in which the stereochemistry at C-3 was established by the enhancements shown.¹³ Compound (5) is a benzylisoquinoline alkaloid called misramine, the structure of which was established by a combination of spectroscopic techniques, and including the NOE enhancements shown.¹⁴ In this case the enhancement data helped to link together partial ^1H spin systems determined by decoupling experiments, to determine the stereochemistry, and to determine that the site of the acetal function was C-11 rather than C-9

indirect enhancements are all negative, and the predominance of W_0 transitions over all others means that indirect enhancements can be transmitted efficiently down a chain of spins. In the limit of slow tumbling, saturation of any spin in a homonuclear multispin system will, at steady state, cause a -100% enhancement of every other spin; in other words, the entire spectrum will become saturated and disappear. This is the ultimate demonstration of the process known as 'spin diffusion', whereby enhancements in large molecules lose their specificity by dissipating onto other nearby spins.

Spin diffusion renders steady state homonuclear experiments on large molecules completely useless in terms of determining structures. Even limited spin diffusion poses a severe problem for interpretation, since direct and indirect enhancements cannot be distinguished a priori, being all negative, making it impossible to equate a given strength of enhancement with a given distance even approximately. In order to overcome this problem, NOE enhancements for such molecules are measured not at steady state but rather during the early stages of their build up.

Two types of simple kinetic experiment are possible. In the first, generally called the truncated driven Overhauser experiment or TOE, the NOE is driven by continuous saturation of the S signal throughout a short, variable period of NOE evolution. This experiment is essentially identical to the NOE difference experiment, except that the period of preirradiation during which the NOE evolves is kept much shorter. In the second type of kinetic experiment, perturbation of the S spin populations is achieved effectively instantaneously using pulses, and the NOE is then allowed to evolve for a short variable period in the absence of saturation. Experiments in this latter category include the two-dimensional NOESY experiment (see *NOESY*) and all its variants (see also *Homonuclear Three-Dimensional NMR of Biomolecules*), and also various transient one-dimensional experiments based on allowing the NOE to evolve after a selective inversion pulse to the signal corresponding to S (note, however, that there can be no true two-dimensional analog of the steady state or TOE experiments).

The period of NOE evolution in any kinetic experiment is generally called the mixing time, or τ_m . Provided that τ_m is sufficiently short, direct enhancements never become large enough to cause substantial indirect enhancements, and the process of spin diffusion has no chance to begin. This limit is known as the 'initial rate approximation'. The limiting form of equation (12) at short times may be found by substituting $S_z = 0$, $I_z = I_z^0$, and $X_z = X_z^0$, leaving

$$\left. \frac{dI_z}{dt} \right|_{t=0} = \sigma_{IS} S_z^0 \quad (14)$$

(for experiments where S is selectively inverted rather than saturated, the appropriate initial condition is $S_z = -S_z^0$, leading to an initial rate of $2\sigma_{IS} S_z^0$).

Thus the initial rate of NOE buildup is directly proportional to σ_{IS} , and therefore also to r^{-6} . It is this simple proportionality that forms the basis for most uses of the NOE in the structure determination of large molecules. At later times, once an appreciable enhancement has built up at I , then relaxation of the I spins at a rate determined by R_I starts significantly to oppose the buildup of the enhancement, and the steady state represents the balance that is eventually reached between these

processes and also the influence of indirect enhancements. This also shows that the period of validity of the initial rate approximation depends on R_I , and may thus be different for different spins. However, broadly speaking, it is the molecular tumbling rate that is the main factor that determines how short mixing times must be if the direct proportionality between NOE intensity and r^{-6} is to be at least approximately preserved; the more slowly the solute tumbles, the faster longitudinal relaxation will occur and the shorter the validity of the initial rate approximation will last.

Although most interpretation of NOESY data and other kinetic NOE experiments is based on the assumption (or hope) that the initial rate approximation is still valid at the particular values of τ_m used, it is also possible to calculate the whole time-course for the evolution of NOE enhancements in multispin systems of known geometry. The relaxation behavior of a multispin system can be fully described in terms of the relaxation matrix $\mathbf{R}$, defined by

$$\mathbf{R} = \begin{bmatrix} R_1 & \sigma_{12} & \sigma_{13} & \cdots & \sigma_{1N} \\ \sigma_{21} & R_2 & \sigma_{23} & \cdots & \sigma_{2N} \\ \sigma_{31} & \sigma_{32} & R_3 & \cdots & \sigma_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sigma_{N1} & \sigma_{N2} & \sigma_{N3} & \cdots & R_N \end{bmatrix} \quad (15)$$

The intensities of the NOESY cross peaks at time τ_m are then given by:

$$\mathbf{a}(\tau_m) = \exp(-\mathbf{R}\tau_m) \mathbf{a}(0) = \mathbf{T} \exp(-\mathbf{D}\tau_m) \mathbf{T}^{-1} \mathbf{a}(0) \quad (16)$$

where $\mathbf{a}(\tau_m)$ is the matrix of cross peak intensities at mixing time τ_m , $\mathbf{a}(0)$ is the corresponding matrix at zero mixing time, $\mathbf{D}$ is the diagonal matrix comprised of the eigenvalues of $\mathbf{R}$, and $\mathbf{T}$ is the matrix comprised of the eigenvectors of $\mathbf{R}$. The matrix $\mathbf{a}(0)$ is of course diagonal, and is needed only for normalization. Figure 8 shows how the intensities of the cross peaks and diagonal peaks in the NOESY spectrum vary as a function of τ_m , for a two-spin system in the extreme narrowing limit, and for one near the spin diffusion limit.

Figure 8 Simulated time course for cross-peak and diagonal peak intensity in a NOESY experiment for an isolated two-spin homonuclear system, as a function of mixing time (τ_m) for two different motional regimes. In a rapidly tumbling molecule ($\omega\tau_c \ll 1$) the cross peak is negative relative to the diagonal, and builds up and decays slowly, whereas for a slowly tumbling molecule ($\omega\tau_c \gg 1$) the cross peak is positive and builds up rapidly before decaying slowly

A slightly more complicated matrix equation also exists for describing the time-course of TOE experiments:

$$\mathbf{f} = [\mathbf{R}'^{-1} \sigma] - [\mathbf{T}' \exp(-\mathbf{D}' \tau_m) \mathbf{T}'^{-1} \mathbf{R}'^{-1} \sigma] \quad (17)$$

where $\mathbf{f}$ is the column matrix of enhancements $f_I\{S\}$, σ is the column matrix of cross-relaxation rates involving S , and $\mathbf{R}'$, $\mathbf{T}'$, and $\mathbf{D}'$ are matrices analogous to $\mathbf{R}$, $\mathbf{T}$, and $\mathbf{D}$ in equation (16), but reduced by the elimination of all entries involving spin S . In addition to these matrix formulations, there are iterative numerical approaches to calculating the time course of NOESY and TOE experiments.^{16,17}

At a practical level, if quantitative intensities are required for estimating internuclear distances, it is important that the spin populations be at equilibrium at the start of each pass through the pulse sequence. This is one reason why such kinetic experiments are used mainly for large molecules; for small molecules, this condition implies that long relaxation delays (tens of seconds) are required, making overall experiment times very long.

5.1 Applications to Biological Macromolecules

Generally, structure determinations of biological macromolecules rely on the assignment and classification of a large number of NOESY cross peaks linking individual spin pairs, followed by the calculation of a family of structures consistent with these data. Methods for assigning such spectra are discussed elsewhere.¹⁸ The simple interpretation of data derived from NOESY spectra is usually based on an assumed validity of the initial rate approximation, so that the intensities of individual cross peaks are identified exclusively with the corresponding internuclear distance. In this context, this approximation is often known as the 'isolated spin-pair approximation', or ISPA. Cross peaks are classified semiquantitatively into groups such as 'strong', 'medium', and 'weak', and each category is interpreted as corresponding to a particular range of internuclear distances, following calibration by comparison with cross peaks corresponding to known distances. Usually, only the upper bound of each distance range is defined by the NOE intensity, in order to allow for the possibility that enhancements due to spins that are actually close together are made weaker by internal motions.

Various types of computer program are then used to generate a structure from the NMR data in conjunction with the known covalent connectivity and ideal covalent geometry. Although the bulk of the NMR data comprise NOE-derived distance constraints, it is common also to use torsion angle constraints derived from scalar coupling constant measurements and hydrogen bonding constraints derived from identification of slowly exchanging NH protons. Methods used for calculating biological macromolecular structures include distance-geometry, simulated annealing, and restrained molecular dynamics calculations, and also probabilistic model-building approaches; details may be found elsewhere (see also *Distance Geometry*).¹⁹ Normally an ensemble of calculations is run with each member starting from a randomly different set of initial conditions. Comparing the structures by superposition identifies which regions are well defined by the data, since only such regions are conserved across the ensemble.

Full matrix calculations of the NOE intensities can also be used to refine structures based on ISPA calculations, since they allow at least limited spin-diffusion to be accounted for explicitly (see *Protein Structures: Relaxation Matrix Refinement*). Although equation (16) allows the prediction of NOE intensities at any point during their evolution for a known structure, the reverse process, calculation of all the internuclear distances directly from the NOE intensities, would require that the *complete* NOESY intensity matrix be known, including all of the diagonal elements. Given that, in practice, such complete information is never available for complicated spectra of macromolecules, various iterative approaches have been developed that improve the fit of a starting structure to the available NOE data, either by progressively modifying the structure (e.g. the program IRMA²⁰), or by iterating on the internuclear distances themselves (e.g. the program MARDIGRAS²¹).

The whole field of application of the NOE to macromolecules has seen a huge growth since the first three-dimensional protein structure derived from NMR (that of BUSI-III) was published by Williamson et al. in 1986.²² The size of proteins that can be tackled is limited principally by the assignment problem, both in terms of assigning all the ¹H chemical shifts within the protein, and in terms of assigning each individual NOE cross peak; the latter becomes a severe problem in its own right for proteins that exhibit extensive chemical shift degeneracy. The homonuclear experiments used for making assignments in unlabeled proteins begin to fail when ¹H linewidths become significantly greater than the values of typical (¹H,¹H) coupling constants, implying that for nonaggregated globular proteins this methodology is usually applicable up to polypeptide chain lengths of a little over 100 residues (see also *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*).¹⁸

More recently, it has become practical to obtain protein samples in which all (<98%) carbon atoms are isotopically substituted with ¹³C, and all nitrogens with ¹⁵N; this is achieved by overexpression of the protein in a bacterial system growing in an appropriately isotopically enriched medium. This has opened the door to a whole barrage of new NMR techniques for the assignment of signals and NOE cross peaks, the details of which may be found elsewhere (see also *Half-Filter Experiments: Proton-Carbon-13; Three- and Four-Dimensional Heteronuclear Magnetic Resonance; Three-Dimensional HMQC-NOESY, NOESY-HMQC, and NOESY-HSQC*).²³ These make use of the much larger one-bond heteronuclear and (¹³C,¹³C) couplings to detect through-bond connectivities and disperse crowded spectra in three or four frequency dimensions. It is not really clear yet what the upper size limit is for studying such isotopically enriched proteins, but systems approaching 200 residues have already been solved and it seems likely that larger ones will follow.

Although perhaps the most spectacular results have been obtained with proteins, related studies for DNA oligonucleotides have yielded much structural information,²⁴ although reliable identification of sequence-dependent conformation of double-helical DNA has proved somewhat elusive due to the essentially linear nature of the DNA molecule (see *DNA Triplexes, Quadruplexes, and Aptamers; DNA: A-, B-, and Z-; Nucleic Acid Structures in Solution: Sequence Dependence; Nucleic Acids: Spectra, Structures, and Dynamics*). Very

recently, NOE-based structure determinations of small RNA molecules have been reported, some making use of global isotopic labeling in a similar fashion to that used for proteins,²⁵ and the first solution structures of protein–nucleic acid complexes are now beginning to appear.²⁶

6 THE ROTATING FRAME NOE

As Figure 2 makes clear, for homonuclear spin systems where $\omega\tau_c \approx 1$, all conventional NOE enhancements are small or zero, irrespective of the internuclear distances involved, representing a severe problem for studies of intermediate-sized molecules. However, this problem can be avoided by carrying out a different type of NOE experiment, in which NOE enhancements evolve not between elements of longitudinal magnetization as in the conventional experiment, but rather between elements of transverse magnetization during a period of spin locking.

Spin locking suppresses the *relative* precession of chemically shifted resonances within the spectrum; in other words, while the spin locking field is switched on, all the transverse magnetization components from the different signals in the spectrum precess *together*, with a constant relative phase. The simplest spin locking sequence comprises a hard 90° pulse followed by application of a spin locking field 90° out of phase with the pulse. If, prior to the 90° pulse, the system is prepared by inverting a particular signal S , then transverse cross relaxation during the spin locking period will lead to a transient rotating frame Overhauser effect, accumulating at signals corresponding to the cross-relaxation partners of S . This is exactly analogous to a conventional one-dimensional transient NOE experiment, in which the S signal is inverted prior to a period for evolution of longitudinal NOE enhancements. The role of the spin locking field is perhaps best viewed as maintaining a constant phase relationship between the inverted signal and the others; had the spin locking field been absent, relative precession due to chemical shifts would have prevented any *net* accumulation of enhancement. Most commonly, ROE enhancements are measured using the two-dimensional ROESY experiment, which is the ROE analog of NOESY (see **ROESY**). Note that since there is no frequency difference between any of the spins while the ROE enhancements are evolving during the spin locking period, it is not possible to saturate selectively any of them separately during this time. There can therefore be no ROE analog of the conventional steady-state experiment.

The reason why ROE experiments differ fundamentally from longitudinal ones is that the transition probabilities for spin locked dipolar relaxation are based on different spectral densities. The transverse cross-relaxation rate σ_2 and transverse direct relaxation rate ρ_2 are given by²⁷

$$\sigma_2 = \frac{1}{40}K^2[\frac{9}{2}J(2\omega_1) - \frac{1}{2}J(0) + 6J(\omega_0)] \quad (18)$$

$$\rho_2 = \frac{1}{40}K^2[\frac{9}{2}J(2\omega_1) + \frac{1}{2}J(0) + 9J(\omega_0) + 6J(2\omega_0)] \quad (19)$$

where ω_0 is the Larmor frequency and ω_1 is the frequency of precession about the B_1 field. For comparison, the equivalent expressions for their longitudinal counterparts, obtained by substituting into equation (8), are

$$\sigma_1 = \frac{1}{20}K^2[-J(\omega_I - \omega_S) + 6J(2\omega_0)] \quad (20)$$

$$\rho_1 = \frac{1}{20}K^2[J(\omega_I - \omega_S) + 3J(\omega_0) + 6J(2\omega_0)] \quad (21)$$

Note that for slowly tumbling molecules where terms in $J(\omega_0)$ and $J(2\omega_0)$ are insignificant, σ_2 is twice σ_1 . If NOESY and ROESY data are to be compared directly in such cases, τ_m should therefore be set twice as long in the NOESY experiment as in the ROESY.

The key difference between these expressions is that, unlike σ_1 , σ_2 cannot become negative unless the extreme narrowing approximation breaks down *with respect to* ω_1 . Typical spin locking field strengths in ROE experiments are between about $\omega_1 = 2$ kHz and $\omega_1 = 10$ kHz, implying that molecular motions in liquid samples will never be significantly slower than this so that direct ROE enhancements are always positive. Another key difference to the conventional experiment concerns spin diffusion. In effect, any size of molecule behaves in an ROE experiment as though it were a small molecule in a conventional NOE experiment (hence the original acronym CAMELSPIN for the experiment;²⁸ this stands for cross relaxation appropriate for mini-molecules emulated by spin locking). Thus, there is an alternation of sign for each intermediate spin over which an indirect enhancement is transmitted, and the transmission of indirect effects is relatively inefficient due to the loss that occurs at each step. For a large molecule, the influence of spin diffusion is markedly reduced in an ROE experiment relative to the corresponding NOE experiment, and what spin diffusion there is can usually readily be identified from the relative sign of the corresponding cross peaks.

Against these advantages, there are some difficulties that arise from the application of the spin locking field. Significant resonance offset effects are inevitable at the relatively low spin locking field strengths that can be applied in practice, implying that the cross relaxation controlling cross-peak intensities will, in general, be a composite of longitudinal and transverse contributions. Also, for coupled spins that are symmetrically disposed about the spin lock frequency, or are both close to it, a net transfer of magnetization may occur through the scalar coupling via the homonuclear Hartmann–Hahn (HOHAHA) interaction. Multistep mechanisms involving both HOHAHA transfer and ROE transfer may also occur, making the interpretation of ROESY data potentially quite complicated (see also **TOCSY in ROESY and ROESY in TOCSY**).²⁹

Nonetheless, there have been many applications of the ROE in the decade or so since its discovery. Mainly, these have been to intermediate-sized molecules, such as small peptides, that often give very poor NOESY spectra. However, it may also be worthwhile running a series of conventional steady state NOE difference spectra, since these are often significantly more sensitive than NOESY for such systems. For macromolecules, although clearly ROESY does not supplant NOESY for obtaining internuclear distance constraints, it can be very useful to compare NOESY and ROESY data in order to help identify spin diffusion pathways in the former.

7 THE HETERONUCLEAR NOE

Figure 9 shows the maximum theoretical steady-state heteronuclear two-spin NOE enhancement ($\eta_{\max}$) for the

Figure 9 Maximum theoretical two-spin NOE enhancements ($\eta_{\max}$) for various heteronuclear systems relaxing exclusively via dipolar interaction, as a function of $\omega\tau_c$. Note that for ^{15}N , the NOE can be negative, and that for ^{13}C and ^{31}P the NOE becomes very small for large molecules

more important heteronuclei and hydrogen, calculated using equations (4)–(6). The commonest application of these heteronuclear NOE enhancements is for sensitivity improvement during direct observation of heteronuclear signals, e.g. the application of ^1H decoupling when acquiring ^{13}C spectra of small molecules (at the extreme narrowing limit, $\eta_{\max}$ for the $^{13}\text{C}\{^1\text{H}\}$ NOE is 199%, corresponding to a threefold gain in signal). Note that $\eta_{\max}$ also corresponds to the theoretical NOE ($\rho^* = 0$) seen in a multispin system when all spins but one are saturated (provided all the saturated spins have the same γ).⁵ However, any value of $\eta_{\max}$ between 0% and –200% means that saturation of the protons causes a *reduced* intensity for the X resonances, and a value of –100% means they are destroyed altogether. Inspection of the curves in Figure 9 shows that such circumstances do occur in some cases where γ_X is negative, e.g. for $^{15}\text{N}\{^1\text{H}\}$ with $\omega_N\tau_c \approx 0.5$. In such cases, if proton decoupling is to be used to collapse the X resonance multiplet structures, it should be applied in a gated fashion during the acquisition time only, and be switched off during the relaxation delay. In several other cases, the heteronuclear NOE becomes very small for slowly tumbling molecules, e.g. at the spin diffusion limit $\eta_{\max}$ for the $^{13}\text{C}\{^1\text{H}\}$ NOE is 15.4%, and for the $^{31}\text{P}\{^1\text{H}\}$ NOE it is only 2.2%. For these cases, there is of course virtually no sensitivity gain to be had from the heteronuclear NOE.

Measurements of specific heteronuclear enhancements to aid in structure determination are much less common than homonuclear applications because the sensitivity of the experiments is much lower, but several applications to small molecules have appeared.³⁰ Although the NOE observed on protons is a lot smaller than that observed on the X resonance, it is still often preferable to use proton observation as the sensitivity gain from detecting the higher frequency nucleus more than compensates; however, such ^1H -detected (inverse) NOE experiments may be compromised by inferior subtraction quality if the X nucleus is a dilute spin. Another factor that makes heteronuclear NOE experiments difficult is that the buildup rate σ_{XH} is slower than the corresponding interproton rate by a factor of $(\gamma_{\text{H}}/\gamma_X)^2$, for the same internuclear

separation. Thus specific steady-state heteronuclear NOE difference experiments with small molecules can be extremely time-consuming, while experiments with macromolecules are usually precluded by the small values of $\eta_{\max}$. Even in cases where $\eta_{\max}$ appears to behave quite similarly to that for the interproton NOE (e.g. for $^{19}\text{F}\{^1\text{H}\}$), one must remember that in the spin diffusion limit W_0 transitions will always be more efficient for the homonuclear case, since for sufficiently large molecules the tumbling rate will always be slower than the heteronuclear frequency difference ($\omega_I - \omega_S$). Thus, for example, in a $^1\text{H}\{^{19}\text{F}\}$ NOE experiment where a single fluorine resonance is saturated in a macromolecule, the buildup of heteronuclear enhancements at the nearest protons will be much slower than the dissipation of those enhancements onto other protons via homonuclear spin diffusion.

Recently, one of the more significant uses for heteronuclear NOE measurements (in conjunction with X nucleus T_1 and T_2 values) has been in the determination of local flexibility in macromolecules (see *Protein Dynamics from NMR Relaxation*). Typically, for each ^{15}N resonance in a ^{15}N -labeled protein, the corresponding T_1 , T_2 , and $^{15}\text{N}\{^1\text{H}\}$ steady-state NOE would be measured, and these data analyzed using a suitable formalism, most commonly the ‘model-free’ formalism of Lipari and Szabo.³¹ For internal motions of the ^{15}N – ^1H vector that are faster than the overall molecular tumbling, this approach yields an ‘order parameter’ S^2 that describes the geometric extent of the internal motion relative to the molecular frame; $S^2 = 1$ implies complete rigidity, while $S^2 = 0$ implies the internal motion is isotropic relative to the molecular frame.

8 EXCHANGING SYSTEMS AND THE TRANSFERRED NOE

There are many types of exchange that can affect NMR spectra, including chemical exchange of labile protons (OH, NH, etc.) in protic solvents, conformational equilibria, and exchange of a solute between free and bound states. The effects that these processes have on NOE experiments depends mainly on their rate, relative both to the T_1 timescale and to the chemical shift timescale (see also *Relaxation Effects of Chemical Exchange*). If exchange is slow relative to T_1 , then NOE enhancements will evolve largely unaffected by the exchange process. However, if exchange is fast relative to T_1 , then many exchange events will occur during NOE evolution, causing the various relaxation rates themselves to be averaged, and it will be as though the NOE had evolved in an ‘averaged molecule’. Thus, if two resonances are linked by exchange that is faster than T_1 , irradiation of one will result in saturation of both (saturation transfer), and if one resonance receives an NOE enhancement, exchange will transfer the enhancement onto the second resonance also. Under these circumstances, NOE enhancements will reflect so-called ‘ $\langle r^{-6} \rangle$ average’ distances, defined as

$$\langle r_{IS}^{-6} \rangle = \left[\frac{1}{N} [(r_{IS}^A)^{-6} + (r_{IS}^B)^{-6} + \dots + (r_{IS}^N)^{-6}] \right]^{-1/6} \quad (22)$$

where r_{IS}^A, r_{IS}^B , etc. represent the IS internuclear distance in each of the N exchanging forms of the system. For internal

motions faster than overall molecular tumbling, it transpires that $\langle r^{-3} \rangle$ averaging of distances is appropriate, and that in addition there is a geometry-dependent reduction of NOE enhancements caused by the anisotropy of the internal motion with respect to the molecular frame; this situation usually applies for methyl group rotations.³²

Note that the rate of exchange relative to $\Delta\delta$ (the chemical shift difference for the same spin in its two environments, for the case of two-site exchange) does not directly affect the NOE intensities at all; however, it does affect the number of separate resonances in the spectrum, and thereby dictates what NOE interactions can be measured separately. In cases of exchange which is slow relative to $\Delta\delta$, where separate signals are seen for each exchanging species, exchange can provide an additional mechanism for magnetization transfer in NOE experiments. For large molecules in conventional NOE experiments, exchange that is fast on the T_1 timescale causes saturation transfer signals that have the same sign as the NOE-enhanced signals; a distinction between the two types of signal can generally only be made on grounds of intensity or buildup rate. Conversely, for conventional NOE experiments with small molecules, and for ROE experiments with any size of solute, exchange will lead to signals of opposite sign to direct enhancements. Although this implies that they have the same sign as indirect enhancements transmitted over one intermediate spin, in the context of a general interpretation of all the cross peaks, the distinction between these two types of signal is usually quite straightforward.

More insidious than the signals due to exchange itself, however, is the possibility that conformational averaging affects the NOE intensities, giving results that reflect an 'averaged structure'. This can lead to data that are inconsistent with any single structure. In the case of slow exchange on the chemical shift timescale there is likely to be warning of the danger since multiple resonances are observed, but in the case of fast exchange on the chemical shift timescale there may be no indication of conformational exchange other than mutual inconsistencies amongst the NOE intensities. If models of the separate exchanging conformers are available from some other source, then in principle it is possible to fit the NOE data, using the relative proportions of the conformers as one of the fitting variables; however, this process is difficult and, given the r^{-6} dependence of the NOE, very heavily dependent upon the accuracy of the initial models. In large molecules, the main issue concerning conformational exchange is usually how to allow for relatively small-scale local motions when interpreting NOE data. These have two principal effects: they reduce the size of the enhancements, by making the effective τ_c shorter, and they change relative intensities by altering the values of $\langle r^{-6} \rangle$. For small-scale motions, these effects are both taken into account, at least approximately, by specifying NOE-derived distance constraints as ranges rather than specific distances, as mentioned earlier.

A particularly significant case of the influence of exchange is in the transferred NOE, or TRNOE experiment. Suppose a small ligand binds to a large molecule, and that exchange between the free and bound states is fast both on the T_1 and chemical shift timescales. The ligand resonances and also its intramolecular NOE enhancements will be averaged over the free and bound states by such an exchange. If the ligand is present in moderate excess, then the averaged ligand resonances will largely retain the narrow linewidths

associated with the free ligand. However, because the tumbling rate of the ligand when bound to the large molecule is very much slower than in the free state, dipolar relaxation rates will be very much faster for the bound ligand than for the free [equations (4)–(6)]. Therefore, the observed NOE interactions will be dominated by the bound state, and thus reflect the bound conformation of the ligand, even though the free ligand concentration is higher than the bound. Although the first applications involved one-dimensional experiments, TRNOE experiments are now usually carried out using either NOESY or ROESY. Typical applications include studies of inhibitors bound to enzymes and small peptides bound to immunoglobulins; however, the generality of the technique is somewhat limited by the requirements for suitable exchange rates for the ligand–macromolecule interaction.³³ More recently, related experiments have been used to investigate protein hydration using intermolecular NOE enhancements between the protein surface and water protons (see *Protein Hydration*).

1 INTRODUCTION

A knowledge of nuclear magnetic relaxation processes is important for a variety of reasons. For example, the proper operation of a Fourier transform spectrometer requires the precise settings of pulse widths and time delays to optimize the sensitivity, resolution, integral accuracy, and nuclear Overhauser enhancements. Measurements of relaxation times are extremely useful for calculating diffusion constants and overall molecular motion, as well as segmental motion. They are also useful for making line assignments, determining internuclear distances, and establishing molecular structure. Finally, knowledge of relaxation times are important for understanding T_1 - and T_2 -weighted images in MRI, and for the synthesis of new contrast agents.

There are a host of excellent books, reviews and articles^{1–6} that cover all aspects of relaxation, from both practical and theoretical viewpoints. Two recent and particularly interesting articles by Hahn⁷ and Bloembergen⁸ describe the historical development of the concepts underlying relaxation, and the experiments they used to measure relaxation phenomena. It is not the intent of this article to review previously published material. Instead, the approach given here is one that is not easily found elsewhere, and is meant to complement the articles already published. In addition, this article will focus only on the introductory aspects of relaxation.

2 PHENOMENOLOGICAL OBSERVATIONS OF RELAXATION

Consider the simple case of delivering a pulse to a single type of nucleus that is not coupled to any other nucleus; for example, the proton in 100% $\text{H}^{12}\text{CCl}_3$. Before an rf pulse is given, the net magnetization $\mathbf{M}_0$ is aligned along the $\mathbf{B}_0$ lines of force. After the pulse, two observations can be made. First, a rather large signal will be obtained initially, but the intensity of the signal will gradually decay as a function of time. Second, if enough time is allowed to elapse after the pulse, the experiment can be repeated with exactly the same results. From these

observations and others, several conclusions can be drawn. First, because the signal is induced in a receiver coil that is wound along the y axis, the pulse must tip $\mathbf{M}_0$ away from the longitudinal z axis and into the (x, y) transverse plane. Second, because it is a magnetization ($\mathbf{M}_{xy}$) that generates the signal in a receiver coil that is wound with its axis in the (x, y) plane, the decay of the signal means that $\mathbf{M}_{xy}$ gradually vanishes from the transverse plane. Finally, the fact that the experiment can be repeated means that, between the pulses, the component of $\mathbf{M}_0$ along the z axis (M_z) must be growing back up along the z axis. The decay of the signal and the recovery of M_z back to M_0 are both called ‘relaxation processes’, even though one is a decay and the other is a growth. More specifically, the growth along the z axis is called a ‘ T_1 process’, and the decay in the (x, y) plane is called a ‘ T_2 process’. Sometimes these two processes are linked, in the sense that one influences the other, and sometimes they are not, as explained later in this article.

If the chloroform sample is placed in the field $\mathbf{B}_0$, the magnetic moment $\boldsymbol{\mu}$ of the nuclei will take up two orientations: parallel to (in the same direction as) the field, and antiparallel to (in the opposite direction as) the field. These two states have different energies, and are called the α (low-energy) and β (high-energy) states, respectively. The energies of these states depend upon the magnitudes of the two interacting fields, $\boldsymbol{\mu}$ and $\mathbf{B}_0$. Hence, the energy of the β state is $+\mu B_0$ and that of the α state is $-\mu B_0$. The difference between these two energies, ΔE , is $2\mu B_0$. Initially, the number of nuclei will be equal in these two states, i.e., the states will be equally populated. However, this is not the lowest energy state for this system. The lowest energy is attained when the populations equal those that are given by the Boltzmann factor:

$$\frac{N_\beta}{N_\alpha} = \exp\left(-\frac{\Delta E}{kT}\right) = \exp\left(-\frac{2\mu B_0}{kT}\right) \quad (1)$$

where N_α and N_β represent the number of nuclei in the low- and high-energy states, respectively, ΔE is the difference in energy between these states, k is Boltzmann’s constant, and T is the absolute temperature. Hence, the nuclei will attempt to reorient themselves to achieve this new distribution. The length of time that it takes for this reorientation to occur is characterized by a constant, T_1 . It is extremely important to note that T_1 is *not the time that it takes for this reorientation to be complete*—it will be shown later that it takes at least five times this long.

When the sample is first placed in the magnet, the difference between the two populations will be zero, i.e., $\Delta N = N_\alpha - N_\beta = 0$. As time progresses, nuclei will drop from the high-energy state into the lower, and ΔN will become increasingly more positive until the ratio given by equation (1) is established. For protons at room temperature in a 7.05 T field (300 MHz for protons), the ratio is approximately 0.999 95. Because the ratio is so close to unity, ΔN is a relatively small number for most sample sizes. Note that the limits of the ratio given by equation (1) are zero and one, as the temperature approaches absolute zero and infinity, respectively. The magnitude of the macroscopic magnetization vector, M_z , is directly proportional to ΔN at any time. Figure 1 shows how M_z grows immediately after the sample is inserted. The growth is exponential, and M_z asymptotically approaches the value M_0 . Theoretically, it takes an infinite length of time to reach the Boltzmann ratio,

but, in practice, the ratio is considered to be reached when M_z has grown to 99% of M_0 .

To gain some physical insight into the growth of M_z , two related phenomena with identical underlying principles will be described below. The first will be the recovery of an ideal spring after it has been stretched, and the second will be the first-order return to equilibrium for a unimolecular chemical system that has been displaced from its equilibrium position.

2.1 Spring Analogy

Consider the case of an ideal spring with one end attached to the ceiling and the other hanging free. The free end is at its *equilibrium* position, i.e., it is neither stretched nor compressed. This ideal spring has three properties that are analogous to a nuclear magnetization vector. Specifically,

1. the spring is weightless, and will have no momentum while moving;
2. while stretching or contracting, it will not lose energy because of internal friction;
3. it can be considered to be a point source.

Suppose the spring is stretched only a short distance toward the floor. When released, its instantaneous velocity will not be very high, because it has not been stretched very far; it has not been displaced very far from its equilibrium position. If stretched further before releasing then its instantaneous velocity will be higher. This property is the basic principle embodied in Hooke's law, which states that 'the stress is proportional to the strain' for an equilibrium system. If snapshots are taken of a series of these stretch-and-release experiments, joined together, and then run backwards, the end of the spring would appear to move very rapidly at first, but then move more and more slowly as it approaches its initial position of equilibrium. A plot of the position of the end of the spring versus time will be identical to that shown in Figure 1. In this figure, the slope at any point on the line

Figure 1 The growth of a magnetization vector along the z axis as a function of time for the case when $T_1 = 10$ s

gives the instantaneous rate of change, which is greatest at the beginning. It will be shown later that this rate of change is directly proportional to the displacement from equilibrium. If several springs manufactured from different sizes of wire were subjected to these stretch-and-release experiments, the ends of each spring would return exponentially to its equilibrium position, but at a rate determined by the force constant of the spring.

Hooke's law can be applied to a spin system because the nuclei that populate the two energy levels are in equilibrium. The ratio of N_α to N_β can be a constant without the nuclei permanently residing in any one state—this would be a *static* equilibrium. For the nuclear system, the ratio given by equation (1) remains constant because the total number of nuclei moving from the α state up to the β state is equal to the number moving from the β state down to the α state—this is a *dynamic* equilibrium. Hence, the end of an ideal spring may be imagined to be connected to the tip of the net magnetization vector M_0 . After a pulse, the component remaining along the z axis, M_z , will be less than M_0 , and the spring will stretch. During relaxation, the spring will return exponentially back to its equilibrium position, pulling M_z up with it. Thus, the force constant for a spring is analogous to the T_1 for a nuclear spin system.

2.2 Chemical Analogy

A first-order, unimolecular equilibrium may be written as $A \rightleftharpoons B$. This is a dynamic equilibrium, and is not chemically the same as a static mixture of $A + B$. In the latter system, a molecule of A never becomes a molecule of B , whereas in the former case, a molecule of A becomes a molecule of B . However, to maintain a constant A/B ratio, for each molecule of A that becomes a B , a molecule of B must become an A . Again, this chemical equilibrium is analogous to the nuclear system, and we may apply the same mathematical treatment to both.

If A is added to the equilibrium mixture of A and B , or if B is removed, the system will attempt to return to its equilibrium concentrations, given by K_{eq} . The application of Hooke's law here states that 'the instantaneous rate of return to equilibrium is directly proportional to its displacement from equilibrium'. For a nuclear system that has been displaced from equilibrium,

$$\frac{dM_z}{dt} \propto M_0 - M_z \quad (2)$$

where dM_z/dt is the rate of change of M_z , and $M_0 - M_z$ is the displacement from equilibrium, i.e., its equilibrium position (M_0) minus its present position (M_z). The proportionality symbol $\propto$ can be replaced by an equals sign and a constant of proportionality, k :

$$\frac{dM_z}{dt} = k(M_0 - M_z) \quad (3)$$

After collecting variables, the indefinite integral can be written as

$$\int \frac{dM_z}{M_0 - M_z} = k \int dt \quad (4)$$

At $t = 0$, when the sample is first placed in the field, $\Delta N = 0$ and $M_z = 0$. After some period of time t , the magnetization

will grow to some new value, M_z . Hence, the limits of the integration are as follows:

$$\int_0^{M_z} \frac{dM_z}{M_0 - M_z} = k \int_0^t dt \quad (5)$$

The solution of this equation is easily obtained by standard mathematical manipulations:

$$\ln \frac{M_0 - M_z}{M_0} = -\frac{t}{T_1} \quad (6)$$

where, in order to make the right-hand side dimensionless, like the left, k has been set equal to T_1^{-1} , with T_1 having dimensions of time. Equation (6) can be written equivalently as

$$M_z = M_0(1 - e^{-t/T_1}) \quad (7)$$

Equation (6) has the form of a straight line $y = mx + b$ and a semilogarithmic plot of $M_0 - M_z$ versus t will give an intercept equal to M_0 and a slope equal to $-1/T_1$. Figure 1 was prepared from equation (7), using a value of 10 s for T_1 . Table 1 was also prepared from equation (7).

As stated previously, M_z asymptotically approaches M_0 , and would take infinitely long to reach its maximum value. However, the recovery is normally considered to be complete when it has reached 99%. Hence, relaxation delays of $5T_1$ are commonly used in pulse sequences.

2.3 The Meaning of T_1

As explained earlier in this section, T_1 is a *measure* of how fast M_z grows back to M_0 —it is *not* how long it takes to grow back to M_0 . In this sense, it is analogous to the force constant of a spring, and not to the length of time it takes the end of a stretched spring to return to its relaxed position when released. After a 90° pulse, T_1 is the time it takes for M_z to grow back to $1 - e^{-1}$ of the original value that it had immediately before the pulse. Figure 2 shows that if the initial slope is extended until it intersects the M_0 line, the intersection occurs at a time equal to T_1 . If—repeat—if the magnetization grew at a constant rate equal to the initial rate then the relaxation would be complete in a time equal to T_1 , which is 10 s in this case.

Table 1 Percentage Recovery of M_z as a Function of Time, in Units of T_1

Time/ T_1	Recovery (%)
0.0	0.00
0.5	39.3
1.0	63.2
1.5	77.7
2.0	86.5
3.0	95.0
4.0	98.2
5.0	99.3

Figure 2 A plot (dashed line) of the *initial* rate of growth of a magnetization vector with $T_1 = 10$ s. This dashed line intersects the M_0 line at a time equal to T_1 , which is the time that the relaxation would be complete *if* it continued at the *initial* rate. At this time, however, the vector *actually* grows to only 63.2% of its maximum value, as shown by the dotted line

3 PHYSICOCHEMICAL ORIGIN OF RELAXATION

Equation (1) shows that at 0 K the N_β/N_α population ratio is zero, and that all of the nuclei will be in the lower energy state, but at room temperature the ratio is approximately 0.999 95, and almost half are in the higher energy state. Based simply on the population ratios, the spin system at room temperature has a higher energy than the one at 0 K. Furthermore, the nuclei must jump back and forth between the α and β states if the nuclear system is to remain in dynamic equilibrium at room temperature. To induce an upward transition requires an input of energy. The only source of this energy is the sample itself, which is called the ‘lattice’. Conversely, a downward transition requires dissipation of energy, whose only sink is again the lattice. This dissipation of spin energy into the lattice is called ‘spin–lattice relaxation’. Any relaxation that alters the population ratio will also alter ΔN , and in turn M_z , which represents the magnetization along the B_0 lines of force. Hence, it is also called ‘longitudinal relaxation’, or ‘ T_1 relaxation’.

3.1 Molecular Motion

The foundations of the quantum theory of nuclear magnetic relaxation were laid in 1948 by the classic work of Bloembergen, Purcell and Pound.⁹ This theory has been extensively developed and has found widespread applications. Redfield¹⁰ and Abragam² have also described relaxation using the density matrix formalism, but these theories are outside the scope of this article (for further details, see **Relaxation Theory: Density Matrix Formulation**). The treatment presented here is based largely on the perturbation theory applied by Solomon,¹¹ who assumed that the Brownian motion of molecules in a sample is random and isotropic. Barring chemical changes effected by

higher temperatures, one main difference between a sample at two different temperatures is increased translational and rotational motion. It is this motion that plays an important role in both the absorption and the dissipation of lattice energy described above. The absorption of energy will be described first, and then, by using reverse arguments, the dissipation will be described.

The motion of a molecule does not directly affect the orientation of the nuclear spin with respect to the B_0 field. The alignment of a spin parallel to the field cannot change as a result of a physical rotation of the molecule. To reorient the spin so that it is antiparallel to the field requires the absorption of an amount of energy equal to the difference in energies between the two possible orientations. One source of this energy is provided by the random motions of other magnetic dipoles, especially other protons in the molecule. Another source is the randomly fluctuating magnetic fields that are generated from the randomly moving electric dipoles in a tumbling molecule. When these magnetic fields change at a rate equal to the Larmor frequency, they act on the spins in the same way as does a B_1 field. Hence, they induce transitions from the lower energy state to the higher one. It is somewhat more difficult to see how this motion can be involved in the dissipation of energy, but Newton's third law can be employed to show that the same mechanisms can operate in reverse. For example, a fluctuating magnetic field from a β -to- α transition produces a fluctuating electric field, which can attract or repel another electric dipole and cause motion. Analogously, a randomly fluctuating electric field can attract or repel a magnetic dipole through the Oersted effect, i.e., the movement of a magnet placed near a wire carrying an electric current (a moving electric field). Hence, the dissipated energy is converted into rotational and translational energy.

3.2 Spin Temperature

An alternative explanation for the dissipation involves the concept of spin temperature, which is valuable in this context. The concept has been thoroughly examined by Abragam and Proctor.¹² For spin- $\frac{1}{2}$ nuclei, the spin temperature T_s may be defined as the temperature that satisfies equation (1) for any given population ratio. It is important to note that the concept of spin temperature is not well defined for nuclei with spin greater than $\frac{1}{2}$. For these nuclei, there will be more than two states, and the populations between adjacent energy levels may not give a unique value for T_s .

For protons at room temperature (293 K) in a field strength of 7.05 T, the ratio is 0.999 95. If an rf pulse between 90° and 270° is given to a proton spin system that is initially in thermal equilibrium with the lattice at 293 K then, immediately after the pulse, the ratio inverts and becomes greater than 1.

At that instant, T_s is negative. Purcell and Pound¹³ were able to achieve this with a crystal of lithium fluoride. For tip angles between 0° and 90°, the ratio remains between 0 and 1, but becomes more positive. Then, the spin temperature is hotter than the lattice. Spin-lattice relaxation then corresponds to the tendency of two thermodynamic systems to approach the same temperature when in contact with each other. Thus, T_1 is a measure of the rate at which the spin system comes into thermal equilibrium with the other degrees of freedom. This concept is frequently used to explain the growth of a ^{13}C

magnetization vector during the 'contact time' employed in a solid state NMR experiment. During this period, the 'hot' carbon spins transfer their energy to the 'cooler' proton spins. It is instructive to note that if a sample is allowed to reach equilibrium in a 1.41 T magnet (60 MHz), and then instantly placed in a field strength of 7.05 T (300 MHz), the spins initially will be 'hotter' than the lattice by only 3×10^{-4} K.

For a sample at equilibrium, transitions are continuously being induced from the α state to the β state by the absorption of energy from the lattice, while transitions from the β to the α state dissipate energy into the lattice. Because these energy differences are equal and opposite, and because there must be as many upward as downward transitions to maintain a population at equilibrium, the net change in energy is zero and the temperature of the sample remains constant.

3.3 Nonexponential Relaxation

It must be emphasized here that nonexponential relaxation may take place even if the spin system consists of identical nuclei. Although it is more common in solids, such behavior is not rare in liquids. This has been predicted theoretically¹⁴ for a group of three protons that are dipolar-coupled. The various mechanisms that contribute to relaxation will be discussed later, but it suffices to say here that if two or more mechanisms contribute significantly to relaxation then non-exponential behavior may be observed. For example, at the higher magnetic field strengths used today, chemical shift anisotropy (CSA) and dipole-dipole (DD) relaxation mechanisms may both be important and may not be purely additive. This effect, which is known as the 'interference of interactions', was predicted theoretically^{15,16} and has been confirmed experimentally.¹⁷ Detailed accounts have been given by Farrar and colleagues,^{18,19} Shimizu,²⁰ Redfield,²¹ Mackor and MacLean,^{22,23} Vold and Vold,²⁴ Noggle and Schirrer,²⁵ and Werbelow and Grant.²⁶ For further details, see *Relaxation Processes: Cross Correlation and Interference Terms*.

4 SPIN-SPIN RELAXATION, T_2

When T_1 longitudinal relaxation is complete, all of the magnetization is aligned along the z axis. At this point, there cannot be any magnetization left in the (x, y) transverse plane; otherwise the magnitude of the vector sum would exceed the original value, M_0 . Hence, T_1 relaxation contributes to T_2 , but even if T_1 is very long, the magnetization vector would still shrink in the (x, y) plane. For high-resolution proton and carbon spectra of liquids, the main cause of shrinking is typically the inhomogeneity of the B_0 field; but even in a perfectly homogeneous field, the vector will still shrink, albeit more slowly, owing to an exchange of energy between two spins. These two mechanisms will be discussed separately.

4.1 Effect of Field Inhomogeneity

This effect is not a true relaxation, in the sense that the nuclei do not drop from a high-energy state to a lower one by a transfer of energy. Nevertheless, inhomogeneous fields cause

the magnetization vector to decay in the (x, y) plane. In this sense, it may be called a relaxation mechanism.

The net magnetization along the z axis is generally pictured as a single, distinct vector. However, it should be remembered that it is a vector sum of many smaller ones. For protons and other spin- $\frac{1}{2}$ nuclei, it can be imagined to be formed from the microscopic nuclear magnetic moments μ by first subtracting the number in the high-energy state from those in the lower, and then, from the remaining moments, vectorially adding their maximum observable components $\mu_z \mathbf{k}$ (where $\mathbf{k}$ is the unit vector along the z axis):

$$\mathbf{M}_0 = (N_\alpha - N_\beta)\mu_z \mathbf{k} \quad (8)$$

If a 90° pulse is given to this vector, its magnitude may be considered to be held constant during the pulse, because the duration of the pulse is usually orders of magnitude shorter than the time constants for the relaxation processes that generally cause the vector to shrink. However, once the vector reaches the (x, y) plane, the inhomogeneous field will act on the individual vector components, which are called 'isochromats'. This inhomogeneity acts in a way that causes the vector sum to decrease. The individual μ_z components will be located in different positions throughout the sample, and, because the field is inhomogeneous, they will experience different field strengths. Hence, there will be a distribution of Larmor frequencies even though the shielding constants for all the nuclei are the same. These isochromats will then precess at different rates, and will begin to separate from each other. This fanning, which is frequently called a 'dephasing', produces a smaller vector sum, and $\mathbf{M}_{xy}$ shrinks in the (x, y) plane, as shown in Figure 3. In this figure, and throughout this chapter, the 'right-hand rule' will be used to be consistent with the product operator formalism. Using this rule, a 90° pulse on the $+x$ axis tips $\mathbf{M}_0$ to the $-y$ axis, and not to the $+y$ axis, as is the case with the 'left-hand rule'. Then, vectors moving faster than the rotating frame (positive frequency) move counterclockwise (ccw), and those moving slower (negative frequency) move clockwise (cw). With the right-hand rule, the definition of positive and negative frequencies is consistent with the rules of mathematics, i.e., a rotation of a vector from the $+x$ axis to the $+y$ axis (ccw) is a positive angle, whereas a rotation from the $+x$ axis to the $-y$ axis (cw) is a negative angle.

Figure 3 After a 90° pulse (a), the isochromats begin to fan, or dephase in the (x, y) plane (b). In this figure, the right-hand rule is used. Hence, a pulse delivered on the $+x$ axis rotates the magnetization vector onto the $-y$ axis. Isochromats whose Larmor frequencies are greater than that of the rotating frame will move counterclockwise, while slower ones will move clockwise

4.2 Spin-Spin Relaxation

Any process that causes a dephasing will cause the resultant vector to shrink. It has been explained above that an inhomogeneous field can cause a dephasing, but even if the field were perfectly homogeneous, a dephasing would still take place by a 'natural process'. Immediately after the pulse, all of the microscopic vector components of $\mathbf{M}_{xy}$ are aligned with each other, and the angle between them is 0° , i.e., they are 'in-phase'. Protons that are in the high-energy state as a result of the pulse can be relaxed by nearby low-energy protons in the same molecule by an exchange of energy between the β and α states. A nucleus that drops to the α state may reabsorb energy and return to the β state. This is a random process, and it is unlikely that it would return with the same phase, i.e., 0° . It is very probable that it would acquire a random phase upon its return, and lose its phase memory. Hence, the isochromats that were originally aligned with each other will scatter in the (x, y) plane as a result of random phase changes. As this scattering occurs, the isochromats will begin to fan out, and the vector sum will decrease toward zero. The decay of $\mathbf{M}_{xy}$ is exponential, with a time constant of T_2 , which is frequently called the 'natural T_2 '.

The overall rate at which $\mathbf{M}_{xy}$ shrinks will be equal to sum of the rates for the two processes described above:

$$\begin{aligned} \text{overall rate} &= \text{rate from field inhomogeneity} \\ &+ \text{natural rate} \end{aligned} \quad (9)$$

It is this rate that causes the decay of the FID collected from the spectrometer. In a B_0 field that has been well shimmed, this is also an exponential decay, and the time constant assigned to it is T_2^* . Because rates and times are the reciprocals of each other, the overall rate in equation (9) is given by

$$\frac{1}{T_2^*} = \frac{1}{T_2'} + \frac{1}{T_2} \quad (10)$$

where T_2' is the rate constant due to field inhomogeneity.

4.3 The Meaning of T_2^*

An FID decays because $\mathbf{M}_{xy}$ shrinks in the (x, y) plane. Both processes are exponential, and T_2^* is a *measure* of how fast the FID decays. It is analogous to the half-life of a radioactive element. After one half-life, the amount of the material remaining is one-half of the original amount at time zero. But there is nothing magical about the number 2: in fact, the number e ($= 2.71828 \dots$) is very special in the sense that it appears much more often in Nature than the number 2. Hence, spectroscopists do not speak of the rate of decay of an FID in terms of its half-life; instead, they speak of its $1/e$ -life, that is, how long it takes for the FID to decay to a value that equals $1/e$ of its original value at time zero. Figure 4(a) depicts a situation in which $T_2^* = 1.5$ s for an FID. Note that after 1.5 s have elapsed, the amplitude is A_0/e , where A_0 is the original amplitude at time zero. Figure 4(b) shows that if the initial slope is extended until it intersects the $\mathbf{M}_{xy}$ axis then the intersection occurs at a time equal to T_2^* . If—repeat—if the FID decayed at a constant rate equal to the initial rate then the FID would be completely decayed in a time equal to T_2^* , which is 1.5 s in this case.

Figure 4 A plot of the decay of an FID as a function of time, for the case in which $T_2^* = 1.5$ s. In (a), the dotted lines show that after 1.5 s have elapsed, the FID has decayed to 36.8%, or $1/e$, of its initial value. In (b), the dashed line shows the *initial* rate of decay. This line intersects the M_{xy} axis at 1.5 s, which is the time that the decay would be complete if it continued at the initial rate

5 MEASUREMENTS OF T_1 AND T_2

There are numerous excellent descriptions of the methods that can be used to measure the T_1 and T_2 time constants in the laboratory (see, e.g., Frye²⁷ and Farrar,⁵ respectively). Hence, only very brief summaries will be given here, and the reader is referred to those articles for further details.

5.1 Measurement of T_1

One of the earliest methods is called the ‘inversion–recovery’, or the ‘ 180° – τ – 90° ’ method. A 180° pulse is first delivered to M_0 , causing it to invert and align along the negative z axis. After waiting a period of time, τ , M_0 exponentially recovers along the z axis, as shown by equation (3). The limits of the integration shown in equation (5) must then be from $-M_0$ to M_z on the left-hand side, and from 0 to τ on the right. Equation (7) then becomes

$$M_z = M_0(1 - 2e^{-\tau/T_1}) \quad (11)$$

After time τ , a 90° pulse is given that has the same phase as the first one. If M_0 has not yet reached the origin and is still aligned along the negative z axis, then M_z will rotate into the (x, y) plane to give a negative signal after Fourier transformation. On the other hand, if it recovers fast enough to have grown through the origin to the positive z axis then a positive signal will be obtained, as shown in Figure 5. A special case occurs when T_1 has a value such that $\tau = (\ln 2)T_1$. Then, M_0 will have grown exactly to the origin, and no signal results. T_1 is experimentally determined by measuring M_z at various values of τ . The article by Frye²⁷ gives an excellent comparison of the various methods for measuring T_1 .

5.2 Measurement of T_2

5.2.1 Spin Echo Experiments

Perhaps the most common method is the Carr–Purcell–Meiboom–Gill (CPMG) modification of the Hahn ‘ 90° – τ – 180° ’ echo experiment. This modification reduces the effects

of the errors in the 180° pulses. In the original Carr–Purcell train of 180° pulses, these errors accumulate, but not in the CPMG sequence. This is well described by Farrar.⁵

After a pulse, M_{xy} begins to shrink because of T_2^* relaxation, which is a combination of the effects of field inhomogeneity and natural relaxation. The decay from T_2' is predictable, at least in the sense that the inhomogeneity will not change during the course of the experiment. It should therefore be possible to reverse this decay. However, the decay from T_2 is a random process—randomness is not predictable, by definition, and no pulse sequence can reverse its effects.

After a 90° pulse is applied on the x axis, M_{xy} shrinks in the rotating frame because some of the isochromats will move clockwise (cw), and others will move counterclockwise (ccw), as shown in Figure 3(a) and (b). They will move in opposite directions and separate from each other because some have a higher Larmor frequency than the frame, while others have a lower one. After some time τ , if a 180° pulse is given along the $\pm y$ axis, as in the CPMG sequence, then the isochromats that were on one side of the $-y$ axis will precess about the axis and move to the other side, i.e., those on one side will exchange places with those on the other, as shown in Figure 6(b). If the nuclei have not diffused through the sample to a location very far from their original positions, then the strength of the B_0 field that they experience will be essentially the same after time τ as it was at the start of the experiment. This is the predictable part. Then, the isochromats that were initially moving cw will continue to move in that same direction, because their Larmor frequencies will still be the same as they were before. Similarly, those that were initially moving ccw also continue to move in that same direction. Hence, the isochromats will begin to move back toward the $-y$ axis. After a time τ , most of the isochromats will be realigned along the $-y$ axis, because the angle that they traverse before the 180° pulse will be equal to the angle they traverse after the pulse—their frequencies remain unchanged. During the time that they are moving back toward the y axis, M_{xy} grows. This process is frequently called ‘refocusing’, because the fanning, or ‘defocusing’, is being reversed. The point at which refocusing is complete is called the ‘echo’ (see Figure 6). After this point, the isochromats continue to move and cross over to the other side of the $-y$ axis, and the FID begins again. Then, if a series of 180° pulses is continually delivered along the $\pm y$ axis, a series of echoes will be produced. If a Fourier transform is performed on the FIDs collected after each echo, the intensity of the line in the spectrum will be proportional to the magnitude of M_{xy} at the echo.

An important question to answer here is ‘At the echoes, how do the magnitudes of M_{xy} compare with each other, and to the initial magnitude of M_{xy} ?’ The answer is that each echo will have a smaller amplitude than its predecessor. The M_{xy} vector formed at the first echo consists of the vector sum of only those isochromats that retained their sense of motion in the rotating frame. However, from the first pulse to the echo, the natural T_2 process is randomly dephasing some of the isochromats. This part is not predictable, and the randomization process cannot be reversed by applying a 180° pulse. If it were possible then, in principle, one could obtain infinitely good S/N in an NMR spectrum by collecting first one FID, and then adding to it another FID obtained by removing the sample and applying a 180° pulse to invert only the noise. Obviously, this experiment

Figure 5 The sequence involved in measuring T_1 by the inversion–recovery method. A magnetization vector (a), is inverted (b), and allowed to recover (c) and (e). A 90° pulse is then given and a signal collected. If the vector has not yet grown up to the origin, the collected signal will be negative (d), whereas if the vector has grown up past the origin, the signal will be positive (f)

would not work. Randomness ignores 180° pulses and remains random.

If M_{xy} is measured at the time of the first echo, its magnitude will be exactly the same as the magnitude that would be measured if a single 90° pulse is applied to a sample placed in a perfectly homogeneous field, and the magnitude measured after the same length of time. The randomization process would have the same length of time to operate and shrink the vector. Hence, the amplitudes of the echoes show how M_{xy} would shrink in a perfect B_0 field, and from these data, T_2 can be obtained.

5.2.2 $T_{1\rho}$ Experiments

For the CPMG experiment described above, it was stated that the predictable part depends, at least partially, on the molecules not diffusing out of their local environments. If this restriction does not hold then a useful alternative is the $T_{1\rho}$ experiment, or ‘ T_1 in the rotating frame’. In this experiment, a 90° pulse on the x axis is immediately followed by the application of a continuous wave B_2 field that is phase-shifted to the $\pm y$ axis. As soon as the isochromats begin to fan, they will precess around the strong B_2 field, which keeps

them ‘spin locked’ along the $-y$ axis (see Figure 7). Here again, however, because of the natural T_2 randomization, the isochromats that are dephasing will not remain spin locked. As long as they keep a given phase, they will precess around B_2 , but at some random time they will change their phases and ‘jump’ to another location in the rotating frame. The overall result is a shrinking due only to random dephasing, a pure T_2 process.

Relaxation in this frame of reference is called $T_{1\rho}$ because it is a type of T_1 relaxation, in the sense that the magnetization vector shrinks longitudinally along the B_2 lines of force. When M_0 is first tipped into the (x, y) plane, it has the same length that it had immediately before the pulse, when it was aligned along the z axis. If the B_2 field is applied ‘on resonance’, i.e., at a frequency equal to the Larmor frequency of the nucleus, then M_{xy} will not precess about the z axis in the rotating frame. Because B_0 vanishes in this rotating frame, the ‘fictitious field’, ΔB_0 is equal to zero. Hence, M_{xy} will stay aligned along the $-y$ axis. However, because B_0 is no longer present in this frame, M_{xy} experiences only the B_2 field, which is stationary in this frame and is very much smaller than B_0 . In this field, M_{xy} is much too long immediately after the 90° pulse; its length is a result of polarization in the field B_0 , not B_2 . Hence, the

Figure 6 The Carr–Purcell–Meiboom–Gill sequence for measuring T_2 . In (a), the isochromats have dephased as shown in Figure 3. A 180° pulse applied along the $\pm y$ axis rotates the dephased isochromats to the opposite side of the y axis (b). If the nuclei have not diffused very far from their original locations in the sample, they will retain their Larmor frequencies and sense of rotation in the rotating frame, and will refocus to form an echo (c)

Figure 7 Spin locking of the isochromats in the measurement of T_2 by a $T_{1\rho}$ experiment. The B_2 field applied along the $\pm y$ axis causes the isochromats to precess around the y axis. After a period of time has elapsed, the resultant shrinks because of T_2 relaxation, and can be measured by turning off the B_2 field and collecting the signal

N_β/N_α ratio is too small, and the spin temperature is too low. The B_2 field is a continuous field and is applied for seconds; it is not pulsed for microseconds, as is a B_1 field. Hence, there is sufficient time for the nuclei to re-establish a new N_β/N_α ratio consistent with that given by equation (1) where ΔE normally equals $2\mu B_0$, but must now be replaced by $2\mu B_2$. This new value of ΔE is very much smaller, and M_{xy} shrinks to near zero. If $\gamma B_2 \tau_c \ll 1$ (τ_c is the molecular correlation time), a condition usually satisfied for small molecules in nonviscous solvents, then $T_{1\rho} = T_2$.

The decay of the vector is observed by first applying B_2 for some time τ , turning it off, and then collecting an FID. After Fourier transformation, the intensity of the signal in the spectrum will be proportional to the length of M_{xy} at time τ . Then, the experiment is repeated using a longer period of time for τ , during which time the vector shrinks further. When B_2 is turned off and the FID collected, the spectrum will show the same signal as before, but with a smaller intensity. From a series of such experiments, $T_{1\rho}$ may be calculated. However, a word of caution is appropriate here. The above description of the shrinking in the rotating frame is accurate only when 'on resonance'. For lines 'off resonance', analysis of the $T_{1\rho}$ data may be difficult.^{28–32} For further details, see *Rotating Frame Spin–Lattice Relaxation Off-Resonance*.

5.3 Pulsed Field Gradient Spin Echo Experiments

As explained earlier, the $T_{1\rho}$ experiment eliminates the effects of diffusion when measuring T_2 . However, if one is interested in measuring the translational diffusion rate of molecules then the pulsed field gradient spin echo experiment (PFGSE) can be used.⁵

6 PHYSICOCHEMICAL MECHANISMS OF RELAXATION

6.1 Randomly Fluctuating Magnetic Fields

It was stated previously that spin–lattice (T_1) relaxation involves an energy exchange between the spin system and the

lattice, via molecular motion. Random Brownian movements in the liquid create small fluctuating fields in the vicinity of the spin. Listed below are six sources for these magnetic fields. For typical organic molecules at field strengths near 7.05 T (300 MHz), only the first two are effective relaxation 'mechanisms'.

1. *Magnetic dipole-dipole interaction* is due to a 'through-space' interaction of magnetic moments of other nuclei.
2. *Spin-rotation interaction* is due to the distribution of electrons in the rotating molecule, or to portions of the molecule (segmental motion).
3. *Chemical shift anisotropy* is due to the variability of the nuclear shielding (chemical shift) as a function of the orientation of the molecule with respect to the B_0 lines of force, (*tropic*, space; *iso*, same; *an*, not—the chemical shift is not the same in all orientations of the B_0 space).
4. *Quadrupolar interaction* (for nuclei with $I > \frac{1}{2}$), is due to the changing direction of the electric field gradient at the nucleus.
5. *Scalar interaction* is due to fluctuations of the coupling constant (J), 'first kind', or fluctuations of the spin state of the coupled nucleus, 'second kind'. This is a 'through-bond' interaction, rather than the dipole–dipole 'through-space' interaction described above. Scalar relaxation of the 'third kind' has been described.^{33,34}
6. *Electron–nuclear or paramagnetic interaction* is due to the presence of unpaired electrons, which have a magnetic moment 685 times larger than that of a proton.

If these fields have a fluctuational component at the Larmor frequency ω_0 then they can induce transitions in a manner similar to the pulsed rf field B_1 . Although it is not obvious, motional frequencies at $2\omega_0$ also provide a relaxation mechanism.^{8,35} Hence, T_1 will depend upon the magnitude and the rate of fluctuation of the local fields. Because the macroscopic viscosity and the temperature of the sample affect molecular motion, these will in turn also affect T_1 .

Under these circumstances, a basic condition for the theory of Brownian motion to be valid is that the molecule makes many collisions with other molecules before it turns around, or moves through a distance characteristic of one molecular spacing. This is a reasonable approximation for many liquids, but not for gases, where a molecule may rotate many times between collisions. This Brownian motion is not a single frequency—it is composed of many frequencies. Just as the Fourier transform of an FID produces a plot (spectrum) of the amplitudes of the frequencies present in the FID, the amplitudes of the frequency components $J(\omega)$ in the Brownian motion can also be plotted. The relationship between $J(\omega)$ and ω is⁴

$$J(\omega) \propto \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad (12)$$

where τ_c is the 'correlation time', which is analogous to the period of a frequency. It is a time that is characteristic of the random motion, and is approximately equal to the average time needed for the molecule to change its orientation. It is a measure of the time it takes for the field to 'lose memory' of a previous value. For a very comprehensive treatment of Brownian motion and correlation times, see *Brownian Motion and Correlation Times*. Table 2 shows the approximate correlation times for some typical molecules of various sizes.

Table 2 Correlation Times for Some Typical Molecules

Compound	Correlation time τ_c (s)
Methyl iodide	10^{-13}
Toluene	10^{-12}
Naphthalene	10^{-11}
Cholestane	10^{-10}
Vitamin B ₁₂	5×10^{-9}
Ribonuclease A	10^{-8}
tRNA	10^{-8}

Figure 8 is a plot of $J(\omega)$ versus ω for three values of τ_c . The intermediate value was chosen to be the reciprocal of the Larmor frequency for protons at a field strength of 11.75 T. Thus, $\omega_0 = 500$ MHz, or 3.14×10^7 rad s⁻¹, and $\tau_c = 2 \times 10^{-9}$ s. When a molecule tumbles at a rate equal to its Larmor frequency, the product $\omega_0\tau_c = 1$.

For large molecules, the overall motion is slow, and the lower frequencies have higher amplitudes than the higher frequencies. For small molecules, the reverse is true; i.e., there are more higher frequency components than lower ones. When a molecule tumbles at the intermediate rate chosen here, $J(\omega)$ at 1.0 has a higher value (indicated by a closed circle in Figure 8) than at slower or faster tumbling rates (indicated by open circles). In other words, protons in these molecules will experience stronger local fields fluctuating at 500 MHz than protons in smaller or larger molecules. Because the rate of relaxation is a function of the strength of the fluctuating field at that frequency, protons in intermediate size molecules will relax faster at this field strength.

Figure 8 A plot of the amplitudes of the frequency components, $J(\omega)$, for randomly tumbling molecules whose overall rate of motion is slow, intermediate, and fast. The horizontal axis is the product of ω times τ_c . This product equals 1 when the molecule tumbles as fast as the Larmor frequency. For the condition specified in the text, $J(\omega)$ has a higher value when the molecule tumbles at an intermediate rate (indicated by a closed circle), than at slower or faster rates (indicated by open circles)

6.2 Dipolar-Coupled Nuclei

A proton that is directly bonded to a ^{13}C atom is coupled to it in two ways: the proton is both scalar- and dipolar-coupled to it. Scalar coupling is transmitted through bonds, and produces the J splitting usually observed in spectra. Dipolar coupling is a ‘through-space’ interaction. It does not produce a splitting, but it is responsible for the NOE effects observed in proton-decoupled ^{13}C spectra. However, these effects are not the result of the removal of the J splitting by decoupling. Instead, they arise from saturating the protons with irradiation from the proton decoupler. When a proton is directly bonded to ^{13}C , the internuclear distance is short. It is this closeness in space, and not the sigma bond, that leads to dipolar coupling and the NOE effects. For details of the NOE, see **Nuclear Overhauser Effect**.

When two different nuclei, such as a proton and a ^{13}C nucleus, are coupled to each other, they are frequently referred to as an AX system. Both the A and X nuclei in the same molecule may be in either the α or in the β state, with approximately the same probability—recall that the N_β/N_α ratio is nearly 1. Hence, four types of molecules will exist in the sample: those in which the AX nuclei are in the $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, and $\beta\beta$ states. These four combinations have different energies, as shown in Figure 9. In this figure, the $\alpha\alpha$ and the $\beta\beta$ states are the lowest and highest energy states, respectively. The $\alpha\beta$ and $\beta\alpha$ states are in between, but these two intermediate states are not at the same level. The symbol ω_1 represents the frequency required to elevate a proton from the α to the β state, while that proton is coupled to a carbon that is in the α state. Similarly, the ω_2 symbol represents the frequency required to elevate a carbon from the α to the β state, while that carbon is coupled to a proton that is in the α state. Hence, ω_1 is four times greater than ω_2 , because an $\alpha\alpha \rightarrow \alpha\beta$ transition represents a ^{13}C transition, which requires 75 MHz at a 7.05 T field, whereas an $\alpha\alpha \rightarrow \beta\alpha$ transition represents a proton transition at 300 MHz, four times as much energy. In Figure 9, ω_1' and ω_2' respectively represent proton and carbon transitions for these nuclei coupled to their partners in the β state. When a single bond connects the proton and the carbon, scalar coupling is also present, and ω_1' will be larger than ω_1 by an amount J , and ω_2' will be larger than ω_2 by the same amount. W_1 and W_1' represent the probabilities of

Figure 9 A diagram indicating the probabilities (W_1 , W_2 , and W_0) and corresponding frequencies (ω_1 , ω_2 , and ω_0) required for single, double, and zero quantum transitions, respectively, for the case of a proton dipolar-coupled to a carbon-13 nucleus

these four single quantum transitions. W_2 and W_0 represent the probabilities of the double quantum and zero quantum transitions, respectively.

The rate of change of the component of the proton spin along the z axis, $\langle I_z^A \rangle$, will depend upon the three possible proton transitions W_0 , W_1 , and W_2 . However, because the $\alpha\beta \rightarrow \beta\alpha$ and the $\alpha\alpha \rightarrow \beta\beta$ proton transitions are both accompanied by carbon transitions, the rate of change will also depend upon the component of the carbon spin along the z axis, $\langle I_z^X \rangle$. For the double quantum transition, energy must be added, because the concomitant carbon transition is from an α to a β state. For the zero quantum transition, energy must be subtracted, because the carbon transition is from a β to an α state. Hence,

$$\begin{aligned} \frac{d\langle I_z^A \rangle}{dt} = & (2W_1 + W_0 + W_2)(I_0^A - I_z^A) \\ & + (W_2 - W_0)(I_0^X - I_z^X) \end{aligned} \quad (13)$$

where I_0^A and I_0^X are the Boltzmann equilibrium values for the A and X spins, respectively, as given by equation (1). If proton transitions are induced without any irradiation of the ^{13}C nuclei then I_0^A will change to some new value, I_z^A , but, because ^{13}C transitions were not induced by the proton pulse, I_z^X will equal I_0^X . Then, equation (13) reduces to

$$\frac{d\langle I_z^A \rangle}{dt} = (2W_1 + W_0 + W_2)(I_0^A - I_z^A) \quad (14)$$

For the homonuclear case, X and A are the same, and equation (13) then becomes

$$\frac{d\langle I_z^A \rangle}{dt} = 2(W_1 + W_2)(I_0^A - I_z^A) \quad (15)$$

It was explained earlier in this article that a transition can take place, either upward or downward, only when a frequency is available whose energy matches that of the transition energy. Hence, the probabilities shown in Figure 9 depend upon the spectral density function, $J(\omega)$, i.e., the frequency components in the Brownian motion. This figure shows that the probabilities for the three possible proton transitions, W_0 , W_1 , and W_2 , require the frequencies $\omega_1 - \omega_2$, ω_1 , and $\omega_1 + \omega_2$, respectively. Hence, these three probabilities are proportional to $J(\omega)$, given in equation (12):

$$W_0 = k_0 \frac{\tau_c}{1 + (\omega_1 - \omega_2)^2 \tau_c^2} \quad (16)$$

$$W_1 = k_1 \frac{\tau_c}{1 + \omega_1^2 \tau_c^2} \quad (17)$$

$$W_2 = k_2 \frac{\tau_c}{1 + (\omega_1 + \omega_2)^2 \tau_c^2} \quad (18)$$

The proportionality constants k_0 , k_1 , and k_2 , are⁶

$$k_0 = \frac{d^2}{10\hbar^2} \quad (19)$$

$$k_1 = \frac{3d^2}{20\hbar^2} \quad (20)$$

$$k_2 = \frac{3d^2}{5\hbar^2} \quad (21)$$

where $d = \gamma_A \gamma_X \hbar^2 / r^3$ is the ‘dipolar coupling constant’ and r is the distance between nuclei A and X.

The dipole–dipole relaxation rate $1/T_1^{\text{DDU}}$ for unlike nuclei (heteronuclear), is obtained from equations (14) and (16)–(21):

$$\frac{1}{T_1^{\text{DDU}}} = \frac{2}{15} \gamma_X^2 \gamma_A^2 \hbar^2 I_A (I_A + 1) \sum_i r_i^{-6} Y \tau_c \quad (22a)$$

where

$$\begin{aligned} Y = & \frac{1}{1 + (\omega_A - \omega_X)^2 \tau_c^2} + \frac{3}{1 + \omega_X^2 \tau_c^2} \\ & + \frac{6}{1 + (\omega_A + \omega_X)^2 \tau_c^2} \end{aligned} \quad (22b)$$

$$I_A = \frac{1}{2} \quad \text{for protons} \quad (22c)$$

and the summation sign indicates the total contribution if more than one nucleus is involved in the relaxation process.

For like nuclei (homonuclear), $1/T_1^{\text{DDL}}$ is obtained from equations (15), (17), (18), (20), and (21):

$$\frac{1}{T_1^{\text{DDL}}} = \frac{2}{5} \gamma^4 \hbar^2 I(I + 1) \sum_i r_i^{-6} \left(\frac{1}{1 + \omega^2 \tau_c^2} + \frac{4}{1 + 4\omega^2 \tau_c^2} \right) \tau_c \quad (23)$$

For protons and other spin- $\frac{1}{2}$ nuclei, equation (23) becomes

$$\frac{1}{T_1^{\text{DDL}}} = \frac{3}{10} \gamma^4 \hbar^2 \sum_i r_i^{-6} \left(\frac{1}{1 + \omega^2 \tau_c^2} + \frac{4}{1 + 4\omega^2 \tau_c^2} \right) \tau_c \quad (24)$$

Similar derivations for transverse relaxation times lead to

$$\frac{1}{T_2^{\text{DDU}}} = \frac{1}{15} \gamma_X^2 \gamma_A^2 \hbar I_A (I_A + 1) \sum_i r_i^{-6} Z \tau_c \quad (25a)$$

where

$$\begin{aligned} Z = & 4 + \frac{1}{1 + (\omega_A - \omega_X)^2 \tau_c^2} + \frac{3}{1 + \omega_X^2 \tau_c^2} \\ & + \frac{6}{1 + (\omega_A + \omega_X)^2 \tau_c^2} + \frac{6}{1 + \omega_A^2 \tau_c^2} \end{aligned} \quad (25b)$$

and

$$\begin{aligned} \frac{1}{T_2^{\text{DDL}}} = & \frac{1}{5} \gamma^4 \hbar^2 I(I + 1) \\ & \times \sum_i r_i^{-6} \left(3 + \frac{5}{1 + \omega^2 \tau_c^2} + \frac{2}{1 + 4\omega^2 \tau_c^2} \right) \tau_c \end{aligned} \quad (26)$$

$$\frac{1}{T_2^{\text{DDL}}} = \frac{3}{20} \gamma^4 \hbar^2 \sum_i r_i^{-6} \left(3 + \frac{5}{1 + \omega^2 \tau_c^2} + \frac{2}{1 + 4\omega^2 \tau_c^2} \right) \tau_c \quad (27)$$

Figure 10 Plots of dipole–dipole relaxation time T_1 versus correlation time τ_c for two protons separated by 0.26 nm, at two different field strengths. In (a), the vertical axis is logarithmic, whereas in (b) the scale is linear and covers a narrower range

For low molecular weight compounds in mobile liquids, τ_c is very small. Hence, $\omega\tau_c \ll 1$, which is referred to as the ‘extreme narrowing condition’. Then, equations (22)–(27) reduce to

$$\frac{1}{T_1^{\text{DDU}}} = \frac{1}{T_2^{\text{DDU}}} = \frac{4}{3}\gamma_X^2\gamma_A^2\hbar^2 I_A(I_A + 1) \sum_i r_i^{-6} \tau_c \quad (28)$$

$$\frac{1}{T_1^{\text{DDL}}} = \frac{1}{T_2^{\text{DDL}}} = 2\gamma^4\hbar^2 I(I + 1) \sum_i r_i^{-6} \tau_c \quad (29)$$

$$\frac{1}{T_1^{\text{DDL}}} = \frac{1}{T_2^{\text{DDL}}} = \frac{3}{2}\gamma^4\hbar^2 \sum_i r_i^{-6} \tau_c \quad (30)$$

Figure 10(a) is a plot of equation (24) for two different field strengths, 7.05 and 11.75 T, and for an average proton–proton distance of 0.26 nm. Note that the relaxation time reaches a minimum when $\tau_c = \omega_0^{-1}$. Although Brownian motion is random, on average the overall motion can still be slower or faster than ω_0 . If this is the case, the component of the overall motion that is at ω_0 will be small, and will not be effective in inducing transitions. Hence, the relaxation time will be longer. Also note that the minimum for the 11.75 T plot is to the left of the minimum for the 7.05 T plot. At the higher field strength, ω_0 is higher; hence, the τ_c required for effective relaxation is smaller. This figure depicts the relaxation times in the same manner as in most articles and books, i.e., in the form of a log–log plot. However, it may be more instructive to visualize the relaxation in the form of a semilogarithmic plot, i.e., one that is linear with respect to the relaxation time, as shown in Figure 10(b).

Figure 11 was prepared from equations (24) and (27), and shows how both T_1^{DDL} and T_2^{DDL} vary as a function of τ_c for a field strength of 7.05 T. The plot shows that in the extreme narrowing condition, when $\omega\tau_c \ll 1$, $T_1^{\text{DDL}} = T_2^{\text{DDL}}$, as shown by equation (30). To the right of the minimum in this plot, the motion is too slow to cause an effective T_1 relaxation. However, as described earlier in this article, there are several mechanisms that give rise to T_2 relaxation. If τ_c is long, as in solids and highly viscous liquids, or at very low temperatures, then the nuclei remain in the same relative positions for a long time. The nuclei will then experience a variety of local magnetic fields due to neighboring dipoles. This variation can be quite large—for example, the magnetic field at a distance of 0.1 nm from a proton is of the order of 10^{-3} T, which will

Figure 11 Plots of dipole–dipole relaxation times T_1 and T_2 versus correlation time, for two protons separated by 2.6 Å, and at a field strength of 7.05 T (300 MHz)

lead to substantial line broadening. The distribution of Larmor frequencies will cause a rapid fanning of the isochromats, as explained earlier in this article, resulting in a short T_2 . Conversely, when τ_c is short, as in gases and mobile liquids, or at higher temperatures, the molecules tumble fast enough to average all of the local fields that might cause line broadening. Under these conditions, T_1 and T_2 become approximately equal and the line narrows—hence the expression ‘extreme narrowing condition’. For a full theoretical treatment of the relaxation times throughout the whole range, see Kubo and Tomita.³⁶

Equations (22a)–(30) were developed specifically for the dipole–dipole relaxation mechanism. Analogous equations and detailed calculations can be found for spin rotation, chemical shift anisotropy, quadrupolar, scalar, and electron–nuclear relaxation mechanisms.³⁷ For decoupled systems, the overall rate of relaxation is simply the sum of the contributions from all of the mechanisms. Because rates and times are reciprocals of each other

$$\left. \begin{aligned} \text{overall rate} &= \text{sum of rates} \\ \frac{1}{T_1} &= \frac{1}{T_1^{\text{DD}}} + \frac{1}{T_1^{\text{SR}}} + \frac{1}{T_1^{\text{CSA}}} + \frac{1}{T_1^{\text{Q}}} + \frac{1}{T_1^{\text{SC}}} + \frac{1}{T_1^{\text{EN}}} \end{aligned} \right\} \quad (31)$$

However, for coupled systems at high fields, this additivity relationship may no longer hold.^{18–24}

7 RELAXATION DUE TO RADIATION DAMPING

For most chemical samples, relaxation from radiation damping is not a significant mechanism. However, when proton spectra are obtained from samples containing primarily H_2O as the solvent, especially at high field strengths, the NMR signal can be relatively large. The relatively large currents induced in the receiver coil create a magnetic field in the same

way that the pulsed radiofrequency currents produce the initial B_1 field. However, this induced field has a phase that acts oppositely to that of the B_1 field. This process is analogous to the actions that take place in an electrical transformer. In a transformer, fluctuating magnetic lines of force from the primary coil induce a current in the secondary coil. These currents create another fluctuating field, whose lines of force cut back through the turns of the primary, inducing a back electromotive force (back-emf). A common statement used to describe this is: 'The impedance of the secondary is reflected back into the primary'. This process also explains why a motor can 'burn out' if the shaft locks, or 'freezes', and why some powerful equipment containing transformers should not be operated without a load connected to the output of the transformer. When a load is not connected, current will not flow through the load from the secondary coil, and a back-emf will not be produced in the primary. The impedance of the primary then drops to a lower value. The current in this coil will then be higher, and could 'burn out' the transformer. In an NMR probe, the sample and the receiver coil are analogous to the primary and secondary windings of a transformer, respectively. The magnetic field created by the current induced in the receiver coil applies a reverse torque to the macroscopic magnetization vector, causing it to precess from the transverse (x, y) plane back to the longitudinal z axis (see Figure 12). When this mechanism is effective, relaxation is faster than usual and results in broader lines in the spectrum.

8 RELATIONSHIP BETWEEN T_1 AND T_2 RELAXATION TIMES

This discussion will be limited to systems in which no mechanisms, except simple relaxation, are available for increasing the magnitude of a net magnetization vector; i.e., it will be limited to systems in which cross polarization, polarization transfer, radiation damping, etc., are either nonexistent or have a negligibly small effect on the relaxation process. However, even with all these restrictions imposed, this discussion will be applicable to the vast majority of proton and ^{13}C high-resolution samples run under typical conditions.

In Figure 12(a), M_0 is shown tipped onto the (x, y) plane while maintaining a constant magnitude. The time elapsed during this period is on the order of $10\ \mu\text{s}$, and is equal to

Figure 12 An illustration of a magnetization vector relaxing solely because of radiation damping. After a 90° pulse (a), the vector returns back to the z axis without changing its length, and its tip traces a circle (dashed line) whose radius is unity (b)

the pulse width. This time is very short compared with most relaxation processes in liquids and gases; hence, the vector is correctly depicted as one that is not changing during this time. However, in the typical high-resolution case, the relaxation processes that tip the vector back take much longer, and are of the order of seconds. Hence, in the absence of radiation damping, the vector does not maintain a constant magnitude as shown in Figure 12(b). Instead, it changes its length while returning to the z axis.³⁸ This can be shown by a simple analysis of the parameters typically used during the acquisition of ^{13}C signals. It is not unusual to acquire such signals for 1–3 s, and to employ a relaxation delay of 5–10 s between the end of the acquisition time and the beginning of the next pulse. This is especially true if a rather large tip angle is used (e.g., 60°). An acquisition time of 1–3 s is generally used, because the typical T_2^* encountered for ^{13}C signals is such that almost all (95%) of the signal has disappeared after that time. This means that if Figure 12(b) correctly depicts the relaxation of M_0 then in 1–3 s, when the component of M_0 in the (x, y) plane (M_{xy}) and the signal have decayed to zero, M_0 is completely realigned along the z axis. If that were true, there would be no need for a relaxation delay, because relaxation would already be complete, and another rf pulse could be given immediately after the signal has disappeared.

8.1 T_2/T_1 Ratio Under Typical Conditions

From the solutions of the Bloch equations, the magnitudes of M_{xy} and M_z at any time are given by

$$M_{xy} = M_0 e^{-t/T_2^*} \quad (32)$$

$$M_z = M_0(1 - e^{-t/T_1}) \quad (33)$$

From these equations, the vector sum of M_{xy} and $M_z \mathbf{k}$ (where $\mathbf{k}$ is the unit vector in the z direction) can be calculated at any time. In ^{13}C NMR spectroscopy, it is not unusual for the linewidth to be 0.2 Hz. From $\Delta\nu = 1/\pi T_2^*$, T_2^* can be estimated to be 1.6 s. For ^{13}C , a T_1 of 5 s is not abnormally long. Thus, a T_1/T_2^* ratio of at least 5 is common. Figure 13 is a plot of the magnitude of the resultant as relaxation takes place. Table 3 lists the magnitudes at 10° increments from the (x, y) plane. The figure clearly shows that the tip of the resultant *does not trace a quarter-circle*, which is shown by the dashed line, on its way back to the z axis. Instead, it first shrinks from its maximum length, reaches a minimum, and then grows back to its maximum length after at least $5T_1$.

8.2 T_2/T_1 Ratio in a Perfectly Homogeneous Field

The shrinking of the resultant, as described above, is not a consequence of using T_2^* instead of T_2 in equation (32). Even in a perfectly homogeneous field, and in the extreme narrowing region, where $T_2 \approx T_1$, the resultant would still shrink. If T_2^* in equation (32) is replaced by T_1 then it can be combined with equation (33) to give

$$M_z = M_0 \left(1 - \frac{M_{xy}}{M_0} \right) = M_0 - M_{xy} \quad (34)$$

Figure 13 An illustration of a magnetization vector relaxing because of a variety of relaxation mechanisms occurring simultaneously, a much more general case than that depicted in Figure 12. For this example, $T_1 = 5T_2^*$, and the vector first shrinks and then grows as it returns

Figure 14 An illustration of a magnetization vector relaxing, as in Figure 13, but with $T_1 = T_2$. The vector still shrinks and then grows, with its tip following a straight line

Table 3 Magnitudes of the Resultants for Figure 13

Angle	Magnitude	Time (s)
0°	1.000	0.00
10°	0.372	1.00
20°	0.261	1.40
30°	0.213	1.69
40°	0.188	1.94
50°	0.176	2.18
60°	0.174	2.44
70°	0.180	2.79
80°	0.203	3.35
90°	1.000	∞

Equation (34) has the form of a straight line $y = b + mx$, where M_0 is the intercept and -1 is the slope of the line in a plot of M_z versus M_{xy} . Figure 14 and Table 4 show that the tip of the resultant follows a straight line back to M_0 on the z axis.

Table 4 Magnitudes of the Resultants for Figure 14

Angle	Magnitude	Time (s)
0°	1.000	0.000
10°	0.864	0.162
20°	0.780	0.310
30°	0.732	0.456
40°	0.710	0.609
50°	0.710	0.785
60°	0.732	1.01
70°	0.780	1.32
80°	0.863	1.90
90°	1.000	∞

8.3 Maximum T_2/T_1 Ratio

A comparison of Figures 13 and 14 shows that the tip of the vector is closer to the dashed quarter-circle line as the T_2/T_1 ratio increases from $\frac{1}{5}$ to $\frac{1}{1}$. If the ratio is increased even further, to 2.0, the trajectory of the tip becomes even closer to the quarter-circle, as shown by Figure 15 and Table 5. Even for this case, the resultant still shrinks immediately after the 90° pulse, reaches a minimum, and then grows back to its maximum value. However, note that the magnitude of the resultant does not exceed 1.0 at any time. According to this treatment, T_2 can be twice as long as T_1 . Similar tables and plots show that if $T_2 > 2T_1$ then at some time the magnitude does exceed 1.0. Figure 16 and Table 6 show the case when T_2 is three times as long as T_1 . Here, the magnitude of the resultant exceeds 1.0, and this is clearly a situation that seems to contradict our present understanding of the laws of physics, although theories to the contrary have been reported.^{39,40} But, at or below the threshold $T_2 = 2T_1$, the mathematical treatment presented above will allow for $T_2 > T_1$. In fact, the T_2/T_1 ratio is 1.16 for the olefinic carbons of tetrachlorocyclopropene in toluene- d_8 at -89°C .⁴¹ Anet has

Table 5 Magnitudes of the Resultants for Figure 15

Angle	Magnitude	Time (s)
0°	1.000	0.000
10°	0.929	0.088
20°	0.888	0.181
30°	0.869	0.285
40°	0.868	0.408
50°	0.884	0.565
60°	0.914	0.783
70°	0.952	1.12
80°	0.986	1.77
90°	1.000	∞

Figure 15 An illustration of a magnetization vector relaxing, as in Figure 13, but with $T_1 = \frac{1}{2}T_2$, i.e., T_2 is twice as long as T_1 . The vector still shrinks, but at its shortest length the tip is closer to the dashed line than in Figure 13 or Figure 14. At no time does the length exceed 1 and extend beyond the dashed line

Table 6 Magnitudes of the Resultants for Figure 16

Angle	Magnitude	Time (s)
0°	1.000	0.000
10°	0.956	0.060
20°	0.936	0.129
30°	0.936	0.210
40°	0.952	0.316
50°	0.980	0.463
60°	1.01	0.686
70°	1.02	1.05
80°	1.01	1.74
90°	1.000	∞

presented a detailed description of this experiment, as well as a very comprehensive paper on the T_2/T_1 ratio.^{42,43}

Figure 16 An illustration of a magnetization vector relaxing, as in Figure 13, but with $T_1 = \frac{1}{3}T_2$, i.e., T_2 is three times as long as T_1 . The vector still shrinks at first, but later its length will exceed 1 and extend beyond the dashed line. Outside this line, the vector is longer than it was before the pulse, which is a case that is generally considered to be impossible

1 INTRODUCTION

Studies of nuclear spin relaxation processes can provide invaluable information regarding the structure and dynamics of biological macromolecules. Numerous methodologies have been proposed for the measurement and interpretation of various nuclear spin relaxation rate constants. In recent years the arsenal of tools available for NMR relaxation studies has expanded rapidly, due in part to the greater appreciation and subsequent exploitation of cross-correlation effects. The presence of cross-correlation, or relaxation interference, effects in nuclear spin relaxation processes has been recognized since the early days of NMR experimentation. One of the earliest reports on this subject was the proposal by McConnell¹ that relaxation interference effects could explain the observed dependence of multiplet linewidths on the nuclear spin quantum number in paramagnetic resonance spectra of solutions of ionic salts. Another pioneering study was that by Hubbard,^{2,3} concerning relaxation interference effects on the spin-lattice relaxation of three- and four-spin-1/2 systems. Despite these early reports, and with some notable exceptions, the prevailing view for many years seemed to be that cross-correlation effects were more of a theoretical curiosity than a practically useful

feature of nuclear spin relaxation. This sentiment was due in part to improper extrapolations of Hubbard's results to other systems.⁴ Fortunately, the rigorous theoretical treatments of cross-correlation effects by several groups, especially those of Werbelow, Grant, and Lynden-Bell,^{5–7} and the development of multi-dimensional and multiple quantum NMR methodologies in the 1970s lead to a renewed interest and solid foundation for the exploitation of cross-correlated relaxation phenomena. As a result, many important and very valuable NMR techniques that rely on the measurement and/or utilization of cross-correlation effects are now available and in common use for obtaining detailed information on the structure and dynamics of a variety of systems, including biological macromolecules.

The purpose of the present article is to provide an overview of the subject of cross-correlated nuclear spin relaxation effects (see also **Relaxation Processes: Cross Correlation & Interference Terms**, Volume 6, and **Relaxation Theory: Density Matrix Formulation**, Volume 6), focusing on those areas of particular importance in studies of the structure and dynamics of proteins, nucleic acids and other biological macromolecules. The basic concepts are emphasized, rather than providing a detailed theoretical description. Readers interested in the theoretical formalism of cross-correlated relaxation and/or a more complete presentation than is possible here are directed to an excellent and comprehensive review of cross-correlations in NMR that was published recently by Kumar et al.⁸ A number of other review and research articles are also highly recommended for those wishing to learn more about this fascinating field.^{5–14}

2 THEORY

A number of interactions can contribute to the overall relaxation behavior of a nuclear spin, including the stochastic modulation of dipole–dipole couplings, chemical shift anisotropies, and quadrupolar couplings (for spin > 1/2). Cross-correlation effects result from the interference of two such relaxation mechanisms, under the conditions that the time-dependent modulation of the two relaxation mechanisms arises from the same source, and that the tensors that describe the time-dependence of the interactions have the same rank. To put this in more formal terms, the stochastic Hamiltonian responsible for the relaxation behavior of a nuclear spin can be written as:¹⁵

$$\mathbf{H}_1(t) = \sum_m \sum_{q=-k}^k F_{mk}^q(t) \mathbf{A}_{mk}^q \quad (1)$$

in which the summation over the index m accounts for the different relaxation mechanisms, $F_{mk}^q(t)$ is a function of spatial variables that describes the effective motional behavior and $\mathbf{A}_{mk}^q$ is a tensor spin operator. The index k gives the rank of the tensor operators for the relevant interactions. The Liouville-von Neumann equation for the density operator is given by:

$$\frac{d\sigma}{dt}(t) = -i[\mathbf{H}_0, \sigma(t)] - \hat{\Gamma}(\sigma(t) - \sigma_0) \quad (2)$$

where $\mathbf{H}_0$ is the time-independent part of the nuclear spin Hamiltonian, $\sigma(t)$ is the time-dependent density operator, σ_0 is the thermal equilibrium density operator, and $\hat{\Gamma}$ is the

relaxation superoperator. If the density operator σ is expanded in terms of a set of basis spin operators $\mathbf{B}_i$, the rate constant for relaxation between the operators $\mathbf{B}_r$ and $\mathbf{B}_s$ is:

$$\begin{aligned} \Gamma_{rs} &= \frac{1}{2} \sum_m \sum_q \sum_p \{ \langle \mathbf{B}_r | [\mathbf{A}_{mkp}^{-q}, [\mathbf{A}_{mkp}^q, \mathbf{B}_s]] \rangle / \langle \mathbf{B}_r | \mathbf{B}_r \rangle \} j^q(\omega_p) \\ &\quad \cdots + \frac{1}{2} \sum_{\substack{m,n \\ m \neq n}} \sum_q \sum_p \{ \langle \mathbf{B}_r | [\mathbf{A}_{mkp}^{-q}, [\mathbf{A}_{nkp}^q, \mathbf{B}_s]] \rangle / \langle \mathbf{B}_r | \mathbf{B}_r \rangle \} j_{mn}^q(\omega_p) \\ &\quad \cdots = \sum_m \Gamma_{rs}^m + \sum_{\substack{m,n \\ m \neq n}} \Gamma_{rs}^{mn} \end{aligned} \quad (3)$$

in which the $\mathbf{A}_{mkp}^q$ are basis operators that can be summed over index p to generate the tensor operators $\mathbf{A}_{mk}^q$ appearing in equation (1), and the cross-correlation spectral density is:

$$j_{mn}^q(\omega) = \text{Re} \left\{ \int_{-\infty}^{\infty} \overline{F_{mk}^q(t)} F_{nk}^{-q}(t + \tau) \exp(-i\omega\tau) d\tau \right\} \quad (4)$$

The terms Γ_{rs}^{mn} represent the contributions to the relaxation between $\mathbf{B}_r$ and $\mathbf{B}_s$ that results from the interference or cross-correlation between the m^{th} and n^{th} relaxation mechanisms. From equation (4) it is clear that if the motional processes modulating relaxation mechanisms m and n are uncorrelated, there will be no cross-correlated relaxation involving these two mechanisms. Likewise, from equation (3) it can be seen that cross-correlated relaxation requires that the double commutator involving spin operators $\mathbf{A}_{mkp}^{-q}$ and $\mathbf{A}_{nkp}^q$ be non-zero. In applications to biomolecules, the most common relaxation interference effects arise from the three cross-correlation combinations involving the dipole–dipole (DD) and chemical shift anisotropy (CSA) relaxation mechanisms.

The concept of cross-correlated nuclear spin relaxation can be illustrated by considering a simple two spin-1/2 system, a ^{15}N – ^1H spin pair in a protein backbone, and analyzing the transverse relaxation of the ^{15}N spin.¹⁶ The relevant cross-correlation in this example is the relaxation interference between the ^{15}N chemical shift anisotropy (CSA) and the ^{15}N – ^1H dipole–dipole (DD) interactions. Figure 1 demonstrates the basic principle of CSA/DD cross-correlated relaxation in the ^{15}N – ^1H system. The case of a ^{15}N spin bonded to a ^1H spin in the $|\alpha\rangle$ state (as indicated by the upward arrow through the ^1H nucleus) is shown in Figure 1(A) and (B); in Figure 1(A) the ^{15}N – ^1H bond vector is oriented parallel to the externally applied magnetic field, whereas Figure 1(B) shows the case where the bond vector is perpendicular to the applied field. Figure 1(C) and (D) show the analogous situations where the ^1H spin is in the $|\beta\rangle$ state. The solid lines drawn to the right of the ^{15}N nuclei indicate the direction of the local magnetic field, arising from the ^1H spin, at the position of the ^{15}N spin, while the dashed lines to the left of the ^{15}N nuclei show the direction of the induced magnetic field arising from the ^{15}N CSA interaction. Relaxation of the ^{15}N spin is caused by fluctuations in the net sum of these local magnetic fields as the orientation of the bond vector is randomly modulated by motional processes. The key observation in this example is that when the ^1H spin is in the $|\alpha\rangle$ state, the local magnetic fields arising from the CSA and DD interactions have the same sign, regardless of the bond orientation, whereas these local fields have opposite signs when the ^1H spin

is in the $|\beta\rangle$ state. Constructive interference of the local magnetic fields arising from the CSA and dipolar interactions will therefore result in a broadening of the ^{15}N resonance associated with the ^1H in the $|\alpha\rangle$ state, while destructive interference of these local fields will lead to a narrowing of the ^{15}N resonance associated with the ^1H in the $|\beta\rangle$ state. This type of cross-correlated relaxation effect forms the basis of TROSY, or transverse relaxation-optimized spectroscopy (see **Transverse Relaxation-optimized NMR Spectroscopy with Biomacromolecular Structures in Solution**).

The measurement of cross-correlated relaxation rate constants is greatly facilitated by the fact that the relaxation behavior can be controlled in a substantial way via the design of the pulse sequences.¹⁷ This is quite different from the situation that exists for the measurement of auto-relaxation processes, where pulse sequence elements normally do not affect relaxation. Thus, pulse sequence design has played an essential role in allowing various cross-correlated relaxation processes to be distinguished from one another and in allowing quantitative analyses to be performed. Cross-correlated relaxation rate constants are normally measured in one of two ways. The first method is to observe changes in individual multiplet intensities after an evolution period (usually a constant-time element) during which the relaxation processes of interest have been active. The second possibility is to observe and measure the cross-correlation-induced cross-relaxation of one spin operator with another. In many cases the cross-correlated relaxation rate constants of interest are rather small, and this can present significant challenges in terms of making reliable measurements. Careful attention to experimental design can reduce some sources of uncertainty and error in cross-correlated relaxation measurements.¹⁸

Figure 1 Schematic illustration of the origin of ^{15}N chemical shift anisotropy/ ^{15}N – ^1H dipole–dipole cross-correlation effects on the relaxation of the ^{15}N spin. Arrows through the ^1H nuclei indicate the ^1H spin state $|\alpha\rangle$ (up arrow) or $|\beta\rangle$ (down arrow). Solid arrows adjacent to the ^{15}N nuclei indicate the direction of the local ^1H dipolar magnetic field at the site of the ^{15}N spin, while the dashed arrows indicate the direction of the induced magnetic field from the ^{15}N chemical shift interaction. In (A) and (C) the ^{15}N – ^1H bond vector is parallel to the applied external field, while in (B) and (D) the bond vector is in the perpendicular orientation

Cross-correlation effects in nuclear spin relaxation can be exploited for a number of useful purposes in studies of biomolecules, including sensitivity and/or resolution enhancement, dynamics studies, and measurement of structural constraints. Cross-correlation contributions to relaxation can also be an undesirable feature in dynamics studies that are based on the measurement of auto-relaxation rate constants, and thus it has been necessary to devise various techniques for eliminating specific, cross-correlation-induced cross-relaxation pathways. The following sections describe examples of both the exploitation and elimination of cross-correlation effects that have been found to be of particular relevance in studies of biological macromolecules.

3 SENSITIVITY AND RESOLUTION ENHANCEMENT VIA CROSS-CORRELATION EFFECTS

3.1 TROSY

One of the most exciting and important developments in recent years in the field of solution-state NMR studies of biomolecules has been the introduction of methodologies for sensitivity and/or resolution enhancement that are based on the exploitation of cross-correlation effects. These enhancements have their origin in the differential relaxation rates of multiplet components in the presence of relaxation interference between DD and CSA interactions. Griffey and Redfield anticipated the potential advantages of DD/CSA cross-correlation, as evidenced by their statement that "In certain cases higher resolution and/or sensitivity might be achieved by operating without decoupling, perhaps using an INEPT or double-INEPT sequence".¹⁹ Their belief was validated ten years later when Pervushin and coworkers²⁰ reported the development of an experimental scheme for transverse relaxation-optimized spectroscopy (TROSY). The TROSY methodology is the subject of another article in this volume, and so only a very brief discussion of the basic principles is presented here.

One of the most important and widely used NMR techniques for studies of biomolecules is the 2D HSQC experiment,¹⁵ which provides correlation information for heteronuclear spin pairs such as ^1H - ^{15}N or ^1H - ^{13}C . The HSQC-type pulse scheme is an integral component in most heteronuclear, multi-dimensional NMR experiments. The sensitivity and resolution of HSQC-based experiments is dependent on the transverse relaxation rates of the spins actively involved in the coherence transfer pathway. As the molecular weight of the system under study increases, so do the transverse relaxation rate constants, and thus the sensitivity and resolution of the HSQC spectra are degraded. In the presence of significant dipole-dipole/CSA relaxation interference, the linewidths of individual spin multiplet components can be quite different. The spin decoupling normally performed during an HSQC-type experiment causes an averaging of the transverse relaxation rates of the multiplet components. However, by carefully avoiding this mixing of spin states, it is possible to take advantage of the line-narrowing of one of the multiplet components that arises due to destructive interference of the dipole-dipole and CSA interactions.¹⁴ This forms the basis for the TROSY scheme, as was illustrated in Figure 1. In the first application reported by Pervushin et al.,²⁰ the TROSY scheme

was incorporated into a 2D ^1H - ^{15}N HSQC experiment. The pulse sequence was designed to select only one of the four multiplet components that would normally be observed for a ^1H - ^{15}N spin pair correlation in an uncoupled 2D HSQC spectrum. Selecting the component with the smallest ^{15}N and ^1H linewidths can lead to significant improvements in sensitivity and/or resolution, under favorable conditions. Heading the list of required conditions of course is that there be a significant dipole-dipole/CSA cross-correlation effect. Thus, the TROSY scheme is most effective at ultra-high magnetic field strengths, due to the field dependence of the CSA interaction, and for heteronuclei with large chemical shift anisotropies, such as ^{15}N or aromatic ^{13}C spins. A number of other factors also affect whether the TROSY scheme will provide useful sensitivity and/or resolution enhancements. Other sources of relaxation, such as dipolar interactions with remote protons, will tend to mask the line narrowing from the DD/CSA interference, as will exchange contributions to the linewidths. Thus, TROSY-based schemes are most useful for large molecular systems that are highly deuterated and not subject to conformational exchange broadening. Even under such conditions, the maximal advantage theoretically possible for a TROSY-based pulse sequence is usually not reached, due to different data acquisition and processing parameters for TROSY and non-TROSY experiments. For example, the advantage of reduced transverse relaxation rates in the ^{15}N evolution period of a TROSY-based HSQC is most useful if relatively long evolution periods are required; such is the case for experiments used to measure small coupling constants. Implementation of the TROSY scheme is also of particular value in constant-time periods in various multi-pulse sequences to minimize relaxation-associated loss of signal intensity.

In practical applications, the TROSY scheme has been extremely useful for studies of deuterated molecules or complexes, especially those that are in excess of 50 kDa in size. The TROSY scheme has been incorporated into a large number of the standard triple resonance experiments employed for resonance assignment as well as other pulse sequences, such as those used to measure small scalar couplings across hydrogen bonds (see **Polarization Transfer Experiments via Scalar Coupling in Liquids**, Volume 6).

The TROSY scheme, as it was originally proposed, was based on the exploitation of relaxation interference between dipole-dipole and CSA interactions to achieve line narrowing of single quantum coherences. Griffey and Redfield¹⁹ pointed out that line-narrowing could also be achieved for zero-quantum (ZQ) coherences, utilizing relaxation interference of the CSA interactions of the two spins actively involved in the ZQ coherence. Pervushin and coworkers²¹ have developed a modified TROSY scheme to take advantage of this ZQ line-narrowing via the cross-correlation of ^{15}N and ^1H CSA interactions for ^{15}N - ^1H spin pairs. They have also incorporated this ZQ-TROSY scheme into a novel 3D ^{15}N -separated ^1H - ^1H NOESY experiment. The three main features/advantages of this so-called 3D NOESY- ^{15}N , ^1H -ZQ-TROSY experiment are: (1) the ^{15}N CSA/ ^1H CSA cross-correlation is used to reduce transverse relaxation during the ^{15}N evolution time; (2) line-narrowing is achieved in all three frequency dimensions; and (3) substantial suppression of the diagonal peaks is achieved, thereby facilitating the observation of NOESY cross-peaks that lie very close to the diagonal.

3.2 CRINEPT

Most multi-dimensional experiments applied to biomolecules employ polarization/coherence transfer steps to transfer magnetization from one nuclear species to another; in some cases this is done solely for sensitivity enhancement, and in others it is done to implement a desired coherence transfer pathway. The coherence transfer between two spins I and S normally involves the evolution of magnetization under the scalar coupling Hamiltonian according to (assuming a pulse-interrupted free precession period)

$$I_x \xrightarrow{H_J} I_x \cos(\pi J_{IS}\tau) + 2I_y S_z \sin(\pi J_{IS}\tau) \quad (5)$$

where J_{IS} is the scalar coupling between spins I and S . Coherence is transferred from I to S by the application of 90° rf pulses to the I and S spins to convert the second term above from anti-phase I spin magnetization to anti-phase S spin magnetization. The 90° rf pulses are applied at a time τ that is chosen to optimize the efficiency of the transfer; in the absence of relaxation, exchange effects, and remote couplings to the I spin, the optimal value of τ would be $1/(2J_{IS})$. However, in the presence of significant I spin relaxation and/or exchange broadening of the I spin, the coherence transfer process is adversely affected and τ will have to be reduced in order to obtain the maximum transfer allowed by the experimental conditions. The loss of magnetization due to relaxation during the scalar coupling evolution period becomes increasingly significant as the size, and thus the rotational correlation time, of the system increases.

Another possibility exists for achieving polarization/coherence transfer between a heteronuclear spin pair. Dalvit²² and Brüschweiler and Ernst²³ have demonstrated the possibility of employing DD/CSA cross-correlation effects to obtain a coherence transfer of the type

$$I_x \xrightarrow{\Gamma_{\text{DD, CSA}}} 2I_x S_z \quad (6)$$

In this case the relevant process is the cross-correlation of the I spin CSA and the dipolar interaction between the I and S spins. Coherence can then be transferred from the I spin to the S spin via the anti-phase term by application of 90° rf pulses to both I and S spins. Riek and coworkers²⁴ have coined the term CRIPT (cross relaxation-induced polarization transfer) for this process, and have discussed the sensitivity advantages achievable, relative to scalar coupling-induced coherence transfer, in applications to very large molecules. They have also developed experimental procedures for utilizing both scalar coupling-induced and cross-correlation-induced coherence transfer pathways in a methodology they have named CRINEPT. Maximum sensitivity enhancements in appropriate applications are obtained by also including the TROSY scheme in the CRINEPT pulse sequences.²⁵

3.3 CSA Tensor Characterization via Cross-Correlation Effects

Accurate knowledge of CSA tensors is important for interpreting the results of many NMR experiments in order to obtain structural and motional parameters. Information concerning the magnitude and orientation of CSA tensors

has most commonly been obtained from solid-state NMR studies of model compounds. However, experimental studies have demonstrated that CSA tensors are very sensitive to the local environment of a nucleus in a biomolecule, and thus the applicability of tensor parameters from small model compounds is limited. Progress has been made in the use of quantum-chemical calculations to obtain CSA tensor parameters,²⁶ but there clearly is still a great need to have procedures for experimentally measuring such parameters directly from the systems of interest. Such measurements are potentially a valuable source of structure and dynamics information.

Several groups have demonstrated that site-specific, quantitative information on ^1H , ^{13}C and ^{15}N chemical shift anisotropies can be obtained for these nuclei in biomolecules from the measurement of dipole–dipole/CSA relaxation interference effects.⁸ Several related procedures have been proposed for obtaining CSA information from DD/CSA relaxation interference measurements. For a heteronuclear two spin (I , S) system, DD/CSA transverse cross-correlation rate constants can be obtained either from measurements of the differential relaxation of the individual doublet components or from measurements of the $I_x \rightarrow 2I_x S_z$ coherence transfer process. The methodology described by Kroenke and coworkers²⁷ also involves measurement of the longitudinal cross-correlation rate constants via the $I_z \rightarrow 2I_z S_z$ polarization transfer process. Fushman and coworkers²⁸ demonstrated that the magnitudes and the orientation of a CSA tensor (^{15}N in their study) can be obtained from magnetic field-dependent measurements of the ratio η/R_2 , where η is the transverse DD/CSA cross-correlation rate constant and R_2 is the heteronuclear transverse relaxation rate constant. Pang and Zuiderweg²⁹ have proposed an elegant procedure for determining the protein backbone $^{13}\text{C}'$ carbonyl CSA tensor that involves measuring the relaxation interference between the $^{13}\text{C}'$ CSA transverse relaxation and three different dipole–dipole relaxation terms: $^{13}\text{C}'\text{--}^{13}\text{C}^\alpha$, $^{13}\text{C}'\text{--}^{15}\text{N}$, and $^{13}\text{C}'\text{--}^1\text{H}^\text{N}$.

4 MEASUREMENT OF ANGLES BETWEEN BOND VECTORS

Due to the dependence of cross-correlated relaxation effects on the relative orientation of the interaction tensors involved, the measurement of such effects can provide valuable structural information in studies of biomolecules. Considering CSA and dipolar interactions, cross-correlated relaxation can arise from the CSA of two different spins, from the CSA of spin i and the dipolar interaction between spins j and k [DD(jk)], from the CSA of spin j or k and the dipolar interaction between spins j and k affecting the relaxation of spin i , and from two pairs of dipolar interactions DD(ij) and DD(kl) with no common spin between them. In such cases the cross-correlation effects depend on the relative orientation of the relevant interaction tensors but not explicitly on distances. These types of cross-correlations are termed ‘remote’,³⁰ since the relaxation interference does not depend explicitly on the distance of other spins from the spin or spins of interest. For example, the CSA/CSA cross-correlation involving spins i and j does not depend explicitly on the distance between i and j . Likewise, the DD/DD cross-correlation between spin pairs i , j and k , l depends on r_{ij} (the distance between spins i and j) and

r_{kl} inter-nuclear distances but not explicitly on the distances between the spin pairs, i.e., the r_{ik} , r_{il} , r_{jk} or r_{jl} distances.

Reif and coworkers³¹ introduced a strategy which utilizes remote cross-correlation effects to measure the relative orientation of bond angles; a major advantage of this strategy is the fact that there is no requirement to establish a parameterized Karplus-type relationship, as there is when scalar couplings are used to measure torsion angles. Another advantage is the fact that the cross-correlated relaxation is not limited to the analysis of local geometry, since there is no explicit distance dependence. In principle, the relative orientation of arbitrary interaction tensors within one molecule, or even between two molecules, can be measured as long as a correlation between these two can be established.¹⁷

An approach that has proven to be very effective for the measurement of remote cross-correlation effects is to examine the relaxation behavior of double and zero quantum coherences created between nuclei affected by the interactions of interest. In the strategy proposed by Reif et al., double quantum coherence is created involving the $^{13}\text{C}^\alpha$ nucleus of amino acid residue i and the backbone ^{15}N nucleus of residue $i + 1$ in a protein, and the effects of relaxation interference between the $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ (residue i) and the $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ (residue $i + 1$) dipolar interactions on the $^{13}\text{C}^\alpha\text{--}^{15}\text{N}$ double quantum coherence is probed. The cross-correlation effects are manifested in the differential relaxation rates of the four double quantum transitions. These rates can be determined either from the linewidths of the double quantum signals or from resonance intensities measured from a constant-time NMR experiment. For practical reasons the latter approach is normally easier to accomplish. Intensity ratios provide a measure of the desired cross-correlation relaxation rate constants. In turn, these rate constants can then be used to determine the relative orientation of the interaction tensors.¹⁴ For the example described here, and assuming a macromolecule that tumbles slowly in solution, the cross-correlated dipolar relaxation depends on the angle θ between the $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ (residue i) and $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ (residue $i + 1$) bonds according to

$$\Gamma = \frac{\gamma_H \gamma_N}{(r_{NH})^3} \frac{\gamma_H \gamma_C}{(r_{CH})^3} \left(\frac{\hbar \mu_o}{4\pi} \right)^2 \frac{2}{5} (3 \cos^2 \theta - 1) \tau_c \quad (7)$$

The γ_H , γ_N and γ_C are the magnetogyric ratios of the ^1H , ^{15}N and ^{13}C nuclei, respectively, r_{NH} and r_{CH} are the $^{15}\text{N}\text{--}^1\text{H}^\text{N}$ and $^{13}\text{C}^\alpha\text{--}^1\text{H}^\alpha$ inter-nuclear distances, respectively, τ_c is the rotational correlation time of the molecule, and $\hbar$ and μ_o are natural constants. This expression does not take fast internal motion or anisotropic reorientation of the molecule into account. Due to the planarity of the peptide bond, the angle θ can be directly related to the dihedral angle ψ , and thus the dipole–dipole cross-correlation measurement provides information on the allowed values of ψ . Such information can provide important new structural constraints in the structure determination of proteins, due to the fact that the dihedral angle ψ is difficult to assess by other experimental means.

Since the pioneering work of Reif et al. was first reported, additional and/or improved schemes for using cross-correlation effects to assess ϕ and ψ dihedral angles in proteins and sugar puckers in nucleic acids have been proposed by several groups (see for example Kloiber and Konrat³² and references cited therein). Almost all of these schemes have been based on the measurement of DD/DD and/or DD/CSA cross-correlation

effects. However, Skrynnikov and coworkers³³ have proposed a technique for measuring CSA cross-correlated relaxation between pairs of carbonyl spins in proteins, and have demonstrated that in the case where the carbonyl spins reside on successive residues, information about the intervening (ϕ , ψ) backbone dihedral angles is obtained. They also demonstrated the possibility of observing CSA/CSA cross-correlated relaxation between carbonyl spins residing on two peptide planes linked via a hydrogen bond, which can provide information about the relative orientation of these planes. With the availability of dihedral angle information, especially for the ψ angles, from various cross-correlated relaxation measurements, it has become possible to use such structural constraints in NMR protein structure calculations. Refinement methods that have been modified to incorporate cross-correlation-based structural constraints can be used to significantly improve the quality of NMR structures and are applicable to larger proteins.³⁴

5 STUDIES OF MOLECULAR DYNAMICS VIA CROSS-CORRELATED RELAXATION EFFECTS

The measurement of nuclear spin relaxation rate constants provides valuable information on motional processes occurring within biomolecules. Experiments for measuring auto-correlated relaxation rate constants for ^1H , ^{13}C , ^{15}N and ^2H are in widespread use, particularly for characterizations of the backbone dynamics and the rotational diffusion tensor of proteins and their complexes.¹¹ Building upon this base, there is growing interest in obtaining more detailed information on conformational dynamics within proteins. Two areas of focus are the development of more realistic models of the local motions of peptide planes in proteins and quantitative measurements of side chain dynamics. Cross-correlated relaxation experiments are proving to be particularly useful for studying the motional properties of structural elements that have a fixed geometry, such as peptide planes and CH_2 , CH_3 and NH_2 groups. The motions of such moieties within proteins and similar elements within other biomolecules are expected in general to be anisotropic. Experimental NMR studies of such anisotropic motions are greatly facilitated by exploiting the sensitivity of cross-correlated relaxation rates to the direction of motion. Cross-correlated relaxation measurements are complementary to the standard auto-correlated relaxation experiments in several ways. Cross-correlation rate constants are not, or only little, affected by conformational or chemical exchange processes (see **Chemical Exchange Effects in Biological Macromolecules**), spin-rotation relaxation, or relaxation by paramagnetic oxygen;³⁵ such contributions can complicate the interpretation of dipolar or CSA auto-relaxation data. An additional advantage is that transverse cross-correlation effects are generally confined to subsystems containing two, three or four spins, with outside spins having little effect. On the other hand, a potential complication in the use of cross-correlation effects involving CSA interactions is that independent knowledge of the CSA tensor parameters is necessary in order to separate out the motional contributions to the cross-correlated relaxation processes. Information from other sources, such as solid-state NMR, molecular dynamics simulations, and CSA quantum chemical calculations, can be employed for characterizing the necessary CSA tensor parameters.^{26,35}

A thorough description of the theory and application of cross-correlated relaxation measurements for studies of motional processes in biomolecules is beyond the scope of this article. The interested reader is directed to several excellent review articles that have appeared recently.^{8–11} Instead, a very limited survey of some of the most promising uses of cross-correlation effects in biomolecular dynamics studies is presented here.

5.1 Dipole–Dipole/Dipole–Dipole Cross-Correlation Measurements

The cross-correlated relaxation measurements most commonly employed in biomolecular NMR studies involve dipole–dipole/dipole–dipole (DD/DD) and DD/CSA interactions. The measurement of DD/DD cross-correlated relaxation has the advantage that no assumptions generally need to be made about the interaction tensors, since they involve known physical constants such as the bond lengths, the orientation of the principal axis of the dipolar tensor is usually known, and the dipolar tensor is axially symmetric. There has been a long history to the use of DD/DD cross-correlated relaxation effects for characterizing molecular motions. Much of the work has focussed on the examination of relaxation effects for proton-coupled ^{13}C spins, especially for AX_2 and AX_3 groups.^{7,8,10} For the ^{13}C multiplet spectra of methylene and methyl groups, the central and outer components of the multiplet exhibit different relaxation behavior as a result of DD/DD cross-correlation.¹⁰ Differences in the high field relaxation behavior of the outer lines of the ^{13}C multiplet result from DD/CSA cross-correlation. Building upon earlier work of their own and that of other groups such as Grant, Werbelow and Bodenhausen, Daragan and Mayo have championed the use of DD/DD cross-correlated relaxation measurements for obtaining information on motional processes in biomolecules.^{10,11}

A particularly useful method for measuring DD/DD cross-correlated relaxation in heteronuclear spin systems is to monitor the cross-relaxation process $S_z \rightarrow 4S_z I_{1z} I_{2z}$; this technique has been referred to as “SIIS cross relaxation”.³⁶ This cross-relaxation process can occur only when the two heteronuclear dipolar interactions SI_1 and SI_2 are modulated in a correlated manner by the random process that causes relaxation. The SIIS-type of experiment is particularly useful for characterizing the motion of CH_2 groups about χ dihedral angles in the side chains of proteins, since the relative orientation of the two interacting dipoles is known. Measurements of scalar coupling constants can provide information concerning the relative populations of χ rotamers, but provides no information on the rate constants for the bond rotations. By measuring the cross-relaxation behavior between the S_z polarization and the three-spin order $4S_z I_{1z} I_{2z}$, Ernst and Ernst³⁶ demonstrated that it is possible to distinguish between equally populated three-site jump or unrestricted rotational diffusion models on the one hand and two-site or restricted rotational diffusion models on the other hand; it is often possible to make this judgement based just on the sign of the cross-relaxation peaks. The SIIS cross-relaxation process is typically measured by creating either the S_z polarization or the three-spin order $4S_z I_{1z} I_{2z}$, and then detecting the cross-relaxation partner. Due to the slow tumbling of large molecules, there is some advantage to performing the experiment in the so-called tilted rotating frame, as in the related T-ROESY experiment.³⁷ The reason for this

is that in the laboratory frame the cross-relaxation process depends only on the spectral density function at the Larmor frequency ω_{os} , which tends towards zero as the tumbling slows. A dependence on $J(0)$ is introduced by performing the experiment in the tilted rotating frame. Yang and coworkers³⁸ have proposed an alternative method, using a triple resonance pulse scheme, for measuring cross-correlated dipole–dipole spin relaxation in proteins. Their experiment records $^{13}\text{C}^\beta$ multiplet component intensities in one of the three dimensions, and the cross-correlation relaxation rate constant for the interaction between the two ^{13}C β -methylene ^{13}C – ^1H dipoles is obtained by taking the appropriate ratio of multiplet component intensities. Kay’s group, among others, has elegantly demonstrated the usefulness of DD/DD cross-correlation measurements for assessing side-chain dynamics in folded and unfolded proteins and for selecting appropriate motional models.^{10,38,39}

A number of DD/DD cross-correlations exist among the various nuclei that form the backbone of a protein, and in principle measurements of the associated cross-correlated relaxation rate constants can provide information about the dynamics of peptide planes. Carlomagno and coworkers⁴⁰ proposed a scheme for measuring the sum of the $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ / ^{15}N – $^1\text{H}^\text{N}$ and $^{13}\text{C}'$ – $^1\text{H}^\text{N}$ / ^{15}N – $^{13}\text{C}^\alpha$ DD/DD cross-correlated relaxation rate constants by analyzing the influence of these processes on ^{15}N – $^{13}\text{C}'$ double and zero quantum coherences. The same experiment gives access to the cross-correlated relaxation rate constants between the $^{13}\text{C}'$ CSA and the ^{15}N – $^1\text{H}^\text{N}$ or $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ dipoles. The rate constants are very small for small proteins, and thus are difficult to interpret quantitatively. However, the rate constants are expected to increase for larger molecules, which would allow a more rigorous, quantitative analysis. Nevertheless, even a qualitative analysis of the DD/DD cross-correlation data can be helpful in identifying anisotropic motions of peptide planes. Another possible DD/DD cross-correlation involving protein backbone nuclei is the $^1\text{H}^\text{N}$ – ^{15}N / $^1\text{H}^\text{N}$ – $^{13}\text{C}'$ dipole–dipole interaction, which has been examined by Zuiderweg’s group.⁴¹

5.2 Dipole–Dipole/CSA Cross-Correlation Measurements

The measurement of dipole–dipole/CSA cross-correlation effects has proven to be quite valuable for studying motional processes in biomolecules. Such experiments have found important applications in characterizing motional processes occurring on both fast timescales (picosecond–nanosecond) and slower timescales (microsecond–millisecond).

Tjandra and coworkers⁴² demonstrated the possibility of measuring ^{15}N – ^1H dipolar/ ^{15}N CSA relaxation interference effects to obtain approximate values of the generalized order parameter S^2 that is frequently used to characterize the motional properties of bond vectors such as the backbone $^1\text{H}^\text{N}$ – ^{15}N amide group in proteins. They proposed a straightforward experiment for monitoring the cross-relaxation between in-phase ^{15}N coherence, S_x (or S_y), and anti-phase coherence, $2I_z S_x$ (or $2I_z S_y$), and measuring the corresponding cross-correlation rate constant η_{xy} . The theoretical expression for this transverse cross-correlation rate constant is^{42,43}

$$\eta_{xy} = -\frac{\sqrt{3}}{6}cdP_2(\cos\beta)[4J(0) + 3J(\omega_N)] \quad (8)$$

in which $d = (\mu_0 h \gamma_H \gamma_N) / (8\pi^2 r_{NH}^3)$, $c = \gamma_N B_0 \Delta\sigma / \sqrt{3}$, μ_0 is the permeability of free space, h is Planck's constant, γ_H and γ_N are the magnetogyric ratios for ^1H and ^{15}N , respectively, r_{NH} is the distance between the two nuclei, B_0 is the static magnetic field strength, $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$, the principal components of the ^{15}N CSA tensor are $\sigma_{\parallel}$ and $\sigma_{\perp}$, $P_2(x) = (3x^2 - 1)/2$, β is the angle between the symmetry axis of the ^{15}N CSA tensor and the ^{15}N – ^1H bond vector, and $J(\omega)$ is the spectral density function. Since the cross-correlation rate constant η_{xy} is proportional to the generalized order parameter S^2 (through the dependence on the spectral density function), measurements of η_{xy} yield information on the amplitude of rapid internal motions within a biomolecule. A major advantage of utilizing measurements of η_{xy} is the fact that this cross-correlation process is not affected by line broadening caused by slow conformational exchange,^{23,42} and thus the interpretation of the data is greatly simplified in that regard. A disadvantage of the method, however, is that variation in S^2 and $\Delta\sigma$ cannot be distinguished from each other in terms of their effect on η_{xy} . Thus, one must be cautious when interpreting changes in η_{xy} , due to the uncertainties there may be in knowledge of $\Delta\sigma$. On the other hand, if the generalized order parameter S^2 has been determined independently, measurement of η_{xy} can provide information on $\Delta\sigma$.⁴²

Dipole–dipole/CSA cross-correlation can cause not only the transverse cross-relaxation process described above but also the longitudinal cross-relaxation process between a single spin order S_z and two-spin order $2I_z S_z$, characterized by a rate constant η_z . The theoretical expression for η_z is⁴³

$$\eta_z = -\sqrt{3}cdP_2(\cos\beta)J(\omega_N) \quad (9)$$

with the various symbols having the same definitions as above in the expression for η_{xy} . Kroenke and coworkers⁴³ have developed a method for distinguishing the contributions of chemical exchange from the contributions due to anisotropic rotational diffusion in ^{15}N spin relaxation studies by measuring both the longitudinal and transverse relaxation interference between the ^1H – ^{15}N dipolar and ^{15}N CSA interactions. Accurate assessment of chemical exchange contributions to transverse relaxation rate constants (R_2) is critical for a proper interpretation of both model-free and spectral density mapping results. If a biomolecule is regarded as a spherical top that rotates isotropically in solution, then the trimmed mean value of the ratio R_2/R_1 (R_1 is the spin-lattice relaxation rate constant) provides an estimate of the isotropic rotational correlation time of the molecule. Atomic sites subject to chemical or conformational exchange have significantly increased R_2/R_1 ratios. A serious complication arises if the rotational diffusion of the molecule is not isotropic. If rotational diffusion anisotropy is significant, increases in the values of R_2/R_1 for a given nucleus can result from particular orientations of the symmetry axis of the dipolar or CSA tensor in the principal axis frame of the diffusion tensor. These increases can be interpreted mistakenly as evidence of conformational exchange. At the same time, real chemical exchange contributions to R_2 interfere with measurements of the rotational diffusion anisotropy by systematically increasing the R_2/R_1 ratio for the affected nuclei. In practice, sites with large R_2/R_1 ratios are excluded from analysis, which reduces the available data and risks exclusion of data important for accurate assessment of rotational diffusion anisotropy.

The basis for the methodology proposed by Kroenke et al.⁴³ is the fact that both η_{xy} and η_z are independent of chemical exchange and that the η_{xy}/η_z ratio is, to a good approximation, independent of the principal values and orientations of the CSA tensor, unlike the η_{xy} and η_z values separately. As a result, the η_{xy}/η_z ratio is sensitive only to internal and overall motions that contribute to dipolar and CSA relaxation mechanisms. The dependence of the η_{xy}/η_z ratio on the orientation of the ^1H – ^{15}N bond vector in a molecular reference frame provides a robust method of determining the rotational diffusion tensor. In addition, comparison of the η_{xy}/η_z ratios to the R_2/R_1 ratios permits unequivocal identification of nuclei that are subject to chemical exchange processes, without the need for multi-field and/or rotating-frame relaxation experiments. The methodology for measuring η_z is straightforward.⁴³ A potential complication in the measurement of η_z is the competing cross-relaxation of the $2I_z S_z$ two-spin order ($I \equiv ^1\text{H}$) with surrounding protons. This problem can be minimized through the use of deuteration or by more complex experimental schemes.^{44,45}

Cross-correlated relaxation measurements are proving to be a rich source of information for characterizing the backbone dynamics of proteins. Such motions have commonly been studied through the use of ^{15}N , $^{13}\text{C}^\alpha$ and, more recently, $^{13}\text{C}'$ carbonyl auto-correlated relaxation experiments. Several groups have demonstrated that the measurement of various relaxation interference effects, many involving the cross-correlation of dipole–dipole and CSA interactions, can provide useful insights concerning the locally anisotropic motions of peptide planes and complement the information obtained from auto-correlated relaxation experiments. A large number of relaxation interference effects are possible among the group of spin-1/2 nuclei in the protein backbone ($^{13}\text{C}'$, ^{15}N , $^1\text{H}^\text{N}$, $^{13}\text{C}^\alpha$, $^1\text{H}^\alpha$), and many have already been exploited. Only some of the possibilities that have been demonstrated are discussed here.

Zuiderweg's group has reported that there is a poor correlation between the generalized order parameters of the C' – C^α and the $^1\text{H}^\text{N}$ – ^{15}N bond vectors, as determined from auto-correlated relaxation studies.⁴⁶ They interpreted the lack of correlation as evidence of local or semi-local anisotropic motion of the peptide planes. To further their studies, they developed a new experiment to measure the relaxation interference between the carbonyl (C') CSA and the $^{13}\text{C}'$ – $^{13}\text{C}^\alpha$ dipole–dipole relaxation interactions. The availability of such additional experimental data that reports on anisotropic motion is of great value for modeling such motions.^{10,11,47} The Zuiderweg group has also developed a novel scheme for measuring transverse $^{13}\text{C}'$ – $^1\text{H}^\text{N}$ dipole–dipole/ $^{13}\text{C}'$ CSA cross-correlated relaxation rates, using an E.COSY-type triple resonance experiment.⁴⁸ The advantage of this method for measuring the cross-correlation effects is that it by-passes the usual requirement for having a resolvable scalar coupling between, in this case, the $^{13}\text{C}'$ and $^1\text{H}^\text{N}$ nuclei.

Brutscher and coworkers⁴⁹ devised a general scheme to use zero-quantum/double-quantum (ZQ/DQ) NMR experiments to measure various dipole–dipole/CSA cross-correlation rate constants. They demonstrated their methodology for the three-spin system consisting of the $^1\text{H}^\text{N}$, ^{15}N and $^{13}\text{C}'$ nuclei of the peptide plane in proteins. The dipole–dipole/CSA relaxation interference effects on the zero- and double-quantum coherences formed between the ^{15}N and $^{13}\text{C}'$ spins are manifested as differential relaxation in the two components of the ^{15}N – $^1\text{H}^\text{N}$ doublet. The measured relaxation rate constants include both

local and remote cross-correlation effects. There is a distinct dependence of the local and remote cross-correlation effects on internal anisotropic reorientational fluctuations of the peptide plane, providing the possibility of using such information to obtain a better understanding of local motions within a protein backbone.

5.3 CSA/CSA Cross-Correlation Measurements

Although the measurement of CSA/CSA cross-correlation effects has not yet attracted as much attention as DD/DD or DD/CSA cross-correlation measurements, the CSA/CSA-based experiments complement the other methods and can also provide valuable information for characterizing motional anisotropy within biomolecules. Vold and Vold¹² anticipated the possibility of observing CSA/CSA relaxation interference effects, which other groups subsequently have verified and elaborated upon.^{8,11} In terms of applications to biomolecules, Pellecchia and coworkers⁴¹ have demonstrated the potential usefulness of measuring the cross-correlation effects between the CSAs of the backbone amide ^{15}N and carbonyl $^{13}\text{C}'$ nuclei in proteins. Their measurement scheme is based upon the differential relaxation of double- and zero-quantum coherences formed between the backbone ^{15}N and carbonyl $^{13}\text{C}'$ spins. As it turns out, their experiment also permits the measurement of the cross-correlation between $^1\text{H}^{\text{N}}\text{--}^{15}\text{N}$ and $^1\text{H}^{\text{N}}\text{--}^{13}\text{C}'$ dipole–dipole interactions. The ^{15}N CSA tensor is, to a good approximation, axially symmetric, which simplifies the theoretical treatment. However, the $^{13}\text{C}'$ tensor is not axially symmetric. However, it is possible to decompose the $^{13}\text{C}'$ CSA tensor into two orthogonal axially symmetric tensors and separately consider the contributions of each.¹¹ Interpretation of CSA/CSA cross-correlated relaxation effects is challenging since observed variations, as reported by Pellecchia et al., can depend on local internal anisotropic motion and variations of tensor parameters and of angles between tensors. However, even though much work is still required in developing a robust procedure for interpreting CSA/CSA relaxation interference effects in biomolecules, such measurements will clearly be useful in characterizing internal motional anisotropies such as that for individual peptide planes. Such studies will be greatly facilitated by developments in the understanding of structural and motional effects on CSA tensor parameters.

6 CROSS-CORRELATION EFFECTS IN PARAMAGNETIC SYSTEMS

The presence of cross-correlation effects in paramagnetic systems has been exploited for a number of useful purposes.⁸ The dipolar interaction between a nucleus and the static electron magnetic moment results in the so-called Curie spin relaxation (CSR). A theoretical analysis demonstrates that, for example, the cross-correlation between the ^1H -Curie spin and $^1\text{H}\text{--}^{15}\text{N}$ dipolar interactions is formally identical to $^1\text{H}\text{--}^{15}\text{N}$ dipolar/ ^1H CSA cross-correlated relaxation. Boissbouvier and coworkers⁵⁰ have demonstrated that the measurement of $^1\text{H}\text{--}^{15}\text{N}$ dipole–dipole/ ^1H CSR cross-correlated relaxation rate constants can provide valuable, long-range structural constraints in NMR studies of paramagnetic molecules, due to the dependence of the rate constant on the distance between the amide proton and the electron spin and on the angle defined

by the triangle $^{15}\text{N}\text{--}^1\text{H}\text{--}\text{S}$ (S is the electron spin). Madhu and coworkers⁵¹ demonstrated that in addition to providing geometric constraints for structure refinement, the presence of cross-correlated relaxation involving the Curie spin relaxation and inter-nuclear dipolar relaxation mechanisms can also permit TROSY-type schemes to be used to obtain sensitivity and/or resolution enhancements. In this case, the enhancements can occur for any of the four components of a 2D $^1\text{H}\text{--}^{15}\text{N}$ multiplet, in contrast to the case for diamagnetic proteins and dipole–dipole/CSA cross-correlations.^{8,51} Another important consequence of cross-correlation effects in paramagnetic systems is the possibility of observing ‘relaxation-allowed’ coherence transfer between two nuclei.^{8,52}

7 CHARACTERIZATION OF HYDROGEN BOND LENGTHS

Hydrogen bond formation is an essential mechanism for the stabilization of biomolecular structures, and thus the development of experimental methods capable of directly detecting the presence of hydrogen bonds is quite valuable. Riek⁵³ has demonstrated that hydrogen bond lengths can be characterized by the measurement of DD/CSA cross-correlated relaxation involving the ^1H CSA and the dipole–dipole couplings of the ^1H to its hydrogen bond acceptor ^{15}N and to its hydrogen bond donor ^{15}N . The ratio of these two cross-correlation rate constants is dependent on the hydrogen bond length and on the generalized order parameter of the dipole–dipole $^1\text{H}\text{--}^{15}\text{N}$ vectors. Although the distance and motional contributions cannot be distinguished in this experiment, qualitative information is obtained concerning the characteristics of the hydrogen bond.

8 RELAXATION-INDUCED VIOLATIONS OF COHERENCE TRANSFER SELECTION RULES IN MULTIPLE QUANTUM NMR SPECTROSCOPY

Homonuclear multiple quantum and multiple quantum-filtered spectroscopy can be quite useful for resonance assignment in NMR studies of biomolecules.^{54,55} The interpretation of multiple quantum and multiple quantum-filtered spectra is greatly assisted by the use of the coherence transfer selection rules given by Braunschweiler and coworkers,⁵⁶ which indicate the conditions required for transfer of multiple quantum coherence to observable single quantum transitions. While the predictions made based on these selection rules generally agree very well with experimental results, some anomalous resonances are frequently observed that violate these selection rules. In particular, multiple quantum coherence actively involving two or three methyl protons (attached to the same carbon atom) can be transferred to observable single quantum transitions of the methyl protons, in violation of the aforementioned selection rules. Such ‘forbidden’ peaks arise due to differential relaxation rates of degenerate single quantum transitions of magnetically equivalent nuclei.^{57–59} Müller and coworkers presented a detailed analysis of the dipolar cross-correlation effects that give rise to the multi-exponential transverse relaxation of degenerate transitions. Müller has also proposed several experiments that exploit the presence of relaxation-allowed coherence transfer pathways in systems of degenerate spins.⁸

9 ADDITIONAL CROSS-CORRELATION EFFECTS

Most of the applications of cross-correlation effects in studies of biomolecules have involved the various combinations of dipole–dipole and CSA interactions and, for paramagnetic molecules, Curie spin relaxation. However, other possibilities exist as well, and a few of these are mentioned here.

Brüschweiler and Ernst²³ pointed out that cross-correlated relaxation effects can occur when a motional process simultaneously modulates a chemical shielding and a spin coupling term. For example, cross-correlated relaxation would occur for an I – S spin pair if the chemical shift of one of the spins and the isotropic scalar coupling J_{IS} were both modulated by the same motional process. Another possibility is the cross-correlation of chemical exchange effects involving multiple quantum coherences.⁶⁰ The latter effect was hypothesized to be a contributing factor in $^1\text{H}^{\text{N}}/^{15}\text{N}$ CSA/CSA cross-correlated relaxation measurements in proteins. Cross-correlation effects can be important in the analysis of dynamic frequency shifts.⁸ For example, a dynamic frequency shift (see **Dynamic Frequency Shift**, Volume 3) can result from DD/CSA cross-correlated relaxation in a two-spin-1/2 system and is manifested as an additive contribution to the apparent scalar J coupling between the two spins.⁶¹ This cross-correlation-induced J coupling is dependent on the motional properties of the spin system and thus can serve as a unique probe of molecular dynamics.

10 ELIMINATION OF CROSS-CORRELATION EFFECTS

The presence of cross-correlation effects can complicate the measurement of various relaxation rate constants by introducing additional terms into the rate equations that describe relaxation. In such cases it is desirable to devise methods for eliminating specific cross-correlation effects. These methods can be as simple as using non-selective 90° measuring pulses to eliminate multiplet effects in homonuclear spin systems,⁸ or more elaborate procedures requiring new elements to be added to the relevant pulse sequences. Among the most common type of experiments in which the elimination of cross-correlation effects is important is the measurement of heteronuclear spin relaxation rate constants. At high magnetic fields, the magnitudes of the ^1H – X dipolar and X spin CSA interactions are comparable for X representing the ^{15}N in a peptide group or the aromatic ^{13}C nuclei; consequently, cross-correlation between these two relaxation mechanisms systematically affects relaxation rate constants measured using conventional experimental methods. Boyd and coworkers⁶² demonstrated that unwanted dipole–dipole/CSA cross-correlation effects in ^{15}N longitudinal (T_1) relaxation measurements can be eliminated by broadband ^1H decoupling during the magnetization recovery period. They also proposed experimental schemes for monitoring the cross-relaxation between S_z and $2I_z S_z$ operators that results from dipole–dipole/CSA cross-correlation, and suggested that such measurements could provide information on the ^{15}N CSA tensor and on the angle θ between the principal axis of the ^{15}N CSA tensor and the ^1H – ^{15}N inter-nuclear vector. Analogous means for suppressing dipole–dipole/CSA cross-correlation effects in CPMG experiments have been proposed,^{63,64} allowing accurate measurements of spin-spin

relaxation rate constants for heteronuclei with significant chemical shift anisotropies.

11 SUMMARY

Rather than being a complicating nuisance, as it was widely perceived to be in the past, cross-correlated relaxation has turned out to be extremely valuable as the basis for many new NMR tools that have been developed for probing the structure and dynamics of biomolecules. The observed effects of cross-correlated relaxation range from subtle to dramatic. The sensitivity and resolution improvements achieved in TROSY- and CRINEPT-type experiments have made it possible to study much larger systems than was previously feasible. New experiments are available for the characterization of CSA tensors, obtaining unique structural constraints, and probing motional processes within biomolecules at an unprecedented level of detail. Although much theoretical and experimental work needs to be done to fully exploit the potential of cross-correlated relaxation phenomena, the rewards are clear and undoubtedly there are many new, valuable discoveries yet to be made in this field.

1 INTRODUCTION

The NMR properties of atomic nuclei in atoms, molecules, and ions depend mainly on short-range effects. For example, the chemical shift of a nucleus in a molecule depends mainly on the molecular structure and only slightly on whether the molecule is in a gas, a liquid, or a solid. In a solid, the chemical shift is anisotropic, depending on the orientation of the molecule in the magnetic field. In a liquid, the molecular motions are very rapid, so that the chemical shift is the weighted average over the solid 'powder pattern'. The liquid molecule moves very rapidly, or exchanges, among all orientations and local molecular associations. In this general sense, exchange is ubiquitous, and the results are readily understood in terms of the appropriate average. Multicomponent NMR relaxation behavior can occur when the nuclei under study are constrained in different regions or at different sites that are characterized by different time-averaged environmental parameters that affect the relaxation times. These parameters include any that affect the nuclear spin energy levels and the mobility or time dependences of these parameters.

The NMR relaxation times are expressed¹ in terms of the Fourier intensities or spectral densities $J_h(\omega)$ of the time correlation function $\langle F_h(t)F_h^*(t + \tau) \rangle$ of nuclear spin interactions $F_h(t)$ at the angular frequency ω as given by

$$J_h(\omega) = \int_{-\infty}^{\infty} \langle F_h(t)F_h^*(t + \tau) \rangle \exp(i\omega\tau) d\tau \quad (1)$$

The interaction function $F_h(t)$ is the product of a nuclear relaxation interaction strength (r^{-3} for magnetic dipolar relaxation) and a function of orientation (second-order spherical harmonic). (The average value $\langle F_h(t) \rangle$ is zero, unless there is preferential orientation such as that imposed by a stationary interface on a nonspherical molecule.) Let us consider the case when the correlation function of a site is

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \langle F_h(t)F_h^*(t) \rangle \exp(-|\tau|/\tau_c) \quad (2)$$

in which the correlation time τ_c depends on the rate of molecular motion (see **Brownian Motion and Correlation Times**). Because equation (2) is an exponential function, the spectral densities $J_h(\omega)$ are given by the Lorentzian functions

$$J_h(\omega) = \langle F_h(t)F_h^*(t) \rangle \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad (3)$$

To illustrate the relationship between the spectral densities and the NMR relaxation times, consider the cases of magnetic dipolar interaction between two identical spin- $\frac{1}{2}$ nuclei and of nuclear quadrupolar interaction of a spin-1 nucleus. In both instances, the relaxation times are given by the equations¹

$$\frac{1}{T_1} = H[J_1(\omega_0) + J_2(2\omega_0)] \quad (4a)$$

$$\frac{1}{T_2} = \frac{1}{4}H[J_0(0) + 10J_1(\omega_0) + J_2(2\omega_0)] \quad (4b)$$

where T_1 is the spin-lattice relaxation time, T_2 is the transverse relaxation time, and ω_0 is the angular Larmor frequency. The interaction strength $H = \frac{9}{8}\gamma^4\hbar^2r^{-6}$ for magnetic dipolar relaxation and $\frac{9}{8}\pi^2\chi^2$ for nuclear quadrupolar interaction with zero asymmetry parameter. These equations apply (see **Relaxation Theory: Density Matrix Formulation**) to the motionally narrowed limit in which $H^{1/2}\tau_c < 1$. When this limit does not apply, the $J_0(0)$ term is incorrect and the transverse relaxation must be calculated differently. We can do this by replacing the $J_0(0)$ term with the time dependence of the ensemble average of $M_+ = M_x + iM_y$ obtained by introducing time dependence into the Larmor frequency. This is done in Sections 5–8 of this article for the transverse relaxation in many systems that involve chemical exchange of nuclei between sites with different Larmor frequencies.

In a more general approach that includes chemical exchange between different types of sites that are designated by j , we need to look closely at the evaluation of the correlation function $\langle F_h(t)F_h^*(t + \tau) \rangle$ in equation (2), which is an ensemble average (see **Relaxation Theory: Density Matrix Formulation**) to calculate NMR relaxation phenomena properly.² Take any given nucleus at time t in site j , evaluate the interaction function at this time to obtain $F_{hj}(t)$, evaluate the autocorrelation function for this nucleus at later times $t + \tau$, and continue to do this as τ increases from zero to 'large' values. Finally, take the sum over all the j -type sites, weighting each site by its fractional population P_j . Note that the fraction of time that a nucleus occupies a j -type site is equal to P_j . The average time that nucleus occupies a j -type site is τ_j .

2 RELAXATION UNDER EXTREMELY RAPID EXCHANGE CONDITIONS

If chemical exchange of nuclei is merely rapid so that all the lifetimes τ_j are long compared with the correlation times τ_{cj} , the relaxation times of nuclei in the different j types of sites are independent of the exchange, and the preceding treatment for calculating the $J_h(\omega)$ for the relaxation times of a given site j is valid. However, when the exchange is extremely rapid so that the lifetimes in a site are shorter than the correlation times, this condition is not met and the effective correlation time depends on the average lifetime in a site. There are several different cases, depending on whether the strength of the nuclear relaxation interaction is the same in the different types of sites.²

When the strength of the relaxation interaction is the same in all sites and when there is complete randomization of the interaction direction upon chemical exchange, each τ_{cj} for equation (3) is replaced by an effective correlation time

$$\tau_{\text{eff},j} = \left(\frac{1}{\tau_{cj}} + \frac{1}{\tau_j} \right)^{-1} \quad (5)$$

If the direction of interaction is retained, instead of randomized, upon exchange, the exchange process can have several different effects on relaxation.² When the rotational correlation time is much longer in one site than in another, exchange involving this site can give a very large contribution to the rate of relaxation. As a nucleus in this slow site moves by chemical exchange to a site with much faster motion, the effective correlation time for the slow site is shortened. Another possible effect is that the strength of the relaxation interaction may be changed. When the exchange is much faster than the molecular rotational motions, there is a single effective correlation time

$$\tau_{\text{eff}} = \left\{ \sum_i \frac{p_i}{\tau_{cj}} \right\}^{-1} \quad (6)$$

Also, the ensemble interaction average $\langle F_h(t)F_h^*(t) \rangle$ for a single type of site in equation (3) is replaced by the square of the weighted average of $F(t)$ at a given orientation, taken over all types j of sites, and then averaged over all orientations. This type of averaging, in the case of extremely rapid motions, is important for nonspherical molecules at the interface in many aqueous heterogeneous systems (see Section 7 of this article).

3 'TWO-SITE' CHEMICAL EXCHANGE

In all the cases described above, the nuclear relaxation is single component. However, when the nuclei are constrained in the sites, the observed NMR relaxation behavior is merely the weighted sum taken over the different sites that are characterized by specific relaxation times. When the nuclei migrate among these sites at rates that are small compared with molecular motions, the observed relaxation behavior is modified even when the relaxation time of each site is unaffected by this migration or exchange. Zimmerman and Brittin³ have treated this situation with a stochastic theory,

and McConnell⁴ has presented a mathematically equivalent approach of adding exchange terms to the Bloch equations. These modified Bloch equations are particularly convenient for discussing the simplest case that illustrates the main features of the effects of chemical exchange on NMR relaxation: exchange between two different types of sites under the condition that the relaxation time of a nucleus in a given site is independent of the lifetime of the nucleus in that given site.

The Bloch equations are written for a rectangular coordinate system that rotates at angular frequency ω about its Z axis, which is parallel to the direction of $\mathbf{B}_0$, i.e., the rotating frame of reference. The modified Bloch equations that include chemical exchange⁵ between states a and b are

$$\frac{dM_{xa}}{dt} = -(\omega_a - \omega)M_{ya} - \frac{M_{xa}}{T_{2a}} - \frac{M_{xa}}{\tau_a} + \frac{M_{xb}}{\tau_b} \quad (7a)$$

$$\frac{dM_{xb}}{dt} = -(\omega_b - \omega)M_{yb} - \frac{M_{xb}}{T_{2b}} - \frac{M_{xb}}{\tau_b} + \frac{M_{xa}}{\tau_a} \quad (7b)$$

$$\begin{aligned} \frac{dM_{ya}}{dt} &= (\omega_a - \omega)M_{xa} - \frac{M_{ya}}{T_{2a}} - \frac{M_{ya}}{\tau_a} + \frac{M_{yb}}{\tau_b} \\ &\quad - \omega_1 M_{za} \end{aligned} \quad (7c)$$

$$\begin{aligned} \frac{dM_{yb}}{dt} &= (\omega_b - \omega)M_{xb} - \frac{M_{yb}}{T_{2b}} - \frac{M_{yb}}{\tau_b} + \frac{M_{ya}}{\tau_a} \\ &\quad - \omega_1 M_{zb} \end{aligned} \quad (7d)$$

$$\frac{dM_{za}}{dt} = -\frac{M_{za} - M_{0a}}{T_{1a}} - \frac{M_{za}}{\tau_a} + \frac{M_{zb}}{\tau_b} + \omega_1 M_{ya} \quad (7e)$$

$$\frac{dM_{zb}}{dt} = -\frac{M_{zb} - M_{0b}}{T_{1b}} - \frac{M_{zb}}{\tau_b} + \frac{M_{za}}{\tau_a} + \omega_1 M_{yb} \quad (7f)$$

where ω is the angular rf frequency and $\omega_1 = \gamma B_1$, with γ the nuclear magnetogyric ratio. Also, P_a is the fraction of nuclei that are in state a , ω_a is the Larmor frequency, τ_a is the average lifetime of a given nucleus in state a before it leaves a and enters state b , T_{1a} and T_{2a} are the longitudinal and transverse relaxation times for nuclei while in state a , and M_{0a} is the equilibrium nuclear magnetization along $\mathbf{B}_0$. Similar definitions apply for state b . Since we are interested in relaxation, and relaxation times are defined in terms of the time-dependent behavior of the nuclear magnetization when $\mathbf{B}_1 = 0$, the coupled differential equations that describe the effects of chemical exchange can be written as

$$\frac{d(M_{0a} - M_{za})}{dt} = -\alpha_{1a}(M_{0a} - M_{za}) + \frac{M_{0b} - M_{zb}}{\tau_b} \quad (8a)$$

$$\frac{d(M_{0b} - M_{zb})}{dt} = -\alpha_{1b}(M_{0b} - M_{zb}) + \frac{M_{0a} - M_{za}}{\tau_a} \quad (8b)$$

for longitudinal relaxation. For transverse relaxation, it is convenient to combine the M_x and M_y magnetizations into the transverse magnetization:

$$\frac{dM_{+a}}{dt} = -\alpha_{2a}M_{+a} + \frac{M_{+b}}{\tau_b} \quad (9a)$$

$$\frac{dM_{+b}}{dt} = -\alpha_{2b}M_{+b} + \frac{M_{+a}}{\tau_a} \quad (9b)$$

In these equations, we use the definitions

$$M_{+a} = M_{xa} + iM_{ya} \quad (10a)$$

$$\alpha_{1a} = \frac{1}{T_{1a}} + \frac{1}{\tau_a} \quad (10b)$$

$$\alpha_{2a} = \frac{1}{T_{2a}} + \frac{1}{\tau_a} - i(\omega_a - \omega) \quad (10c)$$

for state a . Similar definitions apply for state b . The principle of detailed balance requires that $M_{0a}/\tau_a = M_{0b}/\tau_b$.

Equations (8a,b) and (9a,b) represent two sets of two simultaneous differential equations of the form

$$\frac{dm}{dt} = -\alpha m + bn \quad (11a)$$

$$\frac{dn}{dt} = -\beta n + am \quad (11b)$$

The solutions of each of these sets of equations are⁵

$$m(t) = A_+ e^{-\phi_+ t} + A_- e^{-\phi_- t} \quad (12a)$$

$$n(t) = B_+ e^{-\phi_+ t} + B_- e^{-\phi_- t} \quad (12b)$$

where

$$2\phi_{\pm} = (\alpha + \beta) \pm [(\alpha - \beta)^2 + 4ab]^{1/2} \quad (13)$$

and $A_{\pm}$ and $B_{\pm}$ are related by

$$B_{\pm} = -(\phi_{\pm} - \alpha)A_{\pm}/b \quad (14)$$

The net magnetizations are given by the sum $m(t) + n(t)$. The integration constants $A_{\pm}$ and $B_{\pm}$ are determined by the values of m and n at time $t = 0$, with the aid of equation (13). These initial values of m and n are determined by the rf pulse flip angles and the nuclear magnetizations that exist when the pulse is applied.

These solutions to equation (11) fail⁵ mathematically when

$$(\alpha - \beta)^2 + 4ab = 0 \quad (15)$$

As shown later, this condition represents a point at which there is a change in behavior of the solutions when the Larmor frequencies are unequal. The appropriate solutions are

$$m(t) = \{A'[1 - \frac{1}{2}(\alpha - \beta)t] + bB't\} e^{-(\alpha+\beta)t/2} \quad (16a)$$

$$n(t) = \{B'[1 + \frac{1}{2}(\alpha - \beta)t] + aA't\} e^{-(\alpha+\beta)t/2} \quad (16b)$$

The integration constants A' and B' are also determined by the initial conditions.

4 RELAXATION FOR THE CASE OF EQUAL LARMOR FREQUENCIES

4.1 General Case

Here, we apply an rf pulse and examine the subsequent behavior of the longitudinal and transverse magnetization.

We define the relaxation curve as the time dependence of the deviation of the particular nuclear magnetization from its equilibrium value. When there is no chemical exchange and $\omega_a = \omega_b$, the NMR signal is the sum of signals from the 'uncoupled' sites, and the T_1 and T_2 relaxation curves are each the sum of two exponential functions whose preexponential coefficients and decay time constants are the intrinsic state populations and relaxation times, respectively. When chemical exchange occurs, we see from equations (12a) and (12b) that the NMR signal is *still* the sum of two exponential functions. For convenience, we designate state a as that with the longer relaxation time. The mathematical form of the T_1 and T_2 curves is

$$F(t) = P'_a \exp\left(-\frac{t}{T'_a}\right) + P'_b \exp\left(-\frac{t}{T'_b}\right) \quad (17)$$

where T' and P' signify the apparent relaxation times and population fractions, respectively. These quantities are related to the intrinsic values by the equations

$$\frac{1}{T'_a} = C_1 - C_2 \quad (18a)$$

$$\frac{1}{T'_b} = C_1 + C_2 \quad (18b)$$

$$P'_b = \frac{1}{2} - \frac{1}{4} \left[(P_b - P_a) \left(\frac{1}{T_a} - \frac{1}{T_b} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] / C_2 \quad (19a)$$

$$P'_a = 1 - P'_b \quad (19b)$$

in which

$$C_1 = \frac{1}{2} \left(\frac{1}{T_a} + \frac{1}{T_b} + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right) \quad (20a)$$

$$C_2 = \frac{1}{2} \left[\left(\frac{1}{T_b} - \frac{1}{T_a} + \frac{1}{\tau_b} - \frac{1}{\tau_a} \right)^2 + \frac{4}{\tau_a \tau_b} \right]^{1/2} \quad (20b)$$

Under all exchange conditions, the parameters in equation (17) obey the relationship

$$\frac{P'_a}{T'_a} + \frac{P'_b}{T'_b} = \frac{P_a}{T_a} + \frac{P_b}{T_b} = \frac{1}{T_m} \quad (21)$$

where T_m is defined as an effective mean relaxation time. This means that the initial slope of $F(t)$ in equation (17) is independent of the exchange rate between the two states—a consequence of the assumption that the inherent relaxation times are unaffected by chemical exchange. Other relationships that are useful in deriving simplified, approximate relationships for limiting cases are

$$P'_a + P'_b = P_a + P_b = 1 \quad (22)$$

$$P_a/\tau_a = P_b/\tau_b \quad (23)$$

4.2 Limiting Cases

Let us examine the case where $P_a \approx P_b$ and $T_a \gg T_b$ when the exchange rate is increased from small values. Initially, P'_a , P'_b , and T'_b are nearly equal to the inherent values, and

T_a' is decreased from T_a . With increasing exchange rate, T_a' continues to decrease, and can be completely different from T_a . When τ_b becomes of the same order of magnitude as T_b , T_b' decreases, P_b' becomes smaller than P_b , and T_a' continues to decrease. Finally, when τ_b is small compared with T_b , P_b' is very small, and the relaxation decay curve is approximately a single exponential with a relaxation time given by equation (21). Thus, exchange can cause the observed, or apparent, relaxation decay curve parameters to be completely different from the values inherent to the different types of sites.

There are several pertinent limiting cases⁶ that involve the relative values of the inherent relaxation times and the residence times.

When the exchange is very slow so that

$$\frac{1}{\tau_a} + \frac{1}{\tau_b} \ll \frac{1}{T_b} - \frac{1}{T_a} \quad (24)$$

the P_a' and P_b' values are very close to P_a and P_b ; however, the apparent relaxation times are decreased:

$$\frac{1}{T_a'} = \frac{1}{T_a} + \frac{1}{\tau_a} \quad (25a)$$

$$\frac{1}{T_b'} = \frac{1}{T_b} + \frac{1}{\tau_b} \quad (25b)$$

As the exchange rate increases, the values of T_a' and T_b' decrease and the value of P_a' increases. In the special case where the intrinsic relaxation times are very different and the lifetimes are intermediate,

$$T_b \ll \tau_a, \tau_b \ll T_a \quad (26)$$

the results are $P_a' = P_a$, $P_b' = P_b$, and

$$T_a' = \tau_a \quad (27a)$$

$$T_b' = T_b \quad (27b)$$

Clearly, this is a favorable case for the determination of lifetimes.

Finally, when the chemical exchange is very fast so that

$$\frac{1}{\tau_a} + \frac{1}{\tau_b} \gg \frac{1}{T_b} - \frac{1}{T_a} \quad (28)$$

the rapid exchange limit is obeyed in which a single average relaxation time is observed:

$$P_a' = 1 \quad (29)$$

$$T_a' = T_m \quad (30)$$

Another special case involves very different population fractions. When $T_b \ll T_a$ and $P_a \approx 1$ (which also means that $\tau_b \ll \tau_a$), the observable relaxation is approximately a single exponential with

$$\frac{1}{T_a'} = \frac{1}{T_a} + \frac{P_b}{P_a T_b + P_b \tau_a} \quad (31)$$

The observed relaxation time may bear no obvious relationship to that of type a sites. Even by changing the exchange rates by a large factor, such as by changing the temperature, the relaxation curve will not reveal that the system is two-site. The inherent relaxation times of the site types and the value of P_b might not be available from simple relaxation time measurements. This case applies, for example, to heterogeneous systems and biological materials that may have a small concentration of strongly relaxive sites, such as strong adsorption sites or paramagnetic centers. Note that if P_b is very small so that the b sites are widely spaced, τ_a may not be single valued, because the exchange will involve translational diffusion of the molecules of state a (see Section 8 of this article).

5 TRANSVERSE RELAXATION FOR THE CASE OF UNEQUAL LARMOR FREQUENCIES

5.1 General Case for the NMR Signal Following One Pulse

The effect of unequal Larmor frequencies is nonexistent for longitudinal relaxation, but transverse relaxation can be greatly increased. The following general solution⁵ of the set of equations given by equations (9a) and (9b) following the application of a pulse to a spin system at equilibrium is relatively simple because there is no transverse nuclear magnetism at the time of application of the pulse:

$$F_2(t) = \frac{M_+(t)}{M_0 \sin \theta_1} = P_{2+} e^{-(\phi_2+c)t} + P_{2-} e^{-(\phi_2-c)t} \quad (32)$$

where

$$P_{2+} = -(f + ig) e^{-idt} \quad (33)$$

$$P_{2-} = [f - i(1 - g)] e^{idt} \quad (34)$$

$$\phi_2 = \frac{1}{2} \left(\frac{1}{T_{2a}} + \frac{1}{T_{2b}} + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right) \quad (35)$$

$$f = -\frac{1}{4} \left\{ c(P_b - P_a)(\omega_a - \omega_b) + d \left[(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] \right\} (c^2 + d^2)^{-1} \quad (36)$$

$$g = \frac{1}{2} - \frac{1}{4} \left\{ c \left[(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] - d(P_b - P_a)(\omega_a - \omega_b) \right\} (c^2 + d^2)^{-1} \quad (37)$$

$$|c| = [(X^2 + Y^2)^{1/2} + X]^{1/2} / \sqrt{8} \quad (38)$$

$$|d| = [(X^2 + Y^2)^{1/2} - X]^{1/2} / \sqrt{8} \quad (39)$$

with

$$X = \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} + \frac{1}{\tau_a} - \frac{1}{\tau_b} \right)^2 - (\omega_a - \omega_b)^2 + \frac{4}{\tau_a \tau_b} \quad (40)$$

$$Y = -2(\omega_a - \omega_b) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} + \frac{1}{\tau_a} - \frac{1}{\tau_b} \right) \quad (41)$$

and θ_1 is the pulse flip angle. The algebraic sign of d is always positive; the sign of c is positive except for negative Y values. The value of ω is $\frac{1}{2}(\omega_a + \omega_b)$.

This function is even more complicated than the case of equal Larmor frequencies, and examination of limiting cases is necessary to show the effects of the Larmor frequency difference on transverse relaxation. When the exchange is slow so that the term $4/\tau_a\tau_b$ in equation (40) can be neglected, $d = \frac{1}{2}|\omega_a - \omega_b|$, $f \approx 0$, $g = P_b$, and $c = \pm \frac{1}{2}(1/T_{2b} - 1/T_{2a} + 1/\tau_b - 1/\tau_a)$. The upper algebraic sign applies when $\omega_a > \omega_b$, and the lower when $\omega_a < \omega_b$. Equation (32) then becomes

$$F_2(t) \approx -i \left\{ P_a \exp\left[\frac{1}{2}i(\omega_a - \omega_b)t\right] \exp\left[-\left(\frac{1}{T_{2a}} + \frac{1}{\tau_a}\right)t\right] + P_b \exp\left[-\frac{1}{2}i(\omega_a - \omega_b)t\right] \exp\left[-\left(\frac{1}{T_{2b}} + \frac{1}{\tau_b}\right)t\right] \right\} \quad (42)$$

Equation (42) is the sum of the two transverse magnetizations with separate frequencies, because d is not equal to zero. The decay rate of each signal increases (see **Chemical Exchange Effects on Spectra**) with increasing exchange rate, as in equations (25a) and (25b) for equal Larmor frequencies, but it is insensitive to the difference between the Larmor frequencies. This may be expected, since a nucleus that enters a state from the other state has a random phase because it has existed in the former state for many periods of the frequency difference $\omega_a - \omega_b$. When the exchange rate increases, the amount of dephasing per transfer becomes dependent on the Larmor frequency difference.

The terms e^{-idt} and e^{idt} in equations (33) and (34) represent two different nuclear magnetizations rotating at frequencies that differ by $2d$. At very slow exchange rates, as shown above, the frequency difference is $\omega_a - \omega_b$. With increasing exchange rates, as examination of equation (39) reveals, the value of $2d$ decreases. The peaks in the NMR spectrum approach each other (see **Chemical Exchange Effects on Spectra**). In general, the value of d never becomes zero, even at extremely high exchange rates such that $4/\tau_a\tau_b \gg (\omega_a - \omega_b)^2$. This means that, rigorously, there is *some* splitting in the NMR spectrum and that the NMR signal following a pulse *cannot* be a simple sum of two exponential decays when there is a difference in Larmor frequencies.

The above conclusion holds even in the specific case where $d = 0$. Examination of equations (38)–(41) shows that $d = 0$ when $1/T_{2a} - 1/T_{2b} + 1/\tau_a - 1/\tau_b = 0$. When the additional condition $(\omega_a - \omega_b)^2 = 4/\tau_a\tau_b$ holds, the special case in equation (15) holds, and the relatively simple solutions in equations (16a) and (16b) describe the NMR signal. This signal is

$$F_2(t) = -\frac{1}{2}(P_b - P_a)(\omega_a - \omega_b)t e^{-\phi_2 t} - i \left[1 + \frac{1}{2}(P_b - P_a) \times \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) t + \frac{1}{2} \left(\frac{1}{\tau_a} + \frac{1}{\tau_b} \right) t \right] e^{-\phi_2 t} \quad (43)$$

Clearly, this is not a simple exponential decay.

When the exchange rate is very large so that the conditions $1/\tau_a, 1/\tau_b \gg 1/T_{2a}, 1/T_{2b}$, $|(\omega_a - \omega_b)|$ and

$(\omega_a - \omega_b)^2 \gg (1/T_{2a} - 1/T_{2b})^2$ prevail, $F_2(t)$ is closely approximated by

$$F_2(t) = \sin(\omega_{av}t) e^{-t/T_2} \quad (44)$$

where

$$\omega_{av} = P_a\omega_a + P_b\omega_b \quad (45)$$

$$\frac{1}{T_2} = \frac{1}{T_m} + \frac{P_a P_b \tau_a \tau_b}{\tau_a + \tau_b} (\omega_a - \omega_b)^2 \quad (46)$$

This expression shows that the difference in Larmor frequencies enhances the transverse relaxation when the chemical exchange is fast. As the exchange rate increases to extremely large values, the observed T_2 value approaches T_m , the relaxation time when the Larmor frequencies are equal.

5.2 General Case for the NMR Signal Following Two

Pulses

As usual, the NMR signal following the second pulse, applied at time $t = \tau$, is the sum⁵ of three signals. The first signal results from the M_z component of magnetization that exists at the time of application of the second pulse. It is given by

$$\frac{M_+(t)\tau}{M_0 \sin \theta_2 [1 - (1 - \cos \theta_1)]} = F(T_1, \tau) F_2(t)\tau \quad (47)$$

where $F(T_1, \tau)$ is equation (17) evaluated at time τ for T_1 , and $F_2(t > \tau)$ is equation (32) evaluated as a function of the time after the second pulse, $t > \tau$.

The other two signals result from the transverse magnetization that exists at the time of application of the second pulse. The first is the reduced continuation of the signal following the first pulse as follows:

$$\frac{M_+(t)}{\frac{1}{2}M_0 \sin \theta_1 (1 + \cos \theta_2)} = F_2(t) \quad (48)$$

where $F_2(t)$ is given by equation (32).

The other signal is the spin echo that can be found by using the complex conjugate of the one-pulse signal evaluated at time τ as the initial condition for the signal following the second (a 180°) pulse:

$$\begin{aligned} E(t) &= \frac{M_+(t)}{-\frac{1}{2}M_0 \sin \theta_1 (1 - \cos \theta_2)} \\ &= P_{E+} e^{-(\phi_2+c)t} + P_{E-} e^{-(\phi_2-c)t} \\ &\quad + [2[f \cos dt + (g+j) \sin dt] \sinh[c(t-2\tau)] \\ &\quad + 2i[f \sin dt - (g+j) \cos dt] \cosh[c(t-2\tau)]] \\ &\quad \times e^{-\phi_2 t} \end{aligned} \quad (49)$$

where

$$P_{E+} = ij e^{-id(t-2\tau)} \quad (50a)$$

$$P_{E-} = i(2g+j-1) e^{id(t-2\tau)} \quad (50b)$$

with

$$j = \frac{1}{2} - g - \frac{1}{2} \frac{c^2 + \frac{1}{4}(\omega_a - \omega_b)^2}{c^2 + d^2} \quad (51)$$

The dependences of terms in equation (49) on the quantity $t - 2\tau$ clearly show the refocusing action of the second pulse on the attenuation of the signal following the first pulse that is caused by the difference in Larmor frequencies. When the exchange rates and the Larmor frequency differences are comparable, the use of equations (16a) and (16b) shows that the spin echo signal is

$$E(t) = \frac{1}{2}(P_b - P_a)(\omega_a - \omega_b)(t - 2\tau)e^{-\phi_2 t} + i \left[1 + \frac{1}{2}(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) t + \frac{1}{2} \left(\frac{1}{\tau_a} + \frac{1}{\tau_b} \right) t + \frac{1}{2}(\omega_a - \omega_b)^2 \tau(t - \tau) \right] e^{-\phi_2 t} \quad (52)$$

When $P_a = P_b$, comparison of equation (52) with equation (43) shows that at the time of the peak of the spin echo, $t = 2\tau$, the spin echo signal is greater than the signal from a single pulse. This refocusing phenomenon is qualitatively similar to that for the spin echoes of molecules that diffuse into different values of B_0 . Aside from a different statistical problem, the main difference here is that the precession frequency is restricted to two values; in molecular diffusion, a range of values is available to each nucleus.

Transverse relaxation is easily measured from the dependence of the spin echo amplitude at time $t = 2\tau$ determined as a function of 2τ . At very small chemical exchange rates, the Larmor frequency difference has a negligible effect on the transverse relaxation. With increasing exchange rates, the nucleus alternately experiences two different precession frequencies for random periods of time, causing a contribution to transverse relaxation by dephasing of the NMR signal. This dephasing passes through a maximum when the exchange rate and the Larmor frequency difference are comparable. Then, with increasing exchange rates, the transverse relaxation contribution from the frequency difference decreases, and is given by equation (46) when the exchange rates are large compared with the frequency difference. In the intermediate range, the spin echo time dependence is significantly modulated, and is not approximated by a sum of two exponential decays. We can readily see this from the sine and cosine terms in the time dependence of the spin echo amplitude by writing equation (49) at time $t = 2\tau$:

$$E(2\tau) = i \left[j e^{-ct} + (2g + j - 1) e^{ct} + 2f \sin dt - 2(g + j) \cos dt \right] e^{-\phi_2 t} \quad (53)$$

For zero exchange rate, $f = 0$ and $g + j = 0$; the magnitudes of these quantities increase with increasing exchange rate, become greatest when $\frac{1}{2}\pi(1/\tau_a + 1/\tau_b) \approx |\omega_a - \omega_b|$, decrease with further increase in exchange rate, and approach zero as the exchange rates approach infinity. Also, when the exchange rate is large compared with the Larmor frequency difference, the spin echo amplitude closely approximates an exponential decay with a T_2 value given by equation (46). Calculations⁵ of the decay curves show that when $T_{2a}, T_{2b} \approx \infty$, the shapes are closely approximated by exponential decays under the

condition $|\omega_a - \omega_b| \ll 1/\tau_a, 1/\tau_b$. In the intermediate range of $1/\tau_a$ and $1/\tau_b$ values, the decay curves are not exponential, and are modulated. If we define T_{2E}^* as the time required for the curve to decay from its initial value at $t = 0$ to $1/e$ of this value, T_{2E}^* passes through a minimum when $\frac{1}{2}\pi(1/\tau_a + 1/\tau_b) \approx |\omega_a - \omega_b|$.

5.3 The Spin Echo Amplitudes in Carr–Purcell Pulse Sequences

The spin echo for the special mathematical case, equation (52), when evaluated at time $t = 2\tau$ and compared with the single pulse signal, includes the extra term $(\omega_a - \omega_b)^2 \tau^2$; this suggests that the contribution of the Larmor frequency difference to the transverse relaxation can be eliminated by using the Carr–Purcell sequence with sufficiently small pulse separations. The effect of each 180° pulse in the sequence can be calculated by using the complex conjugate of the transverse magnetization at the time of the pulse as the initial condition for the solutions, equations (12a) and (12b), of equations (11a) and (11b) for the time after the pulse. We might expect that the plot of the peak spin echo amplitudes is a sum of two exponential decays or, one exponential when the exchange rates are rapid. Much theoretical work has been done for various cases to obtain exchange rates from Carr–Purcell sequences,^{7–9} and complete solutions for the two-site case are available.^{8,9} Generally, computer-assisted calculations are needed to analyze experimental data. From the complex preexponential coefficients, we may anticipate that alternations in echo amplitudes could occur along the pulse sequence, especially in cases where the exchange rates and the Larmor frequency differences are of the same order of magnitude. The early echoes observed in Carr–Purcell sequences frequently show amplitude alternations. This behavior may be related to the alternations in consecutive spin echo amplitudes for powder pattern distributions of Larmor frequencies, calculated in Section 6.2.1 of this article. These alternations die away with a time constant that is comparable to the reciprocal of the exchange rate. The shift of the peak of the first echo, and presumably other odd-numbered echoes, to ‘short’ times may also be related to this.

6 ‘MULTIPLE SITE’ CHEMICAL EXCHANGE AND TRANSVERSE RELAXATION

6.1 Gaussian Frequency Distribution

The mathematical treatment of the general multiple-site case is extremely complicated. However, the case of a continuous Gaussian distribution¹⁰ of Larmor frequencies ω_j is tractable mathematically and computationally. The results parallel those of the two-site case and are instructive. If the nucleus exchanges among the ω_j values so that the covariance function

$$\langle \Delta\omega(t) \Delta\omega(t + \tau) \rangle = \langle \Delta\omega(t)^2 \rangle e^{-\tau/\tau_c} \quad (54)$$

is obeyed then the decay curve following a single pulse is

$$F_2(t) = \exp \left[-\sigma^2 \tau_c^2 \left(e^{-t/\tau_c} + \frac{t}{\tau_c} - 1 \right) \right] \quad (55)$$

where σ is the rms value of $\Delta\omega = \omega_j - \omega_0$ and τ_e is an exchange time. The signal following the second pulse that is applied at time $t = \tau$ is

$$F_2(t)\tau = \exp \left[-\sigma^2 \tau_e^2 \left(\frac{t}{\tau_e} - 3 - e^{-t/\tau_e} + 2e^{-\tau/\tau_e} + 2e^{-(t-\tau)/\tau_e} \right) \right] \quad (56)$$

and the maximum value of this signal occurs at time

$$t_m = \tau_e [\ln(2e^{\tau/\tau_e} - 1)] \quad (57)$$

Equation (57) shows that $t_m < 2\tau$. For very slow exchange, t_m is nearly equal to 2τ . However, $t_m = 1.4899\tau$ when $\tau_e = \tau$; this is a large shift from the expected value, 2τ . The conventional spin echo amplitude curve is given by equation (56) evaluated at time $t = 2\tau$:

$$E(2\tau) = \exp \left[-\sigma^2 \tau_e^2 \left(\frac{2\tau}{\tau_e} - 3 - e^{-2\tau/\tau_e} + 4e^{-\tau/\tau_e} \right) \right] \quad (58)$$

We can examine the time dependences of these functions by defining T_2^* as the time required for equation (55) to decay from its initial value at $t = 0$ to 1/e of this value, and T_{2E}^* as the comparable quantity for equation (58). When the exchange rate is fast (i.e., $\sigma\tau_e \ll 1$), both of the above curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \sigma^2 \tau_e \quad (59)$$

This result agrees with equation (46) for the two-site case. Also, in qualitative agreement with the two-site case, with changing exchange rate, T_{2E}^* passes through a minimum at $\sigma\tau_e \approx 1$. With decreasing exchange rate, the decay curve $E(2\tau)$ becomes

$$E(2\tau) \approx \exp \left(-\frac{2}{3} \frac{\sigma^2 \tau^3}{\tau_e} \right) \quad (60)$$

below the T_{2E}^* minimum. However, equation (60) shows that T_{2E}^* becomes equal to $(12\tau_e/\sigma^2)^{1/3}$ instead of the value τ_e that is found in the two-site case. This dependence of the attenuation of the spin echo amplitude on τ^3 is analogous to that of nuclei diffusing¹¹ in a gradient in B_0 (see *Diffusion Measurements by Magnetic Field Gradient Methods*). When a molecule diffuses, there is a Gaussian probability distribution of changes in Larmor frequency; the width of this distribution increases in time. Also, with decreasing exchange rate, T_2^* monotonically decreases and asymptotically approaches the constant value $\sigma^{-1}\sqrt{2}$.

6.2 Powder Pattern Frequency Distribution

6.2.1 'Rotational Diffusion' Site Exchange

A logical choice for ω_j values is that which appears in NMR magnetic dipolar splitting and nuclear quadrupolar splitting:

$$\omega_j = C(3 \cos^2 \theta_j - 1) \quad (61)$$

in which C is the splitting constant. For a 'powder' sample, the values of P_j are directly proportional to $\sin \theta_j$ and the number of different sites is very large. The resultant mean square value of ω_j is $\frac{4}{5}C^2$.

The rotational diffusion case¹² allows direct exchanges only between sites with adjacent θ values and thus between adjacent frequencies. The signal following one pulse can be computed¹² by solving the differential equation

$$\begin{aligned} \frac{\partial A}{\partial t} = & (6\tau_e)^{-1} \cot \theta \frac{\partial A}{\partial \theta} + (6\tau_e)^{-1} \frac{\partial^2 A}{\partial \theta^2} \\ & + iC(3 \cos^2 \theta - 1) \end{aligned} \quad (62)$$

as a function of time using the initial condition $A_j(0, \theta_j) = P_j$. The NMR signal following the second pulse is computed by using the complex conjugate $A_j^*(\tau, \theta_j)$ as the initial condition for equation (62). As in the Gaussian case, T_2^* is the time at which the signal following one pulse has 1/e times the value at time $t = 0$; T_{2E}^* is the value of 2τ at which the NMR signal following the second pulse has 1/e times the value at $2\tau = 0$. When the exchange is fast (i.e., $C\tau_e \ll 1$), both the T_2 and T_{2E} curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \frac{4}{5}C^2\tau_e \quad (63)$$

in agreement with equation (46) for the two-site case and equation (59) for the Gaussian case. Also in agreement with these cases, with decreasing exchange rate, T_{2E}^* passes through a minimum at $(\frac{4}{5})^{1/2}C\tau_e \approx 1$. With further decreases in exchange rate, the spin echo amplitude asymptotically approaches

$$E(2\tau) \approx \exp \left(-\frac{8}{15} \frac{C^2 \tau^3}{\tau_e} \right) \quad (64)$$

so that T_{2E}^* becomes equal to $(15\tau_e/C^2)^{1/3}$. Simultaneously, T_2^* decreases monotonically and approaches the constant value $T_2^* = 1.46/C$.

The computed NMR signals in multiple pulse sequences¹² show several interesting features. When pulses are applied at times $t = 0, \tau, 3\tau, 5\tau$, etc., the amplitudes calculated at times $2\tau, 4\tau, 6\tau$, etc., increase when the number of pulses per unit time increases. The result is analogous to that for liquid molecules diffusing in a magnetic field gradient.¹¹ In addition, the odd-numbered spin echoes in a given multipulse sequence, calculated at the above times, are of smaller amplitude than the even-numbered echoes. This amplitude alternation decreases with succeeding spin echoes. The time constant for this decay appears to be equal to τ_e . An alternation of spin echo amplitudes in multiple pulse sequences is also predicted and observed¹¹ for liquid molecules flowing in a magnetic field gradient (see *Diffusion and Flow in Fluids*).

Also, as calculation of the NMR signal shapes for three pulses shows, this formalism predicts that the peak of the first spin echo, as in the Gaussian case, is shifted to times shorter than 2τ . This shift appears to be given approximately by equation (57), which was derived for the Gaussian case.

However, the peak value of the calculated second spin echo appears at the expected time, $t = 4\tau$. This predicted shift of the first echo peak but not of the second is indeed observed experimentally^{12,13} in aqueous heterogeneous systems.

6.2.2 Random Site Exchange

We can predict the NMR behavior of systems with other chemical exchange dynamics¹⁴ by generalizing equations (11a) and (11b) to allow direct exchange among many types of sites that are characterized by different frequencies. To emphasize the contribution of the Larmor frequency distribution to transverse relaxation, we set the T_2 values in equation (10c) equal to infinity.

The total transverse magnetization of a system of N types of sites is

$$M_+(t) = iM_0 \sum_{j=1}^N P_j A_j(t, \omega) \quad (65)$$

where P_j is the occupation probability of sites of type j normalized so that

$$\sum_{j=1}^N P_j = 1 \quad (66)$$

We express the time dependences of the A_j by the set of N coupled differential rate equations

$$\frac{\partial A_j}{\partial t} = i\omega_j - \frac{A_j}{\tau_j} + \sum_{\substack{k=1 \\ k \neq j}}^N \frac{A_k}{\tau_{kj}}, \quad j = 1, 2, \dots, N \quad (67)$$

where ω_j is the difference frequency (compared with the average frequency) for j -type sites, τ_j is the average lifetime of a nucleus in j -type sites, and $1/\tau_{kj}$ is the average rate at which nuclei in k -type sites move to j -type sites.

To solve the set of N equations in equation (67), we must specify the frequencies (ω_j values), occupation probabilities (P_j values), and exchange probabilities (τ_j and τ_{kj} values). We choose the powder pattern frequencies as described by equation (61) and P_j values that are directly proportional to $\sin \theta_j$. The exchange probabilities implicit in the preceding sections of this article represent one extreme case. The opposite extreme case is to allow direct exchanges between sites of all the different frequencies. This case more closely corresponds to the two-site case in that the individual exchange events can involve large changes in Larmor frequency. To set up the exchange probabilities, we use the principle of detailed balance, which requires that the total number of exchanges per second between sites j and k is directly proportional to the product $P_j P_k$. Then, if we define $1/\tau_e$ as the average rate for nuclei to leave the sites that they occupy, we obtain

$$\frac{1}{\tau_j} = V \sum_{\substack{k=1 \\ k \neq j}}^N P_k = V(1 - P_j) \quad (68)$$

$$\frac{1}{\tau_{kj}} = V P_j \quad (69)$$

where

$$V = \left[\tau_e \left(1 - \sum_{j=1}^N P_j^2 \right) \right]^{-1} \quad (70)$$

When N is very large, $V = 1/\tau_e$.

The signal following one pulse¹⁴ can be calculated by solving equation (67) as a function of time using the initial condition $A_j(0, \omega_j) = P_j$. The T_{2E} curves¹³ can be computed by using the complex conjugate $A_j^*(\tau, \omega_j)$ as the initial condition after the second pulse in evaluating the signal at time τ after the second pulse. When the exchange is fast (i.e., $C\tau_e \ll 1$), both the T_2 and T_{2E} curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \frac{4}{5} C^2 \tau_e \quad (71)$$

in agreement with equation (46) for the two-site case and with the Gaussian and rotational diffusion cases. Also in agreement with the two-site case, with decreasing exchange rate, T_{2E}^* passes through a minimum at $(\frac{4}{5})^{1/2} C\tau_e \approx 1$ and approaches τ_e when $C\tau_e \gg 1$. This result represents a much stronger dependence of the spin echo attenuation on exchange rate than in the Gaussian and rotational diffusion cases. Simultaneously, T_2^* decreases monotonically and approaches the constant value $T_2^* = 1.46/C$.

In calculations of the NMR signals for the three-pulse case, the peak of the first spin echo is shifted to times smaller than 2τ , while the second echo peak remains at time 4τ . The shapes of the signals and the effects of changes in exchange rates differ between the present case and the preceding cases, and measurements of them allow us to determine which case better describes the sample under consideration.

7 PREFERENTIAL ORIENTATION, EXCHANGE, AND ORDER IN AQUEOUS HETEROGENEOUS SYSTEMS

In aqueous heterogeneous systems^{14,15} such as biological tissue, biopolymer gels, polyelectrolyte solutions, clay–water gels, etc., the water molecule or a hydrated ion such as sodium can be located in the bulk liquid or at the solid/liquid interface. The nonspherical bonding and electric charge distribution (electric dipole and quadrupole moments) strongly affect the motions and arrangements of water molecules at the interface. When a water molecule is at the solid surface, its motion is slowed down, and some orientations with respect to the local surface plane are more probable than others. This preferential orientation due to the nonspherical interaction causes different rotational rates about different molecular axes. The structure of the interfacial water is different from that of bulk water because this water interacts differently with the relatively immobile solid material compared to other rapidly moving water molecules. At each allowed molecular orientation at the surface, there is a different magnetic dipolar interaction of the protons (H_2O) or nuclear quadrupolar interaction of the deuterons (D_2O). The water molecules not only occupy the various site environments at the interface, but they migrate

among them and also into the bulk liquid away from the interface. This rapid chemical exchange enables all of the water molecules to experience the interfacial environment. Consequently, the spectral densities $J_h(\omega)$ that determine NMR relaxation phenomena are influenced by the effects on the correlation functions caused by the motions and local structure of the interface and the exchange between the bulk and interfacial sites.

The correlation functions of the water in such a heterogeneous system can be written¹⁴ as the sum over the different j environments:

$$\langle F_h(t)F_h^*(t+\tau) \rangle = \sum_j P_j \langle F_{hj}(t)F_{hj}^*(t+\tau) \rangle \quad (72)$$

where the sum of the occupation probabilities P_j is unity. We now assume, with good evidence, that all local permitted molecular reorientations and all local chemical exchange rates are rapid compared with the Larmor frequency ω_0 . Then, at times τ that are long compared with $1/\omega_0$, nuclei that were in a given j at time t are now distributed among all the different j sites in accordance with P_j , and $\langle F_{hj}^*(t+\infty) \rangle = \langle F_h^*(t) \rangle$. Also, for each of these nuclei, the value of $F_{hj}^*(t+\infty)$ is independent of the value of the original $F_{hj}(t)$, and equation (72) can be written as

$$\begin{aligned} \langle F_h(t)F_h^*(t+\infty) \rangle &= \langle F_h(t) \langle F_h^*(t+\infty) \rangle \rangle \\ &= \langle F_h(t) \rangle \langle F_h^*(t+\infty) \rangle \\ &= \langle F_h(t) \rangle \langle F_h^*(t) \rangle \end{aligned} \quad (73)$$

In a bulk liquid, the values of $\langle F_h(t) \rangle$ and $\langle F_h^*(t+\infty) \rangle$ at such long times are zero. However, preferential molecular orientation at the interface can result in nonzero values.

Let us temporarily assume that the surface is an infinite plane, so that the interface is planar. The orientation of the interface in $\mathbf{B}_0$ is defined by the 'director', which is normal to the surface. For simplicity, let the molecular orientation distribution be axially symmetric about the director. If the orientation of the director in $\mathbf{B}_0$ is given by the polar and azimuthal angles θ' and ϕ' , and the orientation of the nuclear spin interaction vector with respect to the director is given by the polar and azimuthal angles θ'' and ϕ'' , then $\langle F_0(t) \rangle = \langle 3 \cos^2 \theta - 1 \rangle$ is given by

$$\langle 3 \cos^2 \theta - 1 \rangle = \frac{1}{2} (3 \cos^2 \theta' - 1) (3 \cos^2 \theta'' - 1) \quad (74)$$

The last term on the right-hand side of equation (74) expresses the preferential orientation. The correlation function is then given by

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle &= \langle F_h(t)F_h^*(t) \rangle \\ &\times \left(P_p e^{-\tau/\tau_{cp}} + \sum_{j=1}^{p-1} P_j e^{-\tau/\tau_{cj}} \right) \end{aligned} \quad (75)$$

where

$$P_p + \sum_{j=1}^{p-1} P_j = 1 \quad (76a)$$

$$P_p = \frac{\frac{1}{4} (3 \cos^2 \theta' - 1)^2 (3 \cos^2 \theta'' - 1)^2_{av}}{\langle F_0(t)F_0^*(t) \rangle} \quad (76b)$$

The τ_{cj} are short correlation times that result from the rapid molecular motions, including exchange. The correlation time associated with the preferential orientation, τ_{cp} , is infinite in the present case.

When τ_{cp} is extremely long, its contributions to $J_1(\omega_0)$ and $J_2(2\omega_0)$ in the relaxation times given in equations (4a) and (4b) are extremely small and can be neglected. However, the $J_0(0)$ term in equation (4b) is incorrect, and the contribution of the terms that involve τ_{cp} to transverse relaxation must be calculated differently. The term $3 \cos^2 \theta - 1$ in equation (74) is $F_0(t)$, and a nonzero average value causes a residual magnetic dipolar or nuclear quadrupolar splitting in the NMR spectrum due to the preferential orientation. From equation (61), this residual splitting is

$$\omega' = \frac{1}{2} C (3 \cos^2 \theta' - 1) (3 \cos^2 \theta'' - 1) \quad (77)$$

where C is the splitting constant for a stationary molecule. At any instant of time, a certain number of water molecules are preferentially oriented by the interface, so that these molecules have a certain nonzero value of $\langle 3 \cos^2 \theta'' - 1 \rangle$ and the remainder of the molecules has a zero value for this quantity. We assume that the value of $\langle 3 \cos^2 \theta'' - 1 \rangle$ for the instantaneously preferentially oriented water molecules and the number of these molecules are independent of the number of other water molecules. When rapid exchange between these two environments occurs, all of the water experiences preferential orientation, as referred to the director, for a fraction F of the time. The value of F is the fraction of the water molecules at any instant that is preferentially oriented, and the value of ω' is

$$\omega' = C' (3 \cos^2 \theta' - 1) \quad (78)$$

where

$$C' = \frac{1}{2} F C (3 \cos^2 \theta'' - 1) \quad (79)$$

The effective splitting constant C' depends on the surface-to-volume ratio of the water.

In addition to the surface-to-volume ratio, the value of C' depends on the geometry of the surface. If the surface is that of the circumference of a cylinder and if rapid exchange occurs over all of the surface of the cylinder, the value of C' is one-half of that for the same surface on a plane, and the direction of the director is along the axis of the cylinder.

A system that contains many parallel planes or cylinders with uniform distribution of water will have a doublet NMR spectrum with a splitting that varies as $3 \cos^2 \theta' - 1$. This is observed in many ordered systems such as water distributed among parallel fibers, water among parallel smectite clay platelets (smectite clay minerals are comprised of 1 nm thick aluminosilicate sheets that are many micrometers or even millimeters in length and width), and lyotropic liquid crystals.

The doublet splitting constant depends on the degree of order in the system. If the system has a large number of cylinders that are not parallel and if rapid exchange occurs among all of them, the value of C' is reduced¹⁶ by this disorder as described by the second-rank order parameter

$$S = \frac{1}{2} (3 \langle \cos^2 \theta_{C1C2} \rangle - 1) \quad (80)$$

where θ_{C1C2} is the angle between the axes of a pair of cylinders C1 and C2. When all the cylinders are parallel, $S = 1$ and the splitting constant is maximum. However, if the cylinders are randomly oriented (i.e., a powder), $S = 0$ and there is no spectral splitting. A similar statement applies to a system of sheets.

The above illustration describes the extreme case of rapid exchange and local disorder. Another case is local order and global disorder as occurs with a powder made of crystallites. A crystallite may be a domain in which there is perfect order. If the molecules are constrained in individual domains, the NMR signal is the superposition of the signals of all the domains, i.e., a powder pattern. This signal will be changed if molecules are exchanged among the domains with different orientations in B_0 . This exchange will affect the transverse relaxation, and the methods described in Section 6 of this article can be used to calculate the NMR signals for various assumed models of order/disorder. In these calculations, the ω_j values are given by equations (78) and (79). If there is less than perfect order in the domains or if the degree of order is changed, the splitting constant must be reduced by the factor in equation (80). Also, if the water content is changed, the splitting constant is changed in accordance with equation (79). The exchange lifetime τ_e will depend on the size of a domain and on the diffusion coefficient of the water. Changes in the domain size or internal order caused by purely physical treatment of the sample, without any change in chemical composition, will cause changes in the transverse NMR relaxation behavior.

These phenomena are observed in deuterium NMR measurements on aqueous biopolymer gels¹⁷ and clay-water systems.^{13,14} Values of τ_e are obtained by using the methods of Section 6 to analyze the data, and the splitting constants and the domain sizes are found. Also, when a hydrated ion such as sodium is at an interface, the distortion of the hydration atmosphere causes a nuclear quadrupolar coupling that is described by a quadrupolar coupling constant and the orientation of the director. The transverse relaxation of sodium in linear polyelectrolyte solutions is quantitatively explained¹⁶ by the scheme described above for the NMR signals of water.

8 EFFECTS OF DIFFUSIVE EXCHANGE IN HETEROGENEOUS SYSTEMS

In the preceding sections, chemical exchange has been modeled so that all nuclei in a given site environment have the same time-independent exchange or transition probability to move to different environments. However, this picture fails to describe completely the spatial aspects of the exchange process.¹⁸⁻²⁰ For example, consider the case of water in heterogeneous and biological systems. The probability per unit time that a given molecule in the interface leaves the interface may be the same for all the interfacial molecules. An interfacial molecule exchanges places with a neighboring bulk water molecule, and the interface is only a molecular layer or two in thickness. Therefore, when the bulk water is many molecular diameters in thickness, the lifetime in the bulk for a molecule that is next to the interface can be much shorter than that of a molecule that is many molecular diameters away from the interface. In order for the latter molecule to be able to exchange with the interface, it first must diffuse to the interface, taking

some time and lowering its effective exchange rate. This is not a simple diffusion problem, because the mobility of water molecules in the interface is less than that in the bulk. Also, because of proximity, a molecule that has just left the interface is likely to reenter¹⁸ the interface before a molecule away from the interface has a chance to enter the interface. The exchange rate of such molecules is thus enhanced. This can lead to some relaxation behavior that is qualitatively different from the simple exchange picture.¹⁸ Also, the occupation probability for a diffusing molecule to occupy a given volume of space is a sum of exponential decays. However, the major term of this probability is generally a single exponential. Thus, the simple exchange view provides a convenient framework that is adequate, in most cases, to formulate the effects of molecular migration on NMR relaxation and interpret experimental results.

1 INTRODUCTION

The concept of magnetization modes is related to longitudinal relaxation (spin–lattice relaxation) of weakly coupled spin- $\frac{1}{2}$ systems, possibly including subsets of magnetically equivalent nuclei. They are useful in two respects:

1. they can be easily associated with observable quantities;
2. they lead to simplifications (factorization) in the kinetic equations describing the evolution of the system under longitudinal relaxation.

Magnetization modes were introduced in 1975 by Werbelow and Grant¹ in the context of ^{13}C relaxation studies of methine, methylene, and methyl moieties, and were discussed thoroughly by these authors in a review article published in 1977.² An attempt to rationalize the construction procedures of magnetization modes as well as their evolution and detection features was provided in an article by Canet in 1989.³ Grant and colleagues⁴ published in 1991 a review about relaxation of coupled nuclear spins and molecular motions in liquids, with emphasis on magnetization modes in the $^{13}\text{CH}_2$ grouping. Finally, magnetization modes have been generalized into ‘magnetization transfer modes’,⁵ which are adapted to selective two-dimensional experiments of the NOESY type.

For the sake of clarity and simplicity, two simple spin- $\frac{1}{2}$ systems will be discussed here in some detail, namely the AX spin system (two weakly J -coupled spins) and the AX₂ spin system (a spin A weakly J -coupled with two magnetically equivalent spins X and X'). An isotropic medium (liquid state) will be assumed most of the time, although molecules partially oriented in liquid crystal matrices will be alluded to in some instances.⁶ Let us first recall that it is a common practice to describe the evolution of the longitudinal magnetization (denoted by $\langle \hat{I}_z \rangle$, the angular brackets specifying the expectation value of the operator $\hat{I}_z$) by means of the Bloch equation

$$\frac{d\langle \hat{I}_z \rangle}{dt} = -R_1(\langle \hat{I}_z \rangle - I_{\text{eq}}) \quad (1)$$

where R_1 is the longitudinal relaxation rate (the inverse of the longitudinal relaxation time T_1) and I_{eq} the equilibrium magnetization. Equation (1) implies a monoexponential recovery, and, although it may often represent a very good approximation, it is strictly valid for a single spin- $\frac{1}{2}$ subjected to randomly fluctuating magnetic fields (as far as spins $\frac{1}{2}$ are considered). As soon as the system includes two spin- $\frac{1}{2}$ nuclei, A and X, mutually interacting by dipolar coupling (the latter being modulated by molecular reorientation and being zero on average), the relevant longitudinal magnetizations no longer exhibit monoexponential recoveries, and their evolution is governed by the Solomon equations

$$\left. \begin{aligned} \frac{d\langle \hat{I}_{A,z} \rangle}{dt} &= -R_1^A(\langle \hat{I}_{A,z} \rangle - I_{A,\text{eq}}) - \sigma_{AX}(\langle \hat{I}_{X,z} \rangle - I_{X,\text{eq}}) \\ \frac{d\langle \hat{I}_{X,z} \rangle}{dt} &= -R_1^X(\langle \hat{I}_{X,z} \rangle - I_{X,\text{eq}}) - \sigma_{AX}(\langle \hat{I}_{A,z} \rangle - I_{A,\text{eq}}) \end{aligned} \right\} \quad (2)$$

where, in addition to the specific relaxation rates R_1^A and R_1^X , there exists a coupling term σ_{AX} , known as the cross-relaxation rate. These three rates can be expressed in terms of structural and motional parameters as explained below. Although, as will be seen later, equation (2) do not fully account for longitudinal relaxation in a two-spin system, the two quantities $\langle \hat{I}_{A,z} \rangle - I_{A,\text{eq}}$ and $\langle \hat{I}_{X,z} \rangle - I_{X,\text{eq}}$ are what will be called magnetization modes. This is because A and X are supposed to be weakly coupled, meaning that the observables (transitions) belong unambiguously either to A or to X and that it is possible by appropriate read pulses to monitor either $\langle \hat{I}_{A,z} \rangle$ or $\langle \hat{I}_{X,z} \rangle$.

In spite of the evident biexponential character of the evolutions implied by equation (2), a familiar exception must be mentioned, concerning the evolution of longitudinal magnetization of spin A (e.g., ^{13}C) while spin X (e.g., ^1H) is irradiated continuously for decoupling purposes. The second of equation (2) ceases to be valid, since the driving term of the decoupling field should be added. Anyhow, the fact that X is completely saturated can be accounted for in the first of these equations by putting $\langle \hat{I}_{X,z} \rangle \equiv 0$. The monoexponential behavior of $\langle \hat{I}_{A,z} \rangle$ becomes apparent on reformulating the relevant equation as

$$\frac{d\langle \hat{I}_{A,z} \rangle}{dt} = -R_1^A(\langle \hat{I}_{A,z} \rangle - I_{A,\text{stat}}) \quad (3)$$

where $I_{A,\text{stat}}$ is the ‘new’ equilibrium value (or stationary state value) of $\langle \hat{I}_{A,z} \rangle$ when X transitions are continuously irradiated:

$$I_{A,\text{stat}} = I_{A,\text{eq}} \left(1 + \frac{\gamma_X}{\gamma_A} \frac{\sigma_{AX}}{R_1^A} \right) \quad (4)$$

γ_X and γ_A being the gyromagnetic ratios. It should be emphasized that this stationary magnetization, different from the equilibrium magnetization, is a manifestation of the well-known nuclear Overhauser effect.^{7,8} Some caution must be exercised regarding the monoexponentiality implied by equation (3); for instance, this feature no longer strictly holds in an AX₂ system, when X transitions are irradiated, owing to the necessity of accounting for additional magnetization modes.

2 THE DENSITY OPERATOR FOR TREATING THE EVOLUTION OF A SPIN SYSTEM

The general approach for treating relaxation phenomena⁹ rests on the Liouville–von Neumann equation, which indicates in a compact and formal way how the so-called reduced density operator $\hat{\sigma}$ evolves:

$$\frac{d\hat{\sigma}}{dt} = i[\hat{\sigma}, \hat{\mathcal{H}}(t)] \quad (5)$$

where the square brackets denote the commutator. For the systems considered here, the total Hamiltonian can be decomposed according to

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}'(t) \quad (6)$$

$\hat{\mathcal{H}}_0$ is the ‘static’ Hamiltonian containing the Zeeman term (which includes the chemical shift information) and the J coupling interaction term. $\hat{\mathcal{H}}'(t)$ embodies all time-dependent interactions responsible for relaxation phenomena. The interest of the density operator stems from the property that any quantity $\langle \hat{G} \rangle$ can be calculated at any time through the relation

$$\langle \hat{G} \rangle = \text{Tr}(\hat{G}\hat{\sigma}) \quad (7)$$

where Tr stands for the trace (sum of all diagonal elements of the matrix associated with $\hat{G}\hat{\sigma}$). For instance, the Bloch equation or the Solomon equations, which relate to the evolution of magnetization modes encountered until now, could be derived in this way, provided that equation (5) has been solved. This is usually done by a perturbation calculation (whose result is outlined below), starting from the equilibrium value of $\hat{\sigma}$:

$$\hat{\sigma}_{\text{eq}} = \frac{1}{2^n} \left(\hat{E} + \sum_{k=1}^n \Delta_k \hat{I}_{kz} \right) \quad (8)$$

Equation (8) has been written for a system of n spin- $\frac{1}{2}$ nuclei; Δ_k is a constant proportional to the gyromagnetic ratio of nucleus k and $\hat{E}$ is the identity operator. It should be recalled that the density matrix, the matrix associated with the density operator, is diagonal when it is constructed on the eigenbasis of $\hat{\mathcal{H}}_0$ and when the magnetization does not involve any transverse component; this is the case for the matrix associated with $\hat{\sigma}_{\text{eq}}$. In general, the evolution of the density operator,

when representative of longitudinal magnetization, can be written as¹⁰

$$\frac{d\hat{\sigma}}{dt} = - \sum_{r,r'} \sum_{m=-2}^2 [\hat{A}_r^{m\dagger}, [\hat{A}_{r'}^m, \hat{\sigma} - \hat{\sigma}_{\text{eq}}]] \mathcal{J}^{rr'}(m\omega_0) \quad (9)$$

where the symbol $\dagger$ indicates the transposed complex conjugate (adjoint). The spin operators $\hat{A}_r^m$, as well as the spectral density $\mathcal{J}^{rr'}(m\omega_0)$, originate from the Hamiltonian $\hat{\mathcal{H}}'(t)$, which, for all relaxation mechanisms involved in $\hat{\mathcal{H}}'(t)$ and labeled by the subscript r , can be expressed in the compact form

$$\hat{\mathcal{H}}'(t) = \sum_r \sum_{m=-2}^2 \hat{A}_r^{m\dagger} F_r^m \quad (10)$$

F_r^m is a function of the space coordinates (in a broad sense), generally depending on molecular motions, and belongs to the class of irreducible tensors,¹¹ as do the spin operators $\hat{A}_r^m$ [among other things, irreducible tensors possess the property that $\hat{A}_r^{m\dagger} = (-1)^m \hat{A}_r^{-m}$]. Since an exhaustive list of these irreducible tensors, for the various relaxation mechanisms affecting spin- $\frac{1}{2}$ nuclei, has been given before,³ only the three most common relaxation mechanisms will be considered here, the relevant $\hat{A}_r^m$ being given in Table 1.

The *intramolecular dipolar interaction* (that is, within the considered spin system) is by far the most informative, since it leads to dynamical and structural information. The F_r^m , as well as the $\hat{A}_r^m$, are of rank 2 (m actually goes from -2 to $+2$). Each F_r^m is simply the spherical harmonic $Y_2^m(\theta, \phi)$ multiplied by a constant and by the inverse of r_{AX}^3 , where r_{AX} is the distance between the two interacting nuclei. The angles θ and ϕ involved in the spherical harmonics specify the orientation of r_{AX} with respect to a laboratory frame defined in such a way that the Z axis coincides with the direction of the static magnetic field $\mathbf{B}_0$. θ and ϕ are of course modulated by molecular reorientational processes.

The so-called *chemical shift anisotropy* (CSA) mechanism arises from the reorientation of the shielding tensor. The spin irreducible tensors $\hat{A}_r^m$ are of rank 1, so that the summation over m goes from -1 to $+1$. However, the ‘space’ irreducible tensors F_r^m are of rank 2, and, provided that the shielding tensor has axial symmetry, each can be expressed as the spherical harmonic $Y_2^m(\theta, \phi)$ multiplied by a factor involving constants and the quantity $B_0 \Delta\sigma$. The molecular frame (x, y, z) is defined by the principal axes of the shielding tensor so that $\sigma_{xx} = \sigma_{yy}$ and $\Delta\sigma = \sigma_{zz} - \sigma_{xx}$. Again, θ and ϕ specify the orientation of the molecular z axis with respect to the laboratory frame defined above.

Table 1 Spin Operators in Irreducible Form, for the Three Essential Relaxation Mechanisms Affecting Spin- $\frac{1}{2}$ Nuclei^a

Mechanism	$\hat{A}^{\pm 2}$	$\hat{A}^{\pm 1}$	$\hat{A}^0$
Random fields		$\mp \sqrt{\frac{1}{2}} \hat{I}_{\pm}$	$\hat{I}_z$
Chemical shift anisotropy		$\mp \sqrt{\frac{3}{8}} \hat{I}_{\pm}$	$\hat{I}_z$
Dipolar interaction	$\frac{1}{2} \hat{I}_{A,\pm} \hat{I}_{X,\pm}$	$\mp \frac{1}{2} (\hat{I}_{A,\pm} \hat{I}_{X,z} + \hat{I}_{A,z} \hat{I}_{X,\pm})$	$[4\hat{I}_{A,z} \hat{I}_{X,z} - (\hat{I}_{A,+} \hat{I}_{X,-} + \hat{I}_{A,-} \hat{I}_{X,+})] \sqrt{24}$

^a $\hat{I}_{\pm}$ are raising and lowering operators, defined as $\hat{I}_x \pm i\hat{I}_y$.

Other relaxation mechanisms (including spin-rotation, intermolecular dipolar interactions, and interactions with paramagnetic impurities) are usually gathered in the so-called *random field* mechanism, for which both $\hat{A}_r^m$ and F_r^m are of rank 1, the F_r^m including randomly fluctuating magnetic fields whose average value is zero.

The spectral densities of equation (9), for an *isotropic* medium, can be expressed as¹²

$$\mathcal{J}^{rr'}(m\omega_0) = \int_0^\infty \overline{F_r^{0*}(t) F_{r'}^0(0)} \exp(-im\omega_0 t) dt \quad (11)$$

where the asterisk indicates the complex conjugate. Since r and r' refer to relaxation mechanisms, $\mathcal{J}^{rr'}$ is an *autocorrelation* spectral density for $r = r'$ (same interaction; e.g., the dipolar interaction between two nuclei A and X), and is a *cross-correlation* spectral density for two different mechanisms ($r \neq r'$; e.g., with r standing for the dipolar interaction between A and X, and r' for the dipolar interaction between A and X'). This terminology comes from the correlation function $\overline{F_r^{0*}(t) F_{r'}^0(0)}$, where the overbar denotes an ensemble average. The dependence on the measurement frequency ω_0 must be understood as $m\omega_0 = \omega_{ab}$, which is the energy difference (expressed in rad s⁻¹) between two $\hat{\mathcal{H}}_0$ eigenstates $|a\rangle$ and $|b\rangle$, the latter being such that $\langle a | \hat{A}_r^m | b \rangle \neq 0$. Examination of equation (11) leads to the conclusion that cross-correlation spectral densities vanish if the ranks of F_r^0 and of $F_{r'}^0$ are different. Consequently, cross correlation is possible only between (i) two different dipolar interactions sharing one spin and (ii) chemical shift anisotropy of a given spin and a dipolar interaction involving that spin.

In the case where F_r^m can be expressed as spherical harmonics of rank 2, equation (11) can be simplified to

$$\mathcal{J}^{rr'}(m\omega_0) = K^{rr'} \tilde{\mathcal{J}}^{rr'}(m\omega_0) \quad (12)$$

where $\tilde{\mathcal{J}}^{rr'}$ is the so-called reduced spectral density involving the spherical harmonics $Y_2^0(\theta)$ (proportional to $3 \cos^2 \theta - 1$):

$$\tilde{\mathcal{J}}^{rr'}(\omega) = \frac{5}{4} \int_{-\infty}^{\infty} \overline{[3 \cos^2 \theta(t) - 1][3 \cos^2 \theta'(0) - 1]} \exp(-i\omega t) dt \quad (13)$$

The correlation function in equation (13) must be evaluated according to a motional model. As an example, for the simplest one that can be thought of (isotropic diffusional reorientation, which is characterized by a single characteristic time τ_c), the calculation of the above integral leads to

$$\tilde{\mathcal{J}}(\omega) = \frac{2\tau_c}{1 + \omega^2 \tau_c^2} \quad (14)$$

which reduces to $2\tau_c$ under extreme narrowing conditions (fast motion; $\omega^2 \tau_c^2 \ll 1$).

$K^{rr'}$ contains the constants alluded to before and the molecular quantities relevant to the considered relaxation mechanism. One has, for an autocorrelation dipolar spectral density (where μ_0 is the permeability of the vacuum and $\hbar$ Planck's constant divided by 2π)

$$K^{d(AX)} = \frac{3}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_A^2 \gamma_X^2 \hbar^2}{r_{AX}^6} \quad (15)$$

for a cross-correlation spectral density

$$K^{d(AX, AX')} = \frac{3}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_A^2 \gamma_X \gamma_{X'} \hbar^2}{r_{AX}^3 r_{AX'}^3} \quad (16)$$

for an autocorrelation CSA spectral density

$$K^{csa(A)} = \frac{2}{45} (\Delta\sigma_A)^2 (\gamma_A^2 B_0^2) \quad (17)$$

and for a CSA-dipolar cross-correlation spectral density (often dubbed an 'interference term')

$$K^{csa(A), d(AX)} = -\frac{1}{5} \sqrt{\frac{2}{3}} \frac{\mu_0}{4\pi} \frac{\Delta\sigma_A B_0 \gamma_A^2 \gamma_X \hbar}{r_{AX}^3} \quad (18)$$

Now, equation (9) can be recast in matrix form by means of the widely used Redfield equations,¹³ which, for the case of longitudinal relaxation, amount to a set of simultaneous first-order kinetic equations governing the evolution of energy level populations:

$$\frac{dP_a}{dt} = \sum_b W_{ab} P_b \quad (19)$$

where P_a is the deviation, with respect to its equilibrium value, of the population of the $\hat{\mathcal{H}}_0$ eigenstate $|a\rangle$ and where the familiar transition probabilities W_{ab} can be expressed as a function of the spectral densities introduced above:

$$\left. \begin{aligned} W_{ab}(a \neq b) &= W_{ba} \\ &= 2 \sum_{r, r'} (-1)^m \mathcal{J}^{rr'}(\omega_a - \omega_b) (\hat{A}_r^m)_{ab} (\hat{A}_{r'}^m)_{ba} \\ W_{aa} &= - \sum_{b \neq a} W_{ab} \end{aligned} \right\} \quad (20)$$

3 CONSTRUCTION OF MAGNETIZATION MODES AND THEIR RELATION TO OBSERVABLE QUANTITIES

3.1 General Considerations

The ultimate goal is to arrive at kinetic equations as simple as the Redfield equations [equations (19) and (20)] but involving quantities easily converted to observables by appropriate read pulses. Since one is dealing with *longitudinal* magnetization in a system of n spins $\frac{1}{2}$, there should be as many magnetization modes as there are eigenstates of $\hat{\mathcal{H}}_0$; that is, 2^n (4 for an AX system and 8 for an AX₂ system). The corresponding Hermitian operators $\hat{V}_i$ must therefore satisfy a condition of commutation with $\hat{\mathcal{H}}_0$:

$$[\hat{\mathcal{H}}_0, \hat{V}_i] = 0 \quad (21)$$

which amounts to saying that their associated matrices must be diagonal in the eigenbasis of $\hat{\mathcal{H}}_0$ (the condition under

which they effectively represent longitudinal magnetization). In addition, conditions of orthogonality and normalization will be imposed:

$$\text{Tr}(\hat{V}_i^\dagger \hat{V}_j) = \delta_{ij} \quad (22)$$

This ensures that the relaxation matrix (the analog of $\mathbf{W}$ in the Redfield equations) will be symmetric (see below). Thus the $\{\hat{V}_i\}$ constitute a basis, over which the part of the density operator pertaining to longitudinal magnetization (denoted by $\hat{\sigma}_L$) can be expanded:

$$\hat{\sigma}_L(t) - \hat{\sigma}_{\text{eq}} = \sum_{i=1}^{2^n} v_i(t) \hat{V}_i \quad (23)$$

which, from equation (7), is equivalent to

$$v_i(t) = \langle \hat{V}_i - \hat{V}_{i,\text{eq}} \rangle \quad (24)$$

The expectation value of $\hat{V}_i - \hat{V}_{i,\text{eq}}$, $v_i(t)$, is called a magnetization mode (although this term can be extended to the operator itself). It can be seen that equations (21) and (22) do not lead to a unique set of magnetization modes. The actual choice is in fact dictated by intuition and practical considerations relevant to the ease with which magnetization modes can be measured.

A unitary transformation necessarily exists when moving from the energy populations to the magnetization modes. Therefore, first-order kinetic equations [having the same structure as the Redfield equations, equation (19)] can be found for magnetization modes; they will be written in the form

$$\frac{dv_i(t)}{dt} = \sum_{j=1}^{2^n} \Gamma_{ij} v_j(t) \quad (25)$$

According to a general property of quantum mechanics, the elements Γ_{ij} constitute a $2^n \times 2^n$ symmetric matrix, since the latter is constructed on an orthogonal and normalized basis of Hermitian operators. The expression for these elements can be derived from equations (9) and (23):

$$\Gamma_{ij} = \sum_{r,r'} \sum_{m=-2}^{+2} (-1)^m \mathcal{J}^{rr'}(m\omega_0) \text{Tr}\{[\hat{A}_r^{-m}, \hat{V}_i][\hat{A}_{r'}^m, \hat{V}_j]\} \quad (26)$$

Factorization of equation (25) may result from the consideration of the symmetry of magnetization modes with respect to total spin inversion.^{2,14,15} This operation can be seen as interchanging a spin function α into β , and vice versa; likewise, any individual operator $\hat{I}_z$ is transformed into its opposite. Of course, changing z into $-z$ must leave equation (25) globally unchanged. If i and j refer to magnetization modes of different symmetries, one mode must change sign (the antisymmetric one) and the other not (the symmetric one); if, at the same time, Γ_{ij} does not change sign, it is necessarily zero. This situation occurs most of the time, leading to the conclusion that *antisymmetric modes do not generally couple into antisymmetric modes*, and vice versa, leading to a factorization of the matrix Γ [relevant to equation (25) in matrix form] into two blocks: one corresponding to antisymmetric modes,

the other to symmetric modes. The possible sign change of Γ_{ij} can arise from a sign change of $\hat{A}_r^{-m} \hat{A}_{r'}^m$ [see equation (26)]; examination of Table 1 shows that this can only occur through CSA–dipolar cross correlation, as discussed further in Section 4.

3.2 The AX Spin System

Regarding weakly coupled spin systems without equivalence, because of the expression of the coupling term in the static Hamiltonian ($\sum_{k<l} J_{kl} \hat{I}_{k,z} \hat{I}_{l,z}$), it is obvious that either individual spin operators $\hat{I}_z$ or any product of operators $\hat{I}_z$ pertaining to different spins do commute with $\hat{\mathcal{H}}_0$. Therefore, as far as a two-spin system is considered, the four magnetization modes satisfying equations (21) and (22) are readily obtained. As for any spin system, they include the identity, which evidently does not evolve, thus leaving three active magnetization modes, which are easily classified according to their symmetric or antisymmetric nature with respect to total spin inversion [this is indicated below by the superscript (a) or (s)]:

$$\begin{aligned} {}^{(a)}v_1 &= \langle \hat{I}_{A,z} - I_{A,\text{eq}} \rangle, & {}^{(a)}v_2 &= \langle \hat{I}_{X,z} - I_{X,\text{eq}} \rangle \\ {}^{(s)}v_3 &= \langle 2\hat{I}_{A,z} \hat{I}_{X,z} \rangle \end{aligned} \quad (27)$$

v_1 and v_2 are simply measured by means of a semiselective read pulse applied to A or X, respectively. Concerning v_3 , sometimes called the longitudinal spin order, it can be seen that the equilibrium value of $\langle 2\hat{I}_{A,z} \hat{I}_{X,z} \rangle$ is zero. It can therefore be created either by a special spin preparation involving selective pulses, or through transfers from antisymmetric modes by relaxation. A semiselective pulse $(\pi/2)_{A,x}$ (i.e., one acting solely on A along the x axis of the rotating frame) converts $2\hat{I}_{A,z} \hat{I}_{X,z}$ into $2\hat{I}_{A,y} \hat{I}_{X,z}$, which corresponds to an antiphase configuration of the A doublet.¹⁶ This is shown in Figure 1, where the line A_1 includes equal contributions from v_1 and v_3 , whereas the intensity of line A_2 represents the contribution of mode v_1 minus the contribution of the mode v_3 . This leads to the well-known differential recovery¹⁷ of the two lines of the doublet as long as v_3 has been activated. The contribution of the sole v_3 can be obtained by considering the same experiment, but preceded by a semiselective inverting pulse applied to X.¹⁸

Figure 1 A semiselective $\pi/2$ pulse (acting only on A) converts the ${}^{(a)}v_1$ mode into the normal A doublet (of an AX spin system), and the ${}^{(s)}v_3$ mode into an antiphase doublet

A situation of practical interest is that of observation of A under X irradiation (e.g., observation of ^{13}C while ^1H transitions are irradiated for decoupling purposes). It can be shown that both $\langle \hat{I}_{X,z} \rangle$ and $\langle 2\hat{I}_{A,z}\hat{I}_{X,z} \rangle$ are identically zero. Consequently, one is left with a simple magnetization mode, namely v_1 , for which equation (3) applies.

3.3 The AX_2 Spin System

The problem is here complicated by the fact that the two spins X and X' are no longer weakly coupled (since they share the same chemical shift). The trick is to start with the Hamiltonian of an X_2 system in an anisotropic medium and to find operators that satisfy both equations (21) and (22). In addition to the identity, a possible set is

$$\frac{1}{2}(\hat{I}_{X,z} + \hat{I}_{X',z}); \quad 2\hat{I}_X \cdot \hat{I}_{X'}; \quad \sqrt{\frac{2}{3}}(3\hat{I}_{X,z}\hat{I}_{X',z} - \hat{I}_X \cdot \hat{I}_{X'}) \quad (28)$$

These operators can be shown to be suitable for an AX_2 system. Yet, four operators have still to be found. It turns out that those can be $\hat{I}_{A,z}$ itself and the operators in equation (28) multiplied by $\hat{I}_{A,z}$ (all with appropriate normalization factors). Choosing normalized combinations adapted to easily measurable quantities leads to the magnetization modes that seem at present to be widely accepted:¹⁹

$$\left. \begin{aligned} {}^{(a)}v_1 &= \sqrt{\frac{1}{2}}(\hat{I}_{A,z} - I_{A,\text{eq}}) \\ {}^{(a)}v_2 &= \frac{1}{2}(\hat{I}_{X,z} + \hat{I}_{X',z} - 2I_{X,\text{eq}}) \\ {}^{(a)}v_3 &= \sqrt{8}(\hat{I}_{A,z}\hat{I}_{X,z}\hat{I}_{X',z}) \\ {}^{(a)}v_4 &= 2(\hat{I}_{A,z}(\hat{I}_{X,x}\hat{I}_{X',x} + \hat{I}_{X,y}\hat{I}_{X',y})) \\ {}^{(s)}v_5 &= \langle \hat{I}_{A,z}(\hat{I}_{X,z} + \hat{I}_{X',z}) \rangle \\ {}^{(s)}v_6 &= \sqrt{2}(\hat{I}_{X,z}\hat{I}_{X',z}) \\ {}^{(s)}v_7 &= \langle (\hat{I}_{X,x}\hat{I}_{X',x} + \hat{I}_{X,y}\hat{I}_{X',y}) \rangle \end{aligned} \right\} \quad (29)$$

In the situation where X transitions are irradiated for decoupling purposes, ${}^{(a)}v_2$ does not evolve and is equal to $\hat{I}_{X,\text{eq}}$ whereas ${}^{(s)}v_5$ is zero. In order to account for other quantities that are also identically zero, ${}^{(a)}v_4$ and ${}^{(a)}v_3$ must be substituted by ${}^{(a)}v'_3 = \sqrt{\frac{8}{3}}(\hat{I}_{A,z}\hat{I}_X \cdot \hat{I}_{X'})$, and ${}^{(s)}v_6$ and ${}^{(s)}v_7$ by ${}^{(s)}v'_6 = \sqrt{\frac{2}{3}}(\hat{I}_X \cdot \hat{I}_{X'})$. One is thus left, in that case, with three active modes: ${}^{(a)}v_1$, ${}^{(a)}v'_3 = \sqrt{\frac{1}{3}}({}^{(a)}v_3 + \sqrt{2} {}^{(a)}v_4)$, and ${}^{(s)}v'_6 = \sqrt{\frac{1}{3}}({}^{(s)}v_6 + \sqrt{2} {}^{(s)}v_7)$.

Returning to the modes given by equation (29), it can be seen that the equilibrium values are zero for all modes except for the first two. Therefore, unless they have benefited by relaxation transfers originating from v_1 and v_2 , or created by dedicated spin preparations, they yield no net result. In the following, it will be assumed that they exist by either means, the emphasis being put on the way in which they can be observed.

The various modes can be related to the line intensities of an AX_2 spin system, whose spectrum is shown schematically at the top of Figure 2. Also shown in Figure 2 are the effects of the two simplest read pulses that can be considered, namely a semiselective $\pi/2$ pulse acting only on A or only on X. These detection schemes deserve some comments.

Figure 2 (a) Schematic representation of the spectrum of an AX_2 system. The lines X_1 and X'_1 on the one hand, and X'_2 and X_2 on the other, are separated only in an anisotropic medium. (b) Effects of semiselective $\pi/2$ pulses (read pulses acting only on A or only on X) on the magnetization modes of an AX_2 spin system

1. A $(\pi/2)_A$ read pulse results in a superposition of contributions from the modes ${}^{(a)}v_1$, ${}^{(a)}v_3$, and ${}^{(s)}v_5$, recognizing that the mode ${}^{(a)}v_4$ contributes nothing, since the lines A'_1 and A'_2 share exactly the same resonance frequency.
2. A $(\pi/2)_X$ read pulse allows one to detect contributions from the modes ${}^{(a)}v_2$ and ${}^{(s)}v_5$. More elaborate detection schemes³ are available for tracing out the different modes of an AX_2 spin system. They involve multipulse experiments, sometimes combined with decoupling of one of the two considered nuclei.
3. Finally, it can be seen that modes ${}^{(s)}v_6$ and ${}^{(s)}v_7$ can only be measured in an anisotropic medium where the lines X_1 , X'_1 on the one hand, and X_2 , X'_2 on the other, can be separated.

4 EVOLUTION OF MAGNETIZATION MODES UNDER RELAXATION PHENOMENA

The evolution of magnetization modes rests on the relaxation matrix, which can be constructed by referring to equations

(25) and (26). It should be stressed that this matrix comprises all types of spectral densities (autocorrelation and cross correlation), in contrast with the so-called relaxation matrix used for interpreting NOESY experiments, which generally involves only autocorrelation spectral densities, giving rise to the sole specific relaxation rates and cross-relaxation rates. In this respect, the relaxation matrices given below provide all the details of relaxation pathways in AX and AX₂ spin systems.

4.1 The AX Spin System

The complete relaxation matrix is given in Table 2. As mentioned above, if CSA–dipolar cross-correlation spectral densities can be considered as negligible (matrix elements Γ_{13} and Γ_{23}), antisymmetric modes are effectively decoupled from symmetric modes, and the simple Solomon equations [equation (2)], hold because the symmetric mode $^{(s)}\nu_3$ is zero at thermal

Table 2 Relaxation Matrix for an AX Spin System^a

$$\begin{aligned}\Gamma_{11} &= -R_1^A \\ \Gamma_{12} &= -\sigma_{AX} \\ \Gamma_{13} &= -\sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(A), \text{d}(AX)}(\omega_A) \\ \Gamma_{22} &= -R_1^X \\ \Gamma_{23} &= -\sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(X), \text{d}(AX)}(\omega_X) \\ \Gamma_{33} &= -\frac{1}{4} [\mathcal{J}^{\text{d}(AX)}(\omega_A) + \mathcal{J}^{\text{d}(AX)}(\omega_X)] - \frac{3}{2} [\mathcal{J}^{\text{csa}(A)}(\omega_A) + \mathcal{J}^{\text{csa}(X)}(\omega_X)] - 2[\mathcal{J}^{\text{rf}(A)}(\omega_A) + \mathcal{J}^{\text{rf}(X)}(\omega_X)]\end{aligned}$$

^aSuperscripts have the following meanings: d = dipolar; csa = chemical shift anisotropy; rf = randomly fluctuating fields. The classical relaxation parameters are given by $R_1^A = \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A + \omega_X) + \frac{1}{4} \mathcal{J}^{\text{d}(AX)}(\omega_A) + \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A - \omega_X) + \frac{3}{2} \mathcal{J}^{\text{csa}(A)}(\omega_A) + 2 \mathcal{J}^{\text{rf}(A)}(\omega_A)$ (interchange A and X for R_1^X); $\sigma_{AX} = \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A + \omega_X) - \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A - \omega_X)$.

Table 3 Relaxation Matrix for an AX₂ Spin System^a

$$\begin{aligned}\Gamma_{11} &= -R_1^{A'} \\ \Gamma_{12} &= -\sqrt{2} \sigma_{AX} \\ \Gamma_{13} &= -\frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A) \\ \Gamma_{14} &= -\sqrt{\frac{1}{2}} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A + \omega_X) - \frac{1}{6\sqrt{2}} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A - \omega_X) \\ \Gamma_{15} &= -\sqrt{3} \mathcal{J}^{\text{csa}(A), \text{d}(AX)}(\omega_A) \\ \Gamma_{16} &= 0 \\ \Gamma_{17} &= 0 \\ \Gamma_{22} &= -R_1^X - \mathcal{J}^{\text{d}(XX')}(2\omega_X) - \frac{1}{4} \mathcal{J}^{\text{d}(XX')}(\omega_X) \\ \Gamma_{23} &= -\sqrt{\frac{1}{2}} \mathcal{J}^{\text{d}(AX, XX')}(\omega_X) \\ \Gamma_{24} &= -\frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A + \omega_X) + \frac{1}{2} \mathcal{J}^{\text{d}(AX, XX')}(\omega_X) + \frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A - \omega_X) \\ \Gamma_{25} &= -\sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(X), \text{d}(AX)}(\omega_X) \\ \Gamma_{26} &= -\sqrt{3} \mathcal{J}^{\text{csa}(X), \text{d}(XX')}(\omega_X) \\ \Gamma_{27} &= -\sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(X), \text{d}(XX')}(\omega_X) \\ \Gamma_{33} &= -\frac{1}{2} [\mathcal{J}^{\text{d}(AX)}(\omega_A) + \mathcal{J}^{\text{d}(AX)}(\omega_X) + \mathcal{J}^{\text{d}(XX')}(\omega_X)] - \frac{3}{2} [\mathcal{J}^{\text{csa}(A)}(\omega_A) + 2 \mathcal{J}^{\text{csa}(X)}(\omega_X)] - 2 \mathcal{J}^{\text{rf}(A)}(\omega_A) - 4 \mathcal{J}^{\text{rf}(X)}(\omega_X) \\ \Gamma_{34} &= \frac{1}{2\sqrt{2}} [\mathcal{J}^{\text{d}(XX')}(\omega_X) + \mathcal{J}^{\text{d}(AX, AX')}(\omega_X)] + 3\sqrt{\frac{1}{2}} \mathcal{J}^{\text{csa}(X), \text{csa}(X')}(\omega_X) + 2\sqrt{2} \mathcal{J}^{\text{rf}(X), \text{rf}(X')}(\omega_X) \\ \Gamma_{35} &= -\sqrt{3} [\mathcal{J}^{\text{csa}(A), \text{d}(AX)}(\omega_A) + \mathcal{J}^{\text{csa}(X), \text{d}(XX')}(\omega_X)] \\ \Gamma_{36} &= -\sqrt{6} \mathcal{J}^{\text{csa}(X), \text{d}(AX)}(\omega_X) \\ \Gamma_{37} &= \sqrt{3} \mathcal{J}^{\text{csa}(X), \text{d}(AX')}(\omega_X) \\ \Gamma_{44} &= -R_1^X - \frac{1}{3} \mathcal{J}^{\text{d}(AX)}(0) - \frac{1}{4} \mathcal{J}^{\text{d}(XX')}(\omega_X) + \frac{1}{3} \mathcal{J}^{\text{d}(AX, AX')}(0) - \frac{3}{2} \mathcal{J}^{\text{csa}(A)}(\omega_A) - 2 \mathcal{J}^{\text{csa}(X)}(0) - 2 \mathcal{J}^{\text{rf}(A)}(\omega_A) - 2 \mathcal{J}^{\text{rf}(X)}(0) \\ &\quad + 2 \mathcal{J}^{\text{csa}(X), \text{csa}(X')}(0) + 2 \mathcal{J}^{\text{rf}(X), \text{rf}(X')}(0) \\ \Gamma_{45} &= \sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(X), \text{d}(XX')}(\omega_X) \\ \Gamma_{46} &= \sqrt{3} \mathcal{J}^{\text{csa}(X), \text{d}(AX')}(\omega_X) \\ \Gamma_{47} &= -\sqrt{\frac{3}{2}} \mathcal{J}^{\text{csa}(X), \text{d}(AX)}(\omega_X) - 2\sqrt{\frac{2}{3}} \mathcal{J}^{\text{csa}(X), \text{d}(AX)}(0) + 2\sqrt{\frac{2}{3}} \mathcal{J}^{\text{csa}(X), \text{d}(AX')}(0) \\ \Gamma_{55} &= -R_1^X - \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A) - \mathcal{J}^{\text{d}(XX')}(2\omega_X) - \frac{1}{4} \mathcal{J}^{\text{d}(XX')}(\omega_X) - \frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A) - \frac{3}{2} \mathcal{J}^{\text{csa}(A)}(\omega_A) - 2 \mathcal{J}^{\text{rf}(A)}(\omega_A) \\ \Gamma_{56} &= -\sqrt{\frac{1}{2}} \mathcal{J}^{\text{d}(AX)}(\omega_A + \omega_X) + \frac{1}{6\sqrt{2}} \mathcal{J}^{\text{d}(AX)}(\omega_A - \omega_X) - \sqrt{\frac{1}{2}} \mathcal{J}^{\text{d}(AX, XX')}(\omega_X) \\ \Gamma_{57} &= \frac{1}{2} \mathcal{J}^{\text{d}(AX, XX')}(\omega_X) + \frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A + \omega_X) - \frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A - \omega_X) \\ \Gamma_{66} &= -2R_1^X - \frac{1}{2} \mathcal{J}^{\text{d}(XX')}(\omega_X) \\ \Gamma_{67} &= \frac{1}{2\sqrt{2}} \mathcal{J}^{\text{d}(XX')}(\omega_X) + \sqrt{\frac{1}{2}} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A + \omega_X) + \frac{1}{2\sqrt{2}} \mathcal{J}^{\text{d}(AX, AX')}(\omega_X) + \frac{1}{6\sqrt{2}} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A - \omega_X) + 3\sqrt{\frac{1}{2}} \mathcal{J}^{\text{csa}(X), \text{csa}(X')}(\omega_X) + 2\sqrt{2} \mathcal{J}^{\text{rf}(X), \text{rf}(X')}(\omega_X) \\ \Gamma_{77} &= -R_1^X - \frac{1}{2} \mathcal{J}^{\text{d}(AX)}(\omega_A) - \frac{1}{3} \mathcal{J}^{\text{d}(AX)}(0) - \frac{1}{4} \mathcal{J}^{\text{d}(XX')}(\omega_X) + \frac{1}{2} \mathcal{J}^{\text{d}(AX, AX')}(\omega_A) + \frac{1}{3} \mathcal{J}^{\text{d}(AX, AX')}(0) - 2 \mathcal{J}^{\text{csa}(X)}(0) + 2 \mathcal{J}^{\text{csa}(X), \text{csa}(X')}(0) - 2 \mathcal{J}^{\text{rf}(X)}(0) \\ &\quad + 2 \mathcal{J}^{\text{rf}(X), \text{rf}(X')}(0)\end{aligned}$$

^aThe various symbols have the same meanings as in Table 2. $R_1^{A'}$ differs from R_1^A by a factor of 2 multiplying the dipolar spectral densities (to account for the two nuclei X and X').

equilibrium. Conversely, with the advent of high-field NMR spectrometers, CSA contributions may become nonnegligible, and so do CSA–dipolar cross-correlation spectral densities. This somewhat complicates the evolution of this simple two-spin system under longitudinal relaxation, but, in turn, yields valuable molecular information of structural nature through the shielding tensor and also information of dynamical nature through the correlated motions of dipolar and shielding tensors. In addition to the early works of Shimizu,²⁰ Mackor and MacLean,²¹ and Blicharsky,²² there has been an abundant (and increasing) literature on the subject from the beginning of the 1980s based either on one-dimensional^{23–34} or two-dimensional^{35–39} experiments.

Invariably, the initial perturbation consists in disturbing semiselectively one longitudinal magnetization (A or X) and looking at recoveries of either A or X longitudinal magnetizations (or both). For this simple two-spin system, one may content oneself with the initial behavior, which yields the whole relaxation information. As an example, let us suppose that the perturbation consists in inverting the A magnetization. Initial behaviors of A and X longitudinal magnetizations yield respectively R_1^A and σ_{AX} . In the same context, converting $(2\hat{I}_{A,z}\hat{I}_{X,z})$ into an antiphase transverse configuration makes it possible to monitor the build-up of longitudinal order through the CSA–dipolar interference term $\mathcal{J}^{csa(A),d(AX)}$. Conversely, an initial perturbation applied to the X nucleus yields the interference term $\mathcal{J}^{csa(A),d(AX)}$.

4.2 The AX₂ Spin System

As can be seen from the relaxation matrix given in Table 3, a wealth of molecular information can be gained through the various spectral densities that are involved. In particular, in a three-spin system, cross-correlation dipolar spectral densities show up; they carry some additional information about correlated motions of internuclear vectors. As for the AX system, antisymmetric modes are coupled into symmetric modes only via interference terms (CSA–dipolar cross-correlation spectral densities). Owing to the large number of spectral densities that have to be determined, it is almost mandatory to analyze the whole recovery curve and not to rely simply on initial behavior. In most studies carried out so far,⁴ the carbon longitudinal magnetization of a ¹³CH₂ grouping has been monitored after an appropriate perturbation. The following perturbations have proven to be sufficient for determining most spectral densities (extreme narrowing assumed), including interference terms:¹⁹

1. semiselective inversion of A magnetization;
2. semiselective inversion of (X, X') magnetizations;
3. selective inversion of one line of the (X, X') doublet;
4. the so-called *J*-pulse preparation,⁴⁰ by which a nonzero initial value is obtained for the ^(a)v₃ mode.

1 INTRODUCTION

Nuclear spin relaxation in liquids arises from random fluctuations of magnetic fields associated with a variety of intramolecular and intermolecular interactions that are modulated by molecular tumbling and other lattice motions. Interactions that produce such temporal magnetic oscillations include the dipole–dipole terms, chemical shift anisotropy, spin rotation, scalar coupling to a chemically exchanging nucleus or to a quadrupolar nucleus, free electrons within the sample, oscillating electrostatic fields for quadrupolar nuclei, etc. This article focuses primarily on the molecular motional aspects of the problem, and it is sufficient to select two prominent relaxation mechanisms, the dipole–dipole (dd) and the chemical shift anisotropy (csa), to illustrate both the nature and potential of nuclear relaxation for characterizing molecular motions. In particular, this article deals with the rotational diffusion of rigid molecules in an isotropic medium. Motional models for asymmetric and symmetric diffusion will be developed and compared with simple spherical diffusion.

The motional models must be developed in a principal molecular diffusion frame, which invariably differs from the laboratory measurement frame and also from the principal axis frames of the various spin interactions. This diversity of coordinate frames introduces a degree of complication in the mathematical development that need not obscure the relatively simple motional models that govern relaxation processes. The various relationships existing between the several coordinate systems are outlined in Figure 1. The laboratory and molecular frames are related to each other by a set of time-dependent Euler angles $\Omega_t \sum (\alpha_t, \beta_t, \gamma_t)$, which introduce the temporal fluctuations into the motional models. The effect of diffusional motion upon relaxation has been discussed for autocorrelated terms by Woessner¹ based on the work of Perrin,² but the approach of Huntress³

Figure 1 Coordinate frames in spin relaxation

using the Favro⁴ diffusion equation provides a preferable approach for treating both autocorrelated and cross-correlated spin relaxation terms. Huntress's discussion of autocorrelated spectral densities was extended to a discussion of both auto- and cross-correlated dipolar spin relaxation.⁵ Recently, Smith⁶ used the Favro method to discuss the effect on relaxation of the chemical shift anisotropy interaction, including cross terms with the dipolar interaction. The Favro diffusion equation is the mathematical method used in this article to relate spin relaxation to molecular motions.

Invariably, the various principal interaction frames differ from the molecular diffusion frame, except for spherical diffusion, where the molecular motion has no unique axis system. In anisotropic diffusion, however, the geometrical relationships between the interaction frames and the molecular diffusion frame become an essential feature of the spatial geometry affecting spin relaxation. These transformations between the interaction and molecular coordinate frames are identified with the Euler angles $\Omega_\mu \sum (\alpha_\mu, \beta_\mu, \gamma_\mu)$ in Figure 1. In coupled-spin relaxation, the number of dipole–dipole interactions increases rather rapidly with the number of spins (i.e., one dipolar term for two spins, three terms for three spins, six for four spins, etc.). Thus, for even modest-size spin systems, the number of independent dipole–dipole interaction frames may become appreciable. To the several dipolar frames must be added the interaction frames for chemical shift anisotropy and other important relaxation interactions. Figure 1 portrays a minimal diversity to indicate the necessary geometric transformations required to describe relaxation in coupled-spin systems dominated by dipolar or chemical shift anisotropy mechanisms.

Recognizing that spin relaxation ensues from a time-correlated pairing of interactions, it becomes easy to understand the difference between auto- and cross-correlated spectral relaxation terms. In the autocorrelated terms, a single relaxation interaction is considered, whereas cross terms require a mixing of two interactions from Figure 1. Thus, in some cross

correlated relaxation terms, one may encounter as many as four different frames: the laboratory, the molecular diffusion, and two interaction frames. Articles on coupled-spin relaxation have appeared in the literature dating back over the past three decades. In addition, several reviews^{7–11} provide important background for this article, which focuses on motional models affecting relaxation.

All discussions of coupled relaxation begin with the Redfield equation,¹² introduced in Section 2, and proceed with secular approximations and time-reversal symmetry considerations to transform the fourth-rank Redfield matrix into autocorrelated and cross-correlated terms in the Hamiltonian. Section 3 expands the Hamiltonian in spin and spatial variables. Separation of these two variables results in spin matrices that contain the spectral selection rules for relaxation and expressions for the spectral densities that measure the strength of both auto and cross terms found for various relaxation mechanisms. Section 3 contains explicit expressions for the dipolar and chemical shift anisotropy spin operators. Section 4 discusses the separation of the spectral densities into the time-dependent motional power densities associated with the molecular motion and into the various time-independent interaction tensors in the molecular frame. Section 5 provides the Favro diffusion equation and its solution in terms of the molecular rotational diffusion tensor. The motional models developed in this section assume a rigid molecule tumbling in an isotropic fluid, but treat spherical, symmetrical, and asymmetrical diffusional cases. This diffusion equation is solved with both first- and second-rank diffusion constants, and therefore information is available to treat both first- and second-rank interactions found in the Hamiltonian. Section 6 discusses the transformations between the principal interaction frames and the principal molecular diffusion frame. Finally, explicit information on the geometrical relationships between these sets of frames is presented in Section 7 for the auto- and cross-correlation spectral densities encountered in dipole–dipole and chemical shift anisotropy relaxation mechanisms.

2 REDFIELD THEORY

Coupled relaxation processes may be described using Redfield theory¹² wherein the time derivatives of the density matrix elements $\sigma_{\kappa\kappa'}^*(t)$ are expressed using the following set of coupled differential equations:

$$\frac{d\sigma_{\kappa\kappa'}^*(t)}{dt} = \sum_{\lambda\lambda'} \exp\left[\frac{i}{\hbar}(E_{\kappa} - E_{\kappa'} - E_{\lambda} + E_{\lambda'})t\right] \times R_{\kappa\kappa'\lambda\lambda'}[\sigma_{\lambda\lambda'}^*(t) - \sigma_{\lambda\lambda'}^*(\infty)] \quad (1)$$

A discussion of this equation and its origin has been given by Slichter.¹³ In equation (1), the terms $\sigma_{\lambda\lambda'}^*(\infty)$ and $\sigma_{\lambda\lambda'}^*(t)$ represent the thermal equilibrium and the time-dependent density matrix elements, respectively. The asterisk designates a spin density matrix in the eigenstate interaction representation. The fourth-rank relaxation matrix $R_{\kappa\kappa'\lambda\lambda'}$ is combined with an exponential oscillating term $\exp[i(\hbar)(E_{\kappa} - E_{\kappa'} - E_{\lambda} + E_{\lambda'})t]$ involving up to four different eigenvalues E_i . Equation (1) allows for significant simplifications using a so-called secular approximation. The explicit oscillatory time dependence is removed whenever $E_{\kappa} - E_{\kappa'} = E_{\lambda} - E_{\lambda'}$. In longitudinal

relaxation, this is especially obvious for diagonal density matrix terms when $\kappa = \kappa'$ and $\lambda = \lambda'$. Rapid temporal oscillations, encountered in off-diagonal terms when $E_{\kappa} - E_{\kappa'} \neq E_{\lambda} - E_{\lambda'}$, eliminate the corresponding relaxation terms from consideration. The terms surviving the secular approximation form block-diagonalized relaxation matrices that can be used to discuss either longitudinal or transverse spin relaxation. The spin symmetry reduces the complexity by separating the longitudinal and transverse blocks from one another. The fit of the relaxation matrix in equation (1) to experimental data describes the time evolution of the spin system, and these spin relaxation solutions to equation (1) may be expressed either as NMR spectral densities appearing in the superoperator $R_{\kappa\kappa'\lambda\lambda'}$ or alternatively as spin interaction terms coupled with a set of molecular rotational diffusion constants.

2.1 The Hamiltonian for Spin Interactions Affecting Relaxation

The Hamiltonian contains a number of interactions, each of which contribute to a variety of spin relaxation mechanisms. These separate terms in the Hamiltonian may be expressed as

$$\begin{aligned} \hat{\mathcal{H}} &= \sum_{\mu} \hat{\mathcal{H}}_{\mu}(t) \\ &= \hat{\mathcal{H}}_{\text{dd}}(t) + \hat{\mathcal{H}}_{\text{csa}}(t) + \hat{\mathcal{H}}_{\text{SR}}(t) + \hat{\mathcal{H}}_{\text{SC}}(t) \\ &\quad + \hat{\mathcal{H}}_{\text{Q}}(t) + \dots \end{aligned} \quad (2)$$

where the index μ designates the respective spin interactions [i.e., dipole–dipole (dd), chemical shielding anisotropy (csa), spin–rotation (SR), scalar coupling (SC), quadrupolar (Q), etc.] associated with a specific relaxation mechanism contributing to $R_{\kappa\kappa'\lambda\lambda'}$. This relaxation matrix is given by

$$\begin{aligned} R_{\kappa\kappa'\lambda\lambda'} &= K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda}) + K_{\kappa\lambda\kappa'\lambda'}(\omega_{\lambda'\kappa'}) - \delta_{\kappa'\lambda'} \sum_{\gamma} K_{\gamma\lambda\gamma\kappa} \\ &\quad \times (\omega_{\gamma\lambda'}) - \delta_{\kappa\lambda} \sum_{\gamma} K_{\gamma\kappa'\gamma\lambda'}(\omega_{\lambda\gamma}) \end{aligned} \quad (3)$$

$\delta_{\kappa\lambda}$ are Kronecker deltas and $\omega_{\kappa\lambda} = (E_{\kappa} - E_{\lambda})/\hbar$. The several relaxation rates $K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda})$ are Fourier transforms of a correlation function in the Hamiltonian as follows:

$$\begin{aligned} K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda}) &= \sum_{\mu,\mu'} \frac{1}{\hbar^2} \int_0^{\infty} \langle \kappa | \hat{\mathcal{H}}_{\mu}(t) | \lambda \rangle \langle \lambda' | \hat{\mathcal{H}}_{\mu'}(t + \tau) | \kappa' \rangle \\ &\quad \times e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (4)$$

Standard matrix notation is used for the $\hat{\mathcal{H}}_{\mu}(t)$ elements involving eigenfunctions $\langle \kappa |$ and $| \lambda \rangle$, etc.

2.2 Time-Reversal Symmetry and Integration Limits

The two Hamiltonian matrix elements in equation (4) are real because of the Hermitian character of $\hat{\mathcal{H}}_{\mu}(t)$, but the imaginary terms, resulting from $e^{-i\omega_{\kappa\lambda}t}$, leave $K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda})$ a complex quantity. While the imaginary part of $K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda})$ does not

contribute directly to spin relaxation, these terms characterize a second-order dynamic frequency shift,¹⁴ which is measurable under certain circumstances. Furthermore, the correlated functions in equation (4) arise in liquids from stationary random motions that must exhibit time-reversal symmetry.¹⁵ Correlated properties with time-reversal symmetry render the integral in equation (4) with a range from 0 to ∞ equal to the corresponding integral from $-\infty$ to 0. Thus, focus on relaxation terms, which must be real, is consistent with a change of the integral in equation (4) to one-half of a full Fourier integral from $-\infty$ to $+\infty$. This change in the integral will be made later in this article after spin and spatial variables have been separated and after developing equation (4) to the point where relaxation and dynamic frequency shift terms are readily separated.

2.3 Autocorrelated and Cross-Correlated Relaxation Terms

The relaxation terms given in equation (4) have both autocorrelated contributions with $\mu' = \mu$ and cross-correlated terms with $\mu \neq \mu'$. In the cross terms there is an implied time ordering in $K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda})$ since μ is identified with t and μ' is associated with $t + \tau$. Thus, to retain time-reversal symmetry in the cross-relaxation expression, it is necessary to link together the pairs of complementary cross terms in μ and μ' . These cross terms, to be appreciable, transform under the same spin symmetry and depend upon the same motional correlation functions. Thus, equation (4) may be written as a sum of autocorrelated and cross-correlated relaxation components as follows:

$$K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda}) = \frac{1}{\hbar^2} \sum_{\mu} \int_0^{\infty} \langle \kappa | \hat{\mathcal{H}}_{\mu}(t) | \lambda \rangle \langle \lambda' | \hat{\mathcal{H}}_{\mu}(t + \tau) | \kappa' \rangle e^{-i\omega_{\kappa\lambda}\tau} d\tau \\ + \frac{1}{\hbar^2} \sum_{\mu \neq \mu'} \int_0^{\infty} [\langle \kappa | \hat{\mathcal{H}}_{\mu}(t) | \lambda \rangle \langle \lambda' | \hat{\mathcal{H}}_{\mu'}(t + \tau) | \kappa' \rangle \\ + \langle \kappa | \hat{\mathcal{H}}_{\mu'}(t) | \lambda \rangle \langle \lambda' | \hat{\mathcal{H}}_{\mu}(t + \tau) | \kappa' \rangle] e^{-i\omega_{\kappa\lambda}\tau} d\tau \quad (5)$$

The restricted summation in $\mu > \mu'$ for the cross terms prevents double counting in equation (5).

2.4 Explicit Expressions for the Dipole–Dipole and Chemical Shift Hamiltonians

The dipolar Hamiltonian is

$$\hat{\mathcal{H}}_{dd}(t) = \hbar \hat{\mathbf{I}}(s) \cdot \mathbf{D}(t) \cdot \hat{\mathbf{I}}(s') \quad (6)$$

where $\hat{\mathbf{I}}(s) = [\hat{I}_x(s), \hat{I}_y(s), \hat{I}_z(s)]$ is the angular momentum vector and the time-dependent dipolar coupling tensor $\mathbf{D}(t)$ is given by

$$\mathbf{D}(t) = \gamma_s \gamma_{s'} \hbar \left(\frac{\mathbf{1}}{r_{ss'}^3} - \frac{3\mathbf{r}_{ss'}(t)\mathbf{r}_{ss'}(t)}{r_{ss'}^5} \right) \\ = \frac{\gamma_s \gamma_{s'} \hbar}{r_{ss'}^5} \begin{bmatrix} r_{ss'}^2 - 3x_{ss'}^2 & x_{ss'}y_{ss'} & x_{ss'}z_{ss'} \\ x_{ss'}y_{ss'} & r_{ss'}^2 - 3y_{ss'}^2 & y_{ss'}z_{ss'} \\ x_{ss'}z_{ss'} & y_{ss'}z_{ss'} & r_{ss'}^2 - 3z_{ss'}^2 \end{bmatrix} \quad (7)$$

where $\mathbf{1}$ is the unit tensor, $x_{ss'}$, $y_{ss'}$ and $z_{ss'}$ are the x , y and z components of the vector $\mathbf{r}_{ss'}(t)$, between nuclei s and s' , and γ_s is the magnetogyric ratio of spin s . The time dependence of this internuclear vector is explicit in most of equation (7), but is suppressed for clarity in the final term. The scalar distance between the two interacting nuclear spins is given by $r_{ss'}$.

Expressions of the type given in equation (6) may be rearranged to give an inner product of two matrices using the relationship

$$\hat{\mathbf{A}} \cdot \mathbf{M} \cdot \hat{\mathbf{B}} = \sum_{i,j}^{x,y,z} M_{ij} \hat{T}_{ij} \quad (8)$$

where M_{ij} are the elements of the matrix $\mathbf{M}$, and the elements of the composite tensor $\mathbf{T}$ are formed from $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$ in accordance with $\hat{T}_{ij} = \hat{A}_i \hat{B}_j$. Thus, for the dipolar interaction,

$$\hat{\mathbf{T}}(s, s') = \begin{bmatrix} \hat{I}_x(s)\hat{I}_x(s') & \hat{I}_x(s)\hat{I}_y(s') & \hat{I}_x(s)\hat{I}_z(s') \\ \hat{I}_y(s)\hat{I}_x(s') & \hat{I}_y(s)\hat{I}_y(s') & \hat{I}_y(s)\hat{I}_z(s') \\ \hat{I}_z(s)\hat{I}_x(s') & \hat{I}_z(s)\hat{I}_y(s') & \hat{I}_z(s)\hat{I}_z(s') \end{bmatrix} \quad (9)$$

and the Hamiltonian for the dipole–dipole interaction becomes

$$\hat{\mathcal{H}}_{dd}(t) = \hbar \mathbf{D}(t) \cdot \hat{\mathbf{T}}(s, s') \quad (10)$$

Using a formulation analogous to that for the dipolar Hamiltonian, the chemical shift Hamiltonian is

$$\hat{\mathcal{H}}_{csa}(t) = \hbar \gamma_s \hat{\mathbf{I}}(s) \cdot \boldsymbol{\delta}(t) \cdot \mathbf{B} = \hbar \boldsymbol{\delta}(t) \cdot \hat{\mathbf{T}}(s, b) \quad (11)$$

where the time-dependent Cartesian chemical shift tensor $\boldsymbol{\delta}(t)$ is given by

$$\boldsymbol{\delta}(t) = \gamma_s B_0 \begin{bmatrix} \delta_{xx}(t) & \delta_{xy}(t) & \delta_{xz}(t) \\ \delta_{yx}(t) & \delta_{yy}(t) & \delta_{yz}(t) \\ \delta_{zx}(t) & \delta_{zy}(t) & \delta_{zz}(t) \end{bmatrix} \quad (12)$$

A composite spin field tensor $\mathbf{T}(a, b)$ is provided by

$$\hat{\mathbf{T}}(s, b) = \begin{bmatrix} \hat{I}_x(s)b_x & \hat{I}_x(s)b_y & \hat{I}_x(s)b_z \\ \hat{I}_y(s)b_x & \hat{I}_y(s)b_y & \hat{I}_y(s)b_z \\ \hat{I}_z(s)b_x & \hat{I}_z(s)b_y & \hat{I}_z(s)b_z \end{bmatrix} \quad (13)$$

where $b_q = B_q/B_0$, for $q = x, y$, and z . These reduced field variables provide a way to track the direction of the magnetic field that quantizes the nuclear spins. It is therefore appropriate that this feature be retained with the spin variables in the mathematical development of spin relaxation.

3 SEPARATION OF THE NUCLEAR SPIN HAMILTONIAN INTO SPIN AND SPATIAL TERMS

3.1 Spin Matrices and Spatial Spectral Densities

In a manner similar to equation (8), all μ mechanistic components in the Hamiltonian may also be formulated with

irreducible spherical tensors in spin, $\hat{T}_{-m}^l(s_\mu)$, and in time-dependent spatial variables, $F_m^l(\mu, t)$, as follows:

$$\hat{\mathcal{H}}_\mu = \hbar \sum_l \sum_{m=-l}^l (-1)^m \hat{T}_{-m}^l(s_\mu) F_m^l(\mu, t) \quad (14)$$

where the spin designator s_μ for the μ th interaction represents either a single spin mechanism such as given by equation (11) for the chemical shift interaction or else the two-spin dipolar mechanism in equation (6). For convenience, s_μ is subsumed into the summation index μ . In equation (14) the indices l and m span all l ranks and corresponding m projections in the irreducible spherical operators. These tensors specified by $\hat{T}_{-m}^l(s_\mu)$ and $F_m^l(\mu, t)$ are defined in the laboratory coordinate system, with the magnetic field along the z axis. Such formulations of the Hamiltonians, defined in terms of spin and spatial spherical tensors, have been treated by Mehring¹⁶ and by Smith et al.¹⁷ Details of the spin, $\hat{T}_{-m}^l(s_\mu)$, and spatial, $F_m^l(\mu, t)$, tensors are provided in Section 3.2.

The Hamiltonian in equation (14) may be introduced into equation (5) to give

$$\begin{aligned} K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda}) = & \sum_{\mu, \mu'} \sum_{l, l'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \int_0^\infty \{ S_{ll'mm'}^{\mu\mu'} \langle F_m^l(\mu, t) \\ & \times F_{m'}^{l'}(\mu, t + \tau) \rangle e^{-i\omega_{\kappa\lambda}\tau} + [S_{ll'mm'}^{\mu\mu'} \\ & \times \langle \hat{F}_m^l(\mu, t) \hat{F}_{m'}^{l'}(\mu', t + \tau) \rangle + S_{ll'mm'}^{\mu'\mu} \\ & \times \langle F_m^l(\mu', t) F_{m'}^{l'}(\mu, t + \tau) \rangle] e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (15)$$

where the $\langle \rangle$ around the spatial correlation functions specifies an ensemble average, and the spin matrix $S_{ll'mm'}^{\mu\mu'}$ in equation (15) is defined by

$$S_{ll'mm'}^{\mu\mu'} = (-1)^m \langle \kappa | \hat{T}_{-m}^l(s_\mu) | \lambda \rangle \langle \lambda' | \hat{T}_{-m'}^{l'}(s_{\mu'}) | \kappa' \rangle \quad (16)$$

The autocorrelation spin function $S_{ll'mm'}^{\mu\mu}$ is obtained by merely setting $\mu' = \mu$ in equation (16).

The spin matrices, embodied in $S_{ll'mm'}^{\mu\mu'}$, provide spin selection rules that impose constraints upon the relaxation process. Included in these constraints is the symmetry of the coupled spin system, which reflects the symmetry of the parent molecule. Selection rules governing the constraints upon the various l and m values, however, have several important consequences for the correlation functions given in equation (16). In order for $S_{ll'mm'}^{\mu\mu'}$ to survive under the secular approximation, i.e., $E_{\kappa'} - E_{\lambda'} = E_\kappa - E_\lambda$, it is necessary that any change in the angular momentum between eigenstates $\langle \lambda' |$ and $\langle \kappa' |$ be equal and opposite in sign to the change in angular momentum between eigenstates $\langle \kappa |$ and $\langle \lambda |$. This requires that the two spin tensors have conjugate angular momentum properties, i.e., $l' = l$ but $m' = -m$. Under these constraints, the summations on rank and projection indices in equation (15) are contracted to a single l and a single m index, and the respective auto- and cross-correlated spin matrices are given

as follows:

$$\left. \begin{aligned} S_{lm}^\mu &= \delta_{l,l'} \delta_{m',-m} S_{ll'mm'}^\mu \\ &= (-1)^m \langle \kappa | \hat{T}_{-m}^l(s_\mu) | \lambda \rangle \langle \lambda' | \hat{T}_m^l(s_\mu) | \kappa' \rangle \\ S_{lm}^{\mu\mu'} &= \delta_{l,l'} \delta_{m',-m} S_{ll'mm'}^{\mu\mu'} \\ &= (-1)^m \langle \kappa | \hat{T}_{-m}^l(s_\mu) | \lambda \rangle \langle \lambda' | \hat{T}_m^l(s_{\mu'}) | \kappa' \rangle \end{aligned} \right\} \quad (17)$$

Using the Kronecker deltas to contract l' and m' converts equation (15) into the following simplified expressions for the auto- and cross-correlation spectral densities:

$$\begin{aligned} K_{\kappa\lambda\kappa'\lambda'}(\omega_{\kappa\lambda}) = & \sum_l \sum_{m=-l}^l \left[\sum_\mu S_{lm}^\mu \mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) \right. \\ & + \sum_{\mu\mu'} \frac{1}{2} (S_{lm}^{\mu\mu'} + S_{lm}^{\mu'\mu}) \text{Re} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) \\ & \left. + \sum_{\mu\mu'} \frac{1}{2} (S_{lm}^{\mu\mu'} - S_{lm}^{\mu'\mu}) \text{Im} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) \right] \end{aligned} \quad (18)$$

where $S_{lm}^{\mu\mu'} + S_{lm}^{\mu'\mu}$ and $S_{lm}^{\mu\mu'} - S_{lm}^{\mu'\mu}$ are, respectively, even and odd spin matrices that select either the real, $\text{Re} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$, or imaginary, $\text{Im} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$, portions of the cross-correlated spatial terms. The factors of $\frac{1}{2}$ in the cross terms are required to avoid double counting with the symmetrizing of spin in equation (18). The following definitions hold for the spatial spectral densities:

$$\begin{aligned} \mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) = & \frac{1}{2} (-1)^m \int_{-\infty}^\infty \langle F_m^l(\mu, t) F_{-m}^l(\mu, t + \tau) \rangle \\ & \times e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (19)$$

$$\begin{aligned} \text{Re} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) = & \frac{1}{2} (-1)^m \int_{-\infty}^\infty [\langle F_m^l(\mu, t) F_{-m}^l(\mu', t + \tau) \rangle \\ & + \langle F_m^l(\mu', t) F_{-m}^l(\mu, t + \tau) \rangle] e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (20)$$

$$\begin{aligned} \text{Im} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) = & (-1)^m \int_0^\infty [\langle F_m^l(\mu, t) F_{-m}^l(\mu', t + \tau) \rangle \\ & - \langle F_m^l(\mu', t) F_{-m}^l(\mu, t + \tau) \rangle] e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (21)$$

The real spectral densities, $\mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda})$ and $\text{Re} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$, given in equations (19) and (20), are Fourier transforms of the spatial auto- and cross-correlation functions, respectively. Both now possess time-reversal symmetry, and the integral may be changed accordingly from $(0, \infty)$ to $(-\infty, \infty)$. The $\frac{1}{2}$ in front of each integral is associated with doubling the range of these integrals.

The imaginary spectral density $\text{Im} \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$ given in equation (21) and selected by the $S_{lm}^{\mu\mu'} - S_{lm}^{\mu'\mu}$ spin matrices, is an odd function in time and must retain the $(0, \infty)$ range in its integral. The spin matrices $S_{lm}^{\mu\mu'}$ are Hermitian, and as such yield only real values, but reversing the order of the interaction labels in individual spin matrices can in some instances change the sign of $S_{lm}^{\mu\mu'}$. Under these conditions, such an alternation in

sign will quench the real terms needed for relaxation, but will introduce the imaginary component of the spatial correlation functions. This imaginary term accounts for the second-order dynamic frequency shift discussed earlier; hence, only the two real terms are considered further in this article on molecular motion and spin relaxation. The angle-bracketed correlation functions specify ensemble averages over all equivalent spins in the sample.

3.2 The General Cartesian Interaction Tensor and its Irreducible Spherical Tensor

A typical interaction tensor, in the principal rotational diffusion frame, is a 3×3 Cartesian tensor that may be separated into three individual tensors of rank zero, one, and two as follows:

$$\begin{bmatrix} \mu_{xx} & \mu_{xy} & \mu_{xz} \\ \mu_{yx} & \mu_{yy} & \mu_{yz} \\ \mu_{zx} & \mu_{zy} & \mu_{zz} \end{bmatrix} = \mu_0 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + \begin{bmatrix} 0 & \mu_{xy}^{(a)} & \mu_{xz}^{(a)} \\ -\mu_{xy}^{(a)} & 0 & \mu_{yz}^{(a)} \\ -\mu_{xz}^{(a)} & -\mu_{yz}^{(a)} & 0 \end{bmatrix} + \begin{bmatrix} \mu_{xx}^{(s)} - \mu_0 & \mu_{xy}^{(s)} & \mu_{xz}^{(s)} \\ \mu_{xy}^{(s)} & \mu_{yy}^{(s)} - \mu_0 & \mu_{yz}^{(s)} \\ \mu_{xz}^{(s)} & \mu_{yz}^{(s)} & \mu_{zz}^{(s)} - \mu_0 \end{bmatrix} \quad (22)$$

where the isotropic scalar term $\mu_0 = \frac{1}{3}(\mu_{xx} + \mu_{yy} + \mu_{zz})$, the antisymmetric elements $\mu_{ij}^{(a)} = \frac{1}{2}(\mu_{ij} - \mu_{ji})$, and the symmetric elements $\mu_{ij}^{(s)} = \frac{1}{2}(\mu_{ij} + \mu_{ji})$ have been isolated, respectively, into zeroth-, first- and second-rank tensors.

Using the prescription of Mehring,¹⁸ the general irreducible spherical tensors are readily obtained from equation (22) as

$$\left. \begin{aligned} T_0^{(0)}(\mu) &= -\sqrt{3}\mu_0 = -\sqrt{\frac{1}{3}}(\mu_{xx} + \mu_{yy} + \mu_{zz}) \\ T_0^{(1)}(\mu) &= -i\sqrt{2}\mu_{xy}^{(a)} = -i\sqrt{\frac{1}{2}}(\mu_{xy} - \mu_{yx}) \\ T_{\pm 1}^{(1)}(\mu) &= \mu_{xz}^{(a)} \pm i\mu_{yz}^{(a)} = \frac{1}{2}[(\mu_{xz} - \mu_{zx}) \pm i(\mu_{yz} - \mu_{zy})] \\ T_0^{(2)}(\mu) &= \sqrt{\frac{1}{6}}[3\mu_{zz}^{(s)} - (\mu_{xx}^{(s)} + \mu_{yy}^{(s)} + \mu_{zz}^{(s)})] \\ &= \sqrt{\frac{3}{2}}(\mu_{zz} - \mu_0) \\ T_{\pm 1}^{(2)}(\mu) &= \mp(\mu_{xz}^{(s)} \pm i\mu_{yz}^{(s)}) \\ &= \mp\frac{1}{2}[(\mu_{xz} + \mu_{zx}) \pm i(\mu_{yz} + \mu_{zy})] \\ T_{\pm 2}^{(2)}(\mu) &= [\frac{1}{2}(\mu_{xx}^{(s)} - \mu_{yy}^{(s)}) \pm i\mu_{xy}^{(s)}] \\ &= \frac{1}{2}[(\mu_{xx} - \mu_{yy}) \pm i(\mu_{xy} + \mu_{yx})] \end{aligned} \right\} \quad (23)$$

These expressions may be used with equations (7), (9), (12), and (13) to define both the spin, $\hat{T}_{-m}^l(s_\mu)$, and spatial, $F_m^l(\mu, t)$, variables used in equations (14)–(21).

3.2.1 Specific Expressions for Various Irreducible Spin Operators

The irreducible spherical tensors defined in equation (23) may be used for the two coupled spin angular momentum

operators $\hat{I}^i$ and $\hat{I}^j$ encountered in equation (9) for the dipole–dipole Hamiltonian; these spin tensors are given by

$$\left. \begin{aligned} \hat{T}_0^{(0)}(i, j) &= -\sqrt{\frac{1}{3}} \left[\hat{I}_z^i \hat{I}_z^j + \frac{1}{2}(\hat{I}_+^i \hat{I}_-^j + \hat{I}_-^i \hat{I}_+^j) \right] \\ \hat{T}_0^{(1)}(i, j) &= \sqrt{\frac{1}{8}}(\hat{I}_+^i \hat{I}_-^j - \hat{I}_-^i \hat{I}_+^j) \\ \hat{T}_{\pm 1}^{(1)}(i, j) &= \frac{1}{2}(\hat{I}_\pm^i \hat{I}_\pm^j - \hat{I}_z^i \hat{I}_\pm^j) \\ \hat{T}_0^{(2)}(i, j) &= \sqrt{\frac{2}{3}} \left[\hat{I}_z^i \hat{I}_z^j - \frac{1}{4}(\hat{I}_+^i \hat{I}_-^j + \hat{I}_-^i \hat{I}_+^j) \right] \\ \hat{T}_{\pm 1}^{(2)}(i, j) &= \mp\frac{1}{2}(\hat{I}_\pm^i \hat{I}_\pm^j + \hat{I}_z^i \hat{I}_\pm^j) \\ \hat{T}_{\pm 2}^{(2)}(i, j) &= \frac{1}{2}\hat{I}_\pm^i \hat{I}_\pm^j \end{aligned} \right\} \quad (24)$$

The ladder spin operators $\hat{I}_\pm = \hat{I}_x \pm i\hat{I}_y$, used extensively in NMR, have been employed here. These ladder operators should not be confused with the similar irreducible spherical angular momentum operators $\hat{I}_{+1}$ and $\hat{I}_{-1}$ used elsewhere.

The appropriate spin–field combined tensors for the anisotropic chemical shift interaction is formed by coupling the first-rank angular momentum operators, for a single spin with the first-rank magnetic field vector $\mathbf{B}_0$. The resulting combined irreducible spherical tensors are given by

$$\left. \begin{aligned} \hat{T}_0^{(0)}(\text{csa}) &= -\sqrt{\frac{1}{3}} \left[\hat{I}_z b_z + \frac{1}{2}(\hat{I}_+ b_- + \hat{I}_- b_+) \right] \\ \hat{T}_0^{(1)}(\text{csa}) &= \sqrt{\frac{1}{8}}(\hat{I}_+ b_- - \hat{I}_- b_+) \\ \hat{T}_{\pm 1}^{(1)}(\text{csa}) &= -\frac{1}{2}(\hat{I}_\pm \hat{b}_\pm - \hat{I}_\pm \hat{b}_z) \\ \hat{T}_0^{(2)}(\text{csa}) &= \sqrt{\frac{2}{3}} \left[\hat{I}_z b_z - \frac{1}{4}(\hat{I}_+ b_- + \hat{I}_- b_+) \right] \\ \hat{T}_{\pm 1}^{(2)}(\text{csa}) &= \mp\frac{1}{2}(\hat{I}_\pm \hat{b}_z + \hat{I}_z \hat{b}_\pm) \\ \hat{T}_{\pm 2}^{(2)}(\text{csa}) &= \frac{1}{2}\hat{I}_\pm \hat{b}_\pm \end{aligned} \right\} \quad (25)$$

where $\mathbf{b}_\pm = (B_x \mathbf{h} \pm iB_y \mathbf{j})/B_0$ and $b_z = B_z/B_0$. B_x , B_y , and B_z are the components of $\mathbf{B}_0$ in a general coordinate frame, with unit vectors $\mathbf{h}$, $\mathbf{j}$, and $\mathbf{k}$ along the x , y , and z axes, respectively.

In the laboratory frame the static magnetic field is $B_z = B_0$, and $B_x = B_y = 0$. This coordinate system simplifies equation (25) considerably to yield the following combined irreducible spin–field tensors:

$$\left. \begin{aligned} \hat{T}_0^{(0)}(\text{csa}) &= -\sqrt{\frac{1}{3}}\hat{I}_z b_z, & \hat{T}_0^{(2)}(\text{csa}) &= \sqrt{\frac{2}{3}}\hat{I}_z b_z \\ \hat{T}_0^{(1)}(\text{csa}) &= 0, & \hat{T}_{\pm 1}^{(2)}(\text{csa}) &= \mp\frac{1}{2}\hat{I}_\pm b_z \\ \hat{T}_{\pm 1}^{(1)}(\text{csa}) &= \frac{1}{2}\hat{I}_\pm b_z, & \hat{T}_{\pm 2}^{(2)}(\text{csa}) &= 0 \end{aligned} \right\} \quad (26)$$

3.2.2 Specific Irreducible Spatial Operators

The time-dependent irreducible spatial terms $\mathbf{F}(\mu, t)$, used in equation (14) for a general second-rank interaction, include $F_0^{(1)}(\mu, t)$, $F_{\pm 1}^{(1)}(\mu, t)$, $F_0^{(2)}(\mu, t)$, $F_{\pm 1}^{(2)}(\mu, t)$, and $F_{\pm 2}^{(2)}(\mu, t)$. The zeroth-rank member, $\hat{F}_0^{(0)}(\mu)$, is proportional to the trace of the Cartesian interaction tensor, and is therefore time-independent under molecular tumbling. Specific expressions for each of the relevant terms may be obtained for the dipolar and chemical shift anisotropy mechanisms, respectively, from

equation (7) and (12) following the prescription of equation (23). These elements of the spatial irreducible tensors characterize the temporal motions of molecular tumbling while introducing the geometry of spin interactions into the relaxation Hamiltonian.

The $F_0^{(0)}(\mu, t)$ term is invariant under molecular tumbling, and therefore cannot create magnetic field oscillations that affect spin relaxation processes; it need not be considered further. Fluctuating magnetic fields arising from first-rank terms, $\hat{F}_0^{(1)}(\mu, t)$ and $\hat{F}_{\pm 1}^{(1)}(\mu, t)$, are modulated by molecular motion and will relax the nuclear spins. These first-rank terms do not exist for the prominent dipolar interactions, but the first-rank antisymmetric chemical shift terms can relax a magnetic spin. Such chemical shift terms, however, are poorly characterized compared with the more commonly encountered second-rank terms. The first-rank chemical shift anisotropy terms are easily formulated with the methods outlined below, but theoretical studies would indicate that these interesting terms are probably restricted to fairly unusual molecular systems.^{19–21} Molecules for which the antisymmetric, first-rank chemical shift anisotropy terms appear to be important include π -electron systems with sterically distorted bond arrangements. The magnitude of such first-rank chemical shift terms, supported theoretically in a few unusual molecules, is difficult to establish experimentally, since only the zeroth- and second-rank chemical shift terms may be measured in Zeeman splittings. Consequently, only the specifics of second-rank terms are developed in this article, which focuses primarily upon molecular diffusional motion. The methods are sufficiently general, however, that they may be extended to first-rank terms when needed.

In order to evaluate the second-rank dipole–dipole and chemical shift anisotropy tensors for all molecules in a sample, an ensemble average of $\mathbf{F}(\mu, t)$ must be obtained using standard statistical mechanical methods to describe the effects of Brownian motion in liquids.²² Attention is therefore directed to separating the molecular motional features that are time-dependent from the specific formulations of the irreducible spatial interaction tensors. Once the time dependence has been extracted in Sections 4 and 5, the exact form of the remaining time-independent interaction tensors will be considered.

4 MOTIONAL POWER DENSITIES IN THE MOLECULAR ROTATIONAL DIFFUSION FRAME

The irreducible spatial tensor, $\mathbf{F}(\mu, t)$, may be obtained by a coordinate transformation from the corresponding spatial tensor in the molecular rotational diffusion frame as follows:

$$F_m^l(\mu, t) = \sum_{n=-l}^l \mathcal{D}_{n,m}^{(l)}(\Omega_t) \mathcal{F}_n^l(\mu) \quad (27)$$

where $F_m^l(\mu, t)$ is in the laboratory frame and $\mathcal{F}_n^l(\mu)$ is in the principal axis frame of the molecular rotational diffusion tensor. The Wigner rotation matrix elements $\mathcal{D}_{n,m}^{(l)}(\Omega_t)$ transform the diffusion frame into the laboratory coordinate frame and simultaneously absorb the explicit time dependence manifest in $F_m^l(\mu, t)$. The time-dependent Euler angles are represented by $\Omega_t \sum (\alpha_t, \beta_t, \gamma_t)$. The interaction tensor $\mathcal{F}_n^l(\mu)$, given in

the principal diffusion frame, provides a time-independent spatial description of the spin interaction for the μ th relaxation mechanism. This division of $F_m^l(\mu, t)$ into time-dependent and time-independent terms separates the molecular dynamics, described by $\mathcal{D}_{n,m}^{(l)}(\Omega_t)$, from the NMR spectral and geometrical parameters contained in $\mathcal{F}_n^l(\mu)$.

Substituting equation (27) into equations (19) and (20) provides expressions for the auto- and cross-correlated spectral densities as follows:

$$\begin{aligned} \mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) &= \frac{1}{2}(-1)^m \sum_{n,n'=-l}^l \int_{-\infty}^{\infty} \langle \mathcal{D}_{n,m}^{(l)}(\Omega_t) \mathcal{F}_n^l(\mu) \\ &\quad \times \mathcal{D}_{n',-m}^{(l)}(\Omega_{t+\tau}) \mathcal{F}_{n'}^l(\mu) \rangle e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (28a)$$

$$\begin{aligned} \text{Re } \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) &= \frac{1}{2}(-1)^m \sum_{n,n'=-l}^l \int_{-\infty}^{\infty} \{ \langle \mathcal{D}_{n,m}^{(l)}(\Omega_t) \mathcal{F}_n^l(\mu) \\ &\quad \times \mathcal{D}_{n',-m}^{(l)}(\Omega_{t+\tau}) \mathcal{F}_{n'}^l(\mu') \rangle + \langle \mathcal{D}_{n,m}^{(l)}(\Omega_t) \mathcal{F}_n^l(\mu') \\ &\quad \times \mathcal{D}_{n',-m}^{(l)}(\Omega_{t+\tau}) \mathcal{F}_{n'}^l(\mu) \rangle \} e^{-i\omega_{\kappa\lambda}\tau} d\tau \end{aligned} \quad (28b)$$

Since all of the interaction tensors typified by $\mathcal{F}_n^l(\mu)$ are time-independent when defined in the principal axis frame of the molecular rotational diffusion tensor, they may be factored out of the ensemble-averaging brackets, and they also pass through the time integrals given in equation (28). The ergodic hypothesis renders both time- and sample-averaged ensembles equivalent, thereby allowing the removal also of the explicit time variable t from equation (28) while retaining the correlation time difference τ . Rearranging equation (28), the following expressions are obtained for $\mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda})$ and $\text{Re } \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$:

$$\mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) = \sum_{n,n'=-l}^l [\mathcal{F}_n^l(\mu) \mathcal{F}_{n'}^l(\mu)] \mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda}) \quad (29)$$

$$\begin{aligned} \text{Re } \mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda}) &= \sum_{n,n'=-l}^l [\mathcal{F}_n^l(\mu) \mathcal{F}_{n'}^l(\mu') + \mathcal{F}_n^l(\mu') \mathcal{F}_{n'}^l(\mu)] \\ &\quad \times \mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda}) \end{aligned} \quad (30)$$

All of the time-dependent terms in equation (28) have been collected together into a molecular motional power density $\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda})$, given by

$$\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda}) = \frac{1}{2}(-1)^m \int_{-\infty}^{\infty} G_{nn'm}^{(l)}(\tau) e^{-i\omega_{\kappa\lambda}\tau} d\tau \quad (31)$$

The correlation function $G_{nn'm}^{(l)}(\tau)$ appearing in $\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda})$ is totally free from nuclear spin parameters, and it is the same function for both the autocorrelated spectral density in equation (29) and the cross-correlated spectral density in equation (30). $G_{nn'm}^{(l)}(\tau)$ characterizes only molecular motional features, and, consistently with equations (28)–(31), it has the form

$$\begin{aligned} G_{nn'm}^{(l)}(\tau) &= \langle \mathcal{D}_{n,m}^{(l)}(\Omega_0) \mathcal{D}_{n',-m}^{(l)}(\Omega_\tau) \rangle \\ &= (-1)^{m-n'} \langle \mathcal{D}_{n,m}^{(l)}(\Omega_0) \mathcal{D}_{-n',m}^{(l)*}(\Omega_\tau) \rangle \end{aligned} \quad (32)$$

The Euler angles for the molecular orientations relative to the laboratory frame are specified at $t + 0$ by Ω_0 and at $t + \tau$ by Ω_τ . As discussed above, the explicit dependence on time t found in equation (28) has been removed in this expression for $G_{nn'm}^{(l)}(\tau)$, which depends only upon the time-difference variable τ . Averaging $G_{nn'm}^{(l)}(\tau)$ with the integral ranging over $(-\infty, \infty)$ recognizes the time-reversal symmetry of correlation functions, such as $G_{nn'm}^{(l)}(\tau)$, that describe stationary random molecular motions.¹⁵

5 THE FAVRO EQUATION AND MOLECULAR ROTATIONAL DIFFUSION IN LIQUIDS

5.1 Conditional Probabilities for Correlation of Molecular Rotational Orientations

The correlation function in equation (32) implies an ensemble average over all possible orientational angles, and this average may be expressed by a double integral over the probabilistic weighted angles Ω_0 and Ω_τ as follows:

$$G_{nn'm}^{(l)}(\tau) = (-1)^{m-n'} \iint d\Omega_0 d\Omega_\tau \times [\mathcal{D}_{n,m}^{(l)}(\Omega_0) \mathcal{D}_{-n',m}^{(l)*}(\Omega_\tau) P(\Omega_0) P(\Omega_0|\Omega_\tau)] \quad (33)$$

where $P(\Omega_0)$ is the probability that the molecule has an orientation Ω_0 at an arbitrary time zero and $P(\Omega_0|\Omega_\tau)$ is a conditional probability that the molecule will have the orientation Ω_τ at a time τ , given that at time zero the orientation was Ω_0 . Molecules dissolved in randomly ordered or isotropic fluids have no preferred orientation, and the initial probability $P(\Omega_0)$ is constant for all values of Ω_0 . Thus, $P(\Omega_0)$ can be evaluated by normalizing to unity over all orientations as follows:

$$\begin{aligned} \int P(\Omega_0) d\Omega_0 &= P(\Omega_0) \int_0^{2\pi} d\alpha \int_0^\pi \sin \beta d\beta \int_0^{2\pi} d\gamma \\ &= 8\pi^2 P(\Omega_0) = 1 \end{aligned} \quad (34)$$

$$P(\Omega_0) = (8\pi^2)^{-1} \quad (35)$$

Note that the assumption of isotropic liquid ordering does not imply that the molecular tumbling is isotropic. This discussion, however, does presume a rigid molecule without internal degrees of motional freedom.

The Favro equation⁴ for molecular diffusion has the same general form as the wave equation for a rigid asymmetric rotor, and characterizes the $P(\Omega_0|\Omega_\tau)$ conditional probability according to

$$\begin{aligned} \frac{\partial P(\Omega_0|\Omega_\tau)}{\partial \tau} &= \sum_{p,q} \hat{\mathcal{L}}_p R'_{pq} \hat{\mathcal{L}}_q P(\Omega_0|\Omega_\tau) \\ &= -\hat{\mathcal{R}} P(\Omega_0|\Omega_\tau) \end{aligned} \quad (36)$$

where $\hat{\mathcal{R}}$ is the rotational diffusion operator (defined by this equation), and $\hat{\mathcal{L}}_p$ and $\hat{\mathcal{L}}_q$ are the p th and q th components

of the angular momentum operator. R'_{pq} is the general pq component of the rotational diffusion tensor in an arbitrary reference frame, and is defined by

$$R'_{pq} = \frac{1}{2} \lim_{\Delta\tau \rightarrow 0} \frac{\langle \varphi_p \varphi_q \rangle}{\Delta\tau} \quad (37)$$

where φ_p and φ_q are the rotational angles about the p th and q th molecular axes, respectively.

Under the assumption of an isotropic fluid, R'_{pq} is a symmetric tensor that may be diagonalized in the principal axis frame (PAF) of the molecular rotational diffusion tensor. This provides the generalized rotational diffusion operator $\hat{\mathcal{R}}$ (PAF) as follows:

$$\begin{aligned} \hat{\mathcal{R}}(\text{PAF}) &= \sum_{p,q} \hat{\mathcal{L}}_p R_{pq}(\text{PAF}) \hat{\mathcal{L}}_q \\ &= R_{xx} \hat{\mathcal{L}}_x^2 + R_{yy} \hat{\mathcal{L}}_y^2 + R_{zz} \hat{\mathcal{L}}_z^2 \end{aligned} \quad (38)$$

where the principal components, without primes, of the rotational diffusion tensor are given by R_{xx} , R_{yy} , and R_{zz} . For convenience, equation (38) may be rewritten using irreducible angular momentum operators as

$$\hat{\mathcal{R}}(\text{PAF}) = A \hat{\mathcal{L}}^2 + \frac{1}{2} B (\hat{\mathcal{L}}_+^2 + \hat{\mathcal{L}}_-^2) + C \hat{\mathcal{L}}_z^2 \quad (39)$$

where

$$\begin{aligned} \hat{\mathcal{L}}_+ &= \hat{\mathcal{L}}_x + i\hat{\mathcal{L}}_y, \quad \hat{\mathcal{L}}_- = \hat{\mathcal{L}}_x - i\hat{\mathcal{L}}_y, \\ \hat{\mathcal{L}}^2 &= \hat{\mathcal{L}}_x^2 + \hat{\mathcal{L}}_y^2 + \hat{\mathcal{L}}_z^2 \end{aligned} \quad (40)$$

$$\begin{aligned} A &= \frac{1}{2} (R_{xx} + R_{yy}) \\ B &= \frac{1}{2} (R_{xx} - R_{yy}) \\ C &= R_{zz} - \frac{1}{2} (R_{xx} + R_{yy}) \end{aligned} \quad (41)$$

Equation (36) has a solution of the general form

$$P(\Omega_0|\Omega_\tau) = \sum_v g_v(\tau) \Psi_v(\Omega_\tau) \quad (42)$$

The explicit dependence of $P(\Omega_0|\Omega_\tau)$ upon τ is now contained in $g_v(\tau)$, and the $\Psi_v(\Omega_\tau)$ are expressed as stationary eigenfunctions of the diffusion operator $\hat{\mathcal{R}}$ with eigenvalues b_v as follows:

$$\hat{\mathcal{R}} \Psi_v(\Omega_\tau) = b_v \Psi_v(\Omega_\tau) \quad (43)$$

By substituting equation (42) into equation (36) and using equation (43) the following expression is obtained:

$$\sum_v \Psi_v(\Omega_\tau) \frac{\partial g_v(\tau)}{\partial t} = - \sum_v b_v g_v(\tau) \Psi_v(\Omega_\tau) \quad (44)$$

Matching the corresponding coefficients of the linearly independent functions $\Psi_v(\Omega_\tau)$, the following differential equation for $g_v(\tau)$ is obtained:

$$\frac{\partial g_v(\tau)}{\partial t} = -b_v g_v(\tau) \quad (45)$$

which has the general solution

$$g_v(\tau) = g_v(0) e^{-b_v \tau} \quad (46)$$

Standard expansion methods, such as used in equation (42), also render an expression for $g_v(\tau)$ as follows:

$$g_v(\tau) = \int d\Omega \Psi_v^*(\Omega_\tau) P(\Omega_0|\Omega_\tau) \quad (47)$$

The boundary condition $P(\Omega_0|\Omega_{\tau=0}) = \delta_{\Omega_0, \Omega_\tau}^{(3)}$ for $\tau = 0$ may be used with equation (47) to evaluate $g_v(0)$, giving the expression

$$\begin{aligned} g_v(0) &= \int d\Omega \Psi_v^*(\Omega_\tau) P(\Omega_0|\Omega_{\tau=0}) \\ &= \int d\Omega \Psi_v^*(\Omega_\tau) \delta_{\Omega_0, \Omega_\tau}^{(3)} = \Psi_v^*(\Omega_0) \end{aligned} \quad (48)$$

Use has been made here of the definition of the three-dimensional Dirac delta function, i.e., $f(a) = \int \delta_{a,b}^{(3)} f(b) db$. Combining equations (42), (46), and (47) provides the following expression for $P(\Omega_0|\Omega_\tau)$:

$$P(\Omega_0|\Omega_\tau) = \sum_v \Psi_v^*(\Omega_0) \Psi_v(\Omega_\tau) e^{-b_v \tau} \quad (49)$$

5.2 Rotational Diffusion Eigenvalues and Eigenvectors

The challenge has now been reduced to finding $\Psi_v(\Omega_\tau)$, the eigenfunctions of $\hat{\mathcal{R}}(\text{PAF})$ given in equation (43). The corresponding eigenvalues b_v are obtained from the typical characteristic equation in the operator $\hat{\mathcal{R}}(\text{PAF})$. Wavefunctions²³ for the analogous asymmetric rotor problem in quantum mechanics are the Wigner rotation functions $\mathcal{D}_{k,m}^{(l)}(\Omega_t)$, and these provide an excellent basis^{3,24} for expanding the eigenfunctions $\Psi_v(\Omega_\tau)$ associated with rotational diffusion as follows:

$$\Psi_v = \sum_{l,k,j} c_{v,k,j}^{(l)} \psi_{l,k,j} = \sum_{l,k,j} c_{v,k,j}^{(l)} \sqrt{\frac{2l+1}{8\pi^2}} \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) \quad (50)$$

The factor $\sqrt{2l+1/8\pi^2}$ is a normalization constant for the functions $\mathcal{D}_{k,j}^{(l)}(\Omega_\tau)$ when integrated over the space of Euler angles Ω_τ . The various $c_{v,k,j}^{(l)}$ are the appropriate eigenvectors to be obtained along with the eigenvalues b_v from the characteristic equation in the diffusion operator $\hat{\mathcal{R}}(\text{PAF})$. Because of the analogy with the asymmetric rigid rotor problem, it is not surprising that expansions in Wigner rotation matrices provide a natural basis for the study of rotational diffusion.

The functions $\mathcal{D}_{k,j}^{(l)}(\Omega_\tau)$ possess a number of angular momentum properties associated with the total angular momentum squared, $\hat{\mathcal{L}}^2$, and the z component of the angular momentum in the molecular diffusion frame, $\hat{\mathcal{L}}_z$. The $\mathcal{D}_{k,j}^{(l)}(\Omega_\tau)$ also manifest a third important property for the z' component

of angular momentum, $\hat{\mathcal{L}}_{z'}$, in the laboratory frame. This property, however, is only used when a molecule is dissolved in ordered solvents, e.g., nematic liquid crystals. Thus,

$$\left. \begin{aligned} \hat{\mathcal{L}}^2 \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) &= l(l+1) \hbar^2 \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) \\ \hat{\mathcal{L}}_z \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) &= k \hbar \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) \\ \hat{\mathcal{L}}_{z'} \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) &= j \hbar \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) \end{aligned} \right\} \quad (51)$$

Expressions may also be obtained for the operator $\hat{\mathcal{L}}_+^2 + \hat{\mathcal{L}}_-^2$ found in equation (39) using the following:

$$\left. \begin{aligned} \hat{\mathcal{L}}_\pm \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) &= \sqrt{(l \mp k)(l \pm k + 1)} \mathcal{D}_{k \pm 1, j}^{(l)}(\Omega_\tau) \\ \hat{\mathcal{L}}_\pm^2 \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) &= \sqrt{(l \mp k)(l \pm k + 1)(l \mp k - 1)(l \pm k + 2)} \\ &\quad \times \mathcal{D}_{k \pm 2, j}^{(l)}(\Omega_\tau) \end{aligned} \right\} \quad (52)$$

It is important to note from equations (51) and (52) that terms in $\hat{\mathcal{R}}(\text{PAF})$ mixes only functions $\mathcal{D}_{k,j}^{(l)}(\Omega_\tau)$ with k values that differ by 0 and ± 2 units. A further useful property of functions $\mathcal{D}_{k,j}^{(l)}(\Omega_\tau)$ involves the orthogonality relationship

$$\int d\Omega_\tau \mathcal{D}_{k',j'}^{(l')*}(\Omega_\tau) \mathcal{D}_{k,j}^{(l)}(\Omega_\tau) = \frac{8\pi^2}{2l+1} \delta_{l',l} \delta_{k',k} \delta_{j',j} \quad (53)$$

Using equations (51)–(53) and the definitions in equations (38)–(40) for $\hat{\mathcal{R}}(\text{PAF})$ and $\Psi_{l,k,j}(\Omega_\tau)$, respectively, the individual matrix elements $\langle \Psi_{l,k,j}^*(\Omega_\tau) \hat{\mathcal{R}}(\text{PAF}) \Psi_{l,k,j}(\Omega_\tau) \rangle$ of the secular determinant required to solve the eigenvalue problem are given by

$$\begin{aligned} &\langle \Psi_{l,k,j}^*(\Omega_\tau) \hat{\mathcal{R}}(\text{PAF}) \Psi_{l,k,j}(\Omega_\tau) \rangle \\ &= \delta_{j',j} \{ \delta_{k',k} [l(l+1)A + k^2C] \\ &\quad + \frac{1}{2} B \delta_{k',k+2} \sqrt{(l-k)(l+k+1)(l-k-1)(l+k+2)} \\ &\quad + \frac{1}{2} B \delta_{k',k-2} \sqrt{(l+k)(l-k+1)(l+k-1)(l-k+2)} \} \end{aligned} \quad (54)$$

The characteristic equations for rank $l = 1$ and $l = 2$ are then given by

$$\begin{bmatrix} C - \epsilon_v^{(1)} & B & 0 \\ B & C - \epsilon_v^{(1)} & 0 \\ 0 & 0 & -\epsilon_v^{(1)} \end{bmatrix} \begin{bmatrix} c_{v,-1}^{(1)} \\ c_{v,+1}^{(1)} \\ c_{v,0}^{(1)} \end{bmatrix} = 0 \quad (55)$$

$$\begin{bmatrix} C - \epsilon_v^{(2)} & 3B & \vdots & & \\ 3B & C - \epsilon_v^{(2)} & \vdots & & \\ \vdots & \vdots & \ddots & \ddots & \\ \vdots & \vdots & \vdots & 4C - \epsilon_v^{(2)} & \sqrt{6}B & 0 \\ \mathbf{0} & \vdots & \sqrt{6}B & -\epsilon_v^{(2)} & \sqrt{6}B & \\ \vdots & \vdots & 0 & \sqrt{6}B & 4C - \epsilon_v^{(2)} & \end{bmatrix} \times \begin{bmatrix} c_{v,-1}^{(2)} \\ c_{v,+1}^{(2)} \\ \vdots \\ c_{v,-2}^{(2)} \\ c_{v,0}^{(2)} \\ c_{v,+2}^{(2)} \end{bmatrix} = 0 \quad (56)$$

The substitution $\epsilon_v^{(l)} = b_v^{(l)} - l(l+1)A$ has been made to simplify these two characteristic equations. The eigenvalues $b_v^{(l)}$ and corresponding eigenvectors $c_{v,k}^{(l)}$ obtained from solution of equations (55) and (56) are given in Table 1. Note that the mixing coefficients in the eigenvectors are simplified with the substitutions of $\sin \frac{1}{2}\chi$ and $\cos \frac{1}{2}\chi$, where $\chi = \tan^{-1}[\sqrt{3}(R_{xx} - R_{yy})/(2R_{zz} - R_{xx} - R_{yy})]$.

Motional symmetry will factor further the characteristic equations given in equations (55) and (56). When the molecular diffusion is symmetric, i.e., $R_{xx} = R_{yy} = R_{\perp}$, then $B = 0$ and the $\hat{L}_+^2 + \hat{L}_-^2$ term is eliminated from $\hat{\mathcal{R}}(\text{PAF})$. In this limit of symmetric diffusion, the individual Wigner rotation matrices are the solutions to the characteristic equation, and the roots for $\pm k$ become doubly degenerate. The eigenvalues and eigenvectors for symmetrical diffusion are given in Table 2 along with the simpler solutions for the spherical diffusion case, i.e., $R_{xx} = R_{yy} = R_{zz} = R_0$.

5.3 Correlation Functions for Molecular Rotational Diffusion

An explicit expression for the correlation function $G_{nn'm}^{(l)}(\tau)$ may now be obtained by first substituting equation (50) into equation (49) and using this result along with equation (35) in equation (33). The expression becomes

$$G_{nn'm}^{(l)}(\tau) = \sum_v \sum_{l'l''} \sum_{kk'} \sum_{jj'} \frac{\sqrt{(2l'+1)(2l''+1)}}{(8\pi^2)^2} c_{v,k,j}^{(l')} c_{v,k',j'}^{(l'')} \times \exp(-b_v^{(l)}\tau) (-1)^{m-n'} \left[\int d\Omega_0 \mathcal{D}_{n,m}^{(l)}(\Omega_0) \times \mathcal{D}_{k,j}^{(l')*}(\Omega_0) \int d\Omega_{\tau} \mathcal{D}_{-n',m}^{(l)*}(\Omega_{\tau}) \mathcal{D}_{k',j'}^{(l'')}(\Omega_{\tau}) \right] \quad (57)$$

The integrals over Ω_0 and Ω_{τ} are readily evaluated using the orthogonality properties of the functions $\mathcal{D}_{n,m}^{(l)}(\Omega_{\tau})$ expressed

by equation (53) to give

$$G_{nn'm}^{(l)}(\tau) = \sum_v \sum_{l'l''} \sum_{kk'} \sum_{jj'} \frac{\sqrt{(2l'+1)(2l''+1)}}{(2l+1)^2} c_{v,k,j}^{(l')} c_{v,k',j'}^{(l'')} \times \exp(-b_v^{(l)}\tau) (-1)^{m-n'} \delta_{l',l} \delta_{l'',l} \delta_{k,n} \delta_{k',-n'} \times \delta_{j',m} \delta_{j,m} \quad (58)$$

The Kronecker deltas in equation (58) provide constraints that relate l to both l' and l'' , k to n , and k' to $-n'$, and force $j' = j = m$. These simplifications render $G_{nn'm}^{(l)}(\tau)$ equal to

$$G_{nn'm}^{(l)}(\tau) = \frac{(-1)^{m-n'}}{2l+1} \sum_v c_{v,n,m}^{(l)} c_{v,-n',m}^{(l)} e^{-b_v^{(l)}\tau} \quad (59)$$

With this expression for $G_{nn'm}^{(l)}(\tau)$ along with the required parameters for the eigenvalues and eigenvectors contained in Tables 1 and 2, the motional power density $\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda})$, from equation (31) becomes

$$\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda}) = \frac{(-1)^{n'}}{2l+1} \sum_v c_{v,n,m}^{(l)} c_{v,-n',m}^{(l)} \frac{1}{2} \int_{-\infty}^{\infty} e^{-b_v^{(l)}\tau} \tau e^{-i\omega_{\kappa\lambda}\tau} d\tau = \frac{(-1)^{n'}}{2l+1} \sum_v c_{v,n,m}^{(l)} c_{v,-n',m}^{(l)} \frac{b_v^{(l)}}{b_v^{(l)2} + \omega_{\kappa\lambda}^2} \quad (60)$$

The integral here provides the Lorentzian form for $\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda})$.

The absence of an m index in the eigenvectors of Tables 1 and 2 results from the absence of an $\hat{L}_{z'}$ term in the rotational diffusion tensor operator $\hat{\mathcal{R}}$. Hence, for the remainder of this development, we omit, for convenience, the subscript m on the eigenvectors $c_{v,n,m}^{(l)}$. This indicates that all interlevel relaxation transitions, expressed in the laboratory frame, are affected equally by the motional power density function. In the event that the diffusing molecule is in an anisotropic ordered solvent, the eigenvalues and eigenvectors will have a dependence upon the m th projection index. The treatment of such ordered solvents^{8,25,26} goes beyond the scope of this article, but the development would follow essentially that given above to

treat isotropic liquids, except that the characteristic equation would have a dependence upon m through the operator $\hat{\mathcal{L}}_z'$. To introduce the effect of solvent ordering into coupled spin relaxation also requires the introduction of an ordering potential function into equation (54).

Substitution of equation (60) into equations (29) and (30) yields the following expressions for the spectral densities:

$$\mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) = \frac{1}{2l+1} \sum_\nu \sum_{n=-l}^l [c_{\nu,n}^{(l)} \mathcal{F}_n^l(\mu)] \times \sum_{n'=-l}^l [(-1)^{n'} c_{\nu,-n'}^{(l)} \mathcal{F}_{n'}^l(\mu)] \frac{b_\nu^{(l)}}{b_\nu^{(l)2} + \omega_{\kappa\lambda}^2} \quad (61)$$

$$\text{Re } \mathcal{K}_{lm}^{\mu'\mu}(\omega_{\kappa\lambda}) = \frac{1}{2l+1} \sum_\nu \sum_{n,n'=-l}^l (-1)^{n'} [c_{\nu,n}^{(l)} \mathcal{F}_n^l(\mu) c_{\nu,-n'}^{(l)} \mathcal{F}_{n'}^l(\mu') + c_{\nu,n}^{(l)} \mathcal{F}_n^l(\mu') \times c_{\nu,-n'}^{(l)} \mathcal{F}_{n'}^l(\mu)] \frac{b_\nu^{(l)}}{b_\nu^{(l)2} + \omega_{\kappa\lambda}^2} \quad (62)$$

Equation (61) and (62) are of the forms

$$\mathcal{J}_{lm}^\mu(\omega_{\kappa\lambda}) = \frac{1}{2l+1} \sum_\nu \mathcal{A}_\nu^{(l)}(\mu) \mathcal{A}_\nu^{(l)*}(\mu) \frac{b_\nu^{(l)}}{b_\nu^{(l)2} + \omega_{\kappa\lambda}^2} \quad (63)$$

$$\text{Re } \mathcal{K}_{lm}^{\mu'\mu}(\omega_{\kappa\lambda}) = \frac{1}{2l+1} \sum_\nu [\mathcal{A}_\nu^{(l)}(\mu) \mathcal{A}_\nu^{(l)*}(\mu') + \mathcal{A}_\nu^*(\mu') \mathcal{A}_\nu^{(l)}(\mu)] \frac{b_\nu^{(l)}}{b_\nu^{(l)2} + \omega_{\kappa\lambda}^2} \quad (64)$$

$\mathcal{A}_\nu^{(l)}(\mu)$ is given by

$$\mathcal{A}_\nu^{(l)}(\mu) = \sum_{n=-l}^l c_{\nu,n}^{(l)} \mathcal{F}_n^l(\mu) \quad (65)$$

The complex conjugate $\mathcal{A}_\nu^{(l)*}(\mu)$ gives an important relationship between n and n' ; consider the following:

$$\begin{aligned} \mathcal{A}_\nu^{(l)*}(\mu) &= \left[\sum_{n=-l}^l c_{\nu,n}^{(l)} \mathcal{F}_n^l(\mu) \right]^* = \sum_{n=-l}^l c_{\nu,n}^{(l)*} \mathcal{F}_n^{l*}(\mu) \\ &= \sum_{n=-l}^l (-1)^n c_{\nu,n}^{(l)} \mathcal{F}_{-n}^l(\mu) \\ &= \sum_{n'=-l}^l (-1)^{n'} c_{\nu,-n'}^{(l)} \mathcal{F}_{n'}^l(\mu) \end{aligned} \quad (66)$$

These relationships rely upon the vectors $c_{\nu,n}^{(l)}$ being real, the properties of complex conjugates of second-rank tensors, and finally the symmetry about zero of the arbitrary index n' as it is summed over the complete set of values allowed by the index l . Thus, the use of the relevant eigenvalues and eigenvectors encountered in molecular rotational diffusion requires that $n' = -n$. Note that the paucity of $c_{\nu,n}^{(l)}$ values given in Tables 1 and 2 considerably reduces the number of terms summed in equation (65) and explicit expressions may be readily obtained for $\mathcal{A}_\nu^{(l)}(\mu)$ for various mechanisms μ , once the orientations of the interaction principal axis frame (PAF) is known relative to the molecular rotational diffusion PAF. The introduction of the molecular dynamics, embodied in $\mathcal{M}_{nn'm}^{(l)}(\omega_{\kappa\lambda})$, has reduced the problem of obtaining spectral densities to that of finding explicit expressions for the interaction tensors $\mathcal{F}_n^l(\mu)$ in the molecular diffusion frame. Attention is therefore directed to the geometrical relationships that transform these tensors from their own PAF to those of the rotational diffusion PAF (e.g., consider again the relationships in Figure 1).

6 INTERACTION TENSORS IN THEIR PRINCIPAL AXIS AND MOLECULAR DIFFUSION FRAMES

The interaction tensor components, $\mathcal{F}_n^l(\mu)$, in the rotational diffusion frame may be obtained from the corresponding PAF

components $\mathcal{F}_p^l(\mu_{\text{PAF}})$ as follows:

$$\mathcal{F}_n^l(\mu) = \sum_{p=-l}^l \mathcal{D}_{p,n}^{(l)}(\Omega_\mu) \mathcal{F}_p^l(\mu_{\text{PAF}}) \quad (67)$$

where $\Omega_\mu \equiv (\alpha_\mu, \beta_\mu, \gamma_\mu)$ represents the Euler angles that transform the PAF of the μ th relaxation interaction into the PAF of the molecular rotational diffusion tensor (see Figure 1). The Wigner rotation matrix elements, $\mathcal{D}_{p,n}^{(l)}(\alpha_\mu, \beta_\mu, \gamma_\mu)$ provide the geometrical constants used to transform between the two coordinate frames. The following convention of Zare²⁷ is used for $\mathcal{D}_{p,n}^{(l)}(\alpha_\mu, \beta_\mu, \gamma_\mu)$ in this treatment:

$$\mathcal{D}_{p,n}^{(l)}(\alpha_\mu, \beta_\mu, \gamma_\mu) = e^{-ip\alpha_\mu} d_{p,n}^{(l)}(\beta_\mu) e^{-in\gamma_\mu} \quad (68)$$

6.1 The Relaxation Interaction Tensor in Its Principal Axis Frame

In the interaction PAF, the second-rank tensor is diagonal, and only two unique values for $\mathcal{F}_p^{(2)}(\mu_{\text{PAF}})$ are encountered; these are obtained from equation (23) as follows:

$$\left. \begin{aligned} \mathcal{F}_0^{(2)}(\mu_{\text{PAF}}) &= \sqrt{\frac{3}{2}} [\mu_{zz}(\text{PAF}) - \mu_0] \\ &= \sqrt{\frac{2}{3}} \left\{ \mu_{zz}(\text{PAF}) - \frac{1}{2} [\mu_{xx}(\text{PAF}) + \mu_{yy}(\text{PAF})] \right\} \\ &= \sqrt{\frac{2}{3}} \zeta \\ \mathcal{F}_{\pm 1}^{(2)}(\mu_{\text{PAF}}) &= 0 \\ \mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) &= \frac{1}{2} [\mu_{xx}(\text{PAF}) - \mu_{yy}(\text{PAF})] \\ &= \frac{1}{2} \eta \zeta \end{aligned} \right\} \quad (69)$$

The parameters ζ and η are the tensor's anisotropy and asymmetry parameters, respectively.

The explicit forms of $\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$ and $\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})$ for the dipolar and chemical shift tensors may be obtained from equations (7) and (12), respectively, and are provided for the reader's convenience in Table 3. The $\mathcal{F}_0^{(2)}(\text{dd}_{\text{PAF}})$ in Table 3 is given for a heteronuclear dipolar coupling constant. Note that heteronuclear and homonuclear splittings, obtained from Pake doublets in solid NMR powder patterns, exhibit a quantum mechanical degeneracy effect for dipolar coupled spins. In homonuclear A_2 spin systems, a larger Pake splitting, by a factor of 1.5, is found when compared with a heteronuclear splitting in the corresponding AX spin system. Thus, the measured heteronuclear splittings render $D_{\text{hetero}} = \gamma_A \gamma_X \hbar / r_{AX}^3$ and the homonuclear $D_{\text{homo}} = 3\gamma_A^2 \hbar / 2r_{AA'}^3$. This feature of dipolar couplings is discussed by Harris.²⁸

Table 3 Values of $\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$ and $\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})$ Parameters for Dipolar and Chemical Shift Anisotropy

$\mathcal{F}_p^{(l)}(\mu_{\text{PAF}})$	Dipolar interaction	Chemical shift anisotropy
$\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	$-\sqrt{6} \frac{\gamma_A \gamma_X}{r_{AX}^3} = -\sqrt{6} D$	$\sqrt{\frac{3}{2}} [\delta_{zz}(\text{PAF}) - \delta_0] \gamma_s B_0$
$\mathcal{F}_{-2}^{(2)}(\mu_{\text{PAF}})$	0	$\frac{1}{2} [\delta_{xx}(\text{PAF}) - \delta_{yy}(\text{PAF})] \gamma_s B_0$

6.2 Explicit Geometrical Relationships for $\mathcal{F}_n^l(\mu)$ in the Rotational Diffusion PAF

The Wigner rotation matrices $\mathcal{D}_{p,n}^{(l)}(\Omega_\mu)$ in equation (67) contain the geometrical information implied by Figure 1 for the transformations between the interaction frames and the molecular rotational diffusion frame. The Ω_μ in the rotation matrices represents the Euler angles for the designated coordinate transformation. Using equation (67), the expressions for both axial and asymmetric tensors $\mathcal{F}_n^l(\mu)$ in the rotational diffusion frame are of the following respective forms:

$$\mathcal{F}_n^{(2)}(\mu_{\text{axial}}) = \mathcal{D}_{0,n}^{(2)}(\Omega_\mu) \mathcal{F}_0^{(2)}(\mu_{\text{PAF}}) \quad (70)$$

$$\begin{aligned} \mathcal{F}_n^{(2)}(\mu_{\text{asym}}) &= \mathcal{D}_{0,n}^{(2)}(\Omega_\mu) \mathcal{F}_0^{(2)}(\mu_{\text{PAF}}) \\ &+ [\mathcal{D}_{2,n}^{(2)}(\Omega_\mu) + \mathcal{D}_{-2,n}^{(2)}(\Omega_\mu)] \mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) \end{aligned} \quad (71)$$

Equation (70) is the equation that is used for dipolar and axially symmetric chemical shift tensors, and equation (71) is for an asymmetric interaction such as encountered in a general asymmetric chemical shift tensor. Values of $\mathcal{F}_n^{(2)}(\mu_{\text{axial}})$ are obtained from equation (70) or from equation (71) by setting $\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) = 0$. The $\mathcal{D}_{p,n}^{(l)}(\alpha_\mu, \beta_\mu, \gamma_\mu)$ may be obtained from equation (68) along with explicit expressions for $d_{p,n}^{(l)}(\beta_\mu)$, given in Table 4 for the reader's convenience.

Equations (70) and (71) may now be used in equation (65) to evaluate $\mathcal{A}_v^{(l)}(\mu, \text{asym})$ and $\mathcal{A}_v^{(l)}(\mu, \text{axial})$, and these expression are given in Table 5 in terms of the three Euler angles $(\alpha_\mu, \beta_\mu, \gamma_\mu)$ that define the transformation between the interaction and the molecular rotational diffusion frames. The designations 'axial' and 'asym' here apply to motional diffusion models, and should not be confused with similar designations of the symmetry of the interaction tensors given in equations (70) and (71).

In Table 6 corresponding expressions for $\mathcal{A}_v^{(l)}(\mu, \text{asym})$ and $\mathcal{A}_v^{(l)}(\mu, \text{axial})$ also are given using directional cosines to relate the interaction and diffusion frames. For axially symmetric interaction tensors, only three directional cosines (l_Z, m_Z, n_Z) are required to relate the unique z principal axis of the interaction PAF to the three principal axes in the rotational diffusion frame. For asymmetric tensors, all nine directional cosines are required to relate the interaction tensor's PAF (X, Y, Z) to the PAF (x, y, z) of the diffusion tensor. The traditional rotational transformation matrix,²⁹ expressed in both directional cosines and Euler angles, establishes the relationship between these two set of variables, and is

Axially symmetric diffuser	
$\mathcal{A}_0^{(2)}(\mu, \text{axial}) = \sqrt{\frac{3}{2}}(\sin^2 \beta \cos 2\alpha)\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) + \frac{1}{2}(3 \cos^2 \beta - 1)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	
$\mathcal{A}_1^{(2)}(\mu, \text{axial}) = [-\frac{1}{2} \cos 2\alpha \sin 2\beta (\cos \gamma - i \sin \gamma) + \sin 2\alpha \sin \beta (\sin \gamma + i \cos \gamma)]\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) + \sqrt{\frac{3}{8}} \sin 2\beta (\cos \gamma - i \sin \gamma)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	
$\mathcal{A}_2^{(2)}(\mu, \text{axial}) = [\frac{1}{2} \cos 2\alpha (1 + \cos^2 \beta)(\cos 2\gamma - i \sin 2\gamma) - \sin 2\alpha \cos \beta (\sin 2\gamma + i \cos 2\gamma)]\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) + \sqrt{\frac{3}{8}} \sin^2 \beta (\cos 2\gamma - i \sin 2\gamma)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	

expressed as follows:

$$R = \begin{bmatrix} l_X & l_Y & l_Z \\ m_X & m_Y & m_Z \\ n_X & n_Y & n_Z \end{bmatrix} \quad (72)$$

$$= \begin{bmatrix} c_\alpha c_\beta c_\gamma - s_\alpha s_\gamma & s_\alpha c_\beta c_\gamma + c_\alpha s_\gamma & -s_\beta c_\gamma \\ -c_\alpha c_\beta s_\gamma - s_\alpha c_\gamma & -s_\alpha c_\beta s_\gamma + c_\alpha c_\gamma & s_\beta s_\gamma \\ c_\alpha s_\beta & s_\alpha s_\beta & c_\beta \end{bmatrix}$$

The l , m , and n designations relate to the x , y , and z axes, respectively, in the molecular diffusion frame, and the subscripts X , Y , and Z designate the interaction principal axes. Directional cosines enjoy a certain conceptual simplicity, and the redundancy embodied in these nine cosines tends to make the notation for $\mathcal{A}_v^{(l)}(\mu, \text{asym})$ in Table 6 rather compact. Fortunately, the explicit expressions contained in equation (72) relate all nine directional cosines to the three unique Euler angles, thereby removing any ambiguity that could ensue from the oversubscription of directional cosine parameters for the rotational transformation.

7 SPECIFIC EXPRESSIONS FOR SPECTRAL DENSITY FUNCTIONS AND RELAXATION RATES

With equations (63)–(65) and Tables 1–3 and 5 or 6, explicit expressions for both auto- and cross-correlated relaxation spectral densities may be obtained for a variety of spin interactions. The interaction may be described with

both axially symmetric or asymmetric interaction tensors. Spherically symmetric interaction tensors do not provide fluctuating magnetic fields with rotational diffusion, and cannot relax magnetic spins. The diffusion model governs the form of the relaxation expression, and explicit expressions will be presented in this section. The procedure for assembling the spectral densities for the various diffusion models is straightforward, though considerably more laborious for the more complex cases when cross-correlated spectral densities between asymmetric interactions are encountered in the asymmetric diffusional limit. This article allows only for a detailed discussion of a few of the simpler cases, but some of the more complicated cases have been discussed elsewhere.^{7,11} The spherical and axial diffusion cases are common but still sufficiently complex to illustrate the procedure for assembling different spectral density expressions.

7.1 Spherical Rotational Diffusion Model

The second-rank spectral densities for the simple but important spherical diffusion case are given by

$$\left. \begin{aligned} \mathcal{J}_{2m}^\mu(\omega_{\kappa\lambda}, \text{spher diff}) &= A_{\text{spher}}^{(2)\mu} \frac{6R_0}{(6R_0)^2 + \omega_{\kappa\lambda}^2} \\ \mathcal{K}_{2m}^{\mu\mu'}(\omega_{\kappa\lambda}, \text{spher diff}) &= A_{\text{spher}}^{(2)\mu\mu'} \frac{6R_0}{(6R_0)^2 + \omega_{\kappa\lambda}^2} \end{aligned} \right\} \quad (73)$$

The rotational diffusion is isotropic, with diffusion constant R_0 , and $A_{\text{spher}}^{(2)\mu}$ and $A_{\text{spher}}^{(2)\mu\mu'}$ become

Table 6 $\mathcal{A}_\nu$ Values in Terms of Direction Cosines for Asymmetric Interaction Tensors

$\mathcal{A}_0^{(2)}(\mu, \text{axial}) = \sqrt{\frac{3}{2}}(n_X^2 - n_Y^2)\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) + \frac{1}{2}(3n_Z^2 - 1)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	
$\mathcal{A}_1^{(2)}(\mu, \text{axial}) = [-n_X(l_X + im_X) + n_Y(l_Y + im_Y)]\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) - \sqrt{\frac{3}{2}}n_Z(l_Z + im_Z)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	
$\mathcal{A}_2^{(2)}(\mu, \text{axial}) = [\frac{1}{2}(l_X^2 - l_Y^2 + m_Y^2 - m_X^2) + i(l_X m_X - l_Y m_Y)]\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) + [\sqrt{\frac{3}{8}}(l_Z^2 - m_Z^2) + i\sqrt{\frac{3}{2}}l_Z m_Z]\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})$	

$$A_{\text{spher}}^{(2)\mu} = \frac{1}{5}\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})^2 + \frac{2}{5}\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})^2 \quad (74a)$$

$$A_{\text{spher}}^{(2)\mu\mu'} = \frac{1}{5}(3n_Z^2 - 1)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})\mathcal{F}_0^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{1}{5}\sqrt{6}(n_X^2 - n_Y^2)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})\mathcal{F}_{\pm 2}^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{1}{5}\sqrt{6}(l_Z^2 - m_Z^2)\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})\mathcal{F}_0^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{2}{5}(l_X^2 - l_Y^2 + m_Y^2 - m_X^2)\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) \\ \times \mathcal{F}_{\pm 2}^{(2)}(\mu'_{\text{PAF}}) \quad (74b)$$

The above autocorrelation coefficient $A_{\text{spher}}^{(l)\mu}$ for spherical diffusion was obtained by placing the arbitrary rotational diffusion frame on the PAF of the μ th interaction. The cross term, represented by $A_{\text{spher}}^{(l)\mu\mu'}$, again places the arbitrary rotational diffusion frame on the μ interaction frame, and then the μ' frame is transformed into this diffusion frame. Thus, the directional cosines in equation (74) relate the μ' interaction frame (l, m, n) to the μ interaction frame (X, Y, Z). Using equation (72), the equivalent expression in Euler angles to that given in equation (74b) becomes

$$A_{\text{spher}}^{(2)\mu\mu'} = \frac{1}{5}(3\cos^2\beta - 1)\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})\mathcal{F}_0^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{1}{5}\sqrt{6}\sin^2\beta\cos 2\alpha\mathcal{F}_0^{(2)}(\mu_{\text{PAF}})\mathcal{F}_{\pm 2}^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{1}{5}\sqrt{6}\sin^2\beta\cos 2\gamma\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})\mathcal{F}_0^{(2)}(\mu'_{\text{PAF}}) \\ + \frac{2}{5}[\cos 2\alpha(\cos^2\beta + 1)\cos 2\gamma \\ - 2\sin 2\alpha\cos\beta\sin 2\gamma] \\ \times \mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}})\mathcal{F}_{\pm 2}^{(2)}(\mu'_{\text{PAF}}) \quad (75)$$

The symmetry between the two interaction frames has been preserved in equation (75), even though the μ th frame was selected as the rotational diffusion frame. The Euler angle α is associated with frame μ and γ with frame μ' . The spherical diffusion expressions for the autocorrelated spectral density in an axially symmetric tensor may be obtained when $\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) = 0$, and for centrosymmetric tensors when $\mathcal{F}_0^{(2)}(\mu_{\text{PAF}}) = 0$.

7.2 Axially Symmetric Rotational Diffusion Model

7.2.1 Autocorrelation Spectral Densities

The autocorrelated spectral densities given in equation (63) along with the values for $b_\nu^{(l)}(\text{axial})$ from Table 2 and for $\mathcal{A}_\nu^{(l)}(\mu, \text{axial})$ from Table 6 yield the following expression:

$$\mathcal{J}_{2m}^\mu(\omega_{\kappa\lambda}, \text{axial diff}) = A_{\text{axial}}^{(2)\mu} \frac{6R_\perp}{(6R_\perp)^2 + \omega_{\kappa\lambda}^2} \\ + B_{\text{axial}}^{(2)\mu} \frac{5R_\perp + R_\parallel}{(5R_\perp + R_\parallel)^2 + \omega_{\kappa\lambda}^2} \\ + C_{\text{axial}}^{(2)\mu} \frac{2R_\perp + 4R_\parallel}{(2R_\perp + 4R_\parallel)^2 + \omega_{\kappa\lambda}^2} \quad (76)$$

The coefficients $A_{\text{axial}}^{(2)\mu}$, $B_{\text{axial}}^{(2)\mu}$, and $C_{\text{axial}}^{(2)\mu}$ for an autocorrelated and axially symmetric diffusion tensor are given by

$$\left. \begin{aligned} A_{\text{axial}}^{(2)\mu} &= \frac{1}{5}\mathcal{A}_0^{(2)*}(\mu, \text{axial})\mathcal{A}_0^{(2)}(\mu, \text{axial}) \\ B_{\text{axial}}^{(2)\mu} &= \frac{2}{5}\mathcal{A}_1^{(2)*}(\mu, \text{axial})\mathcal{A}_1^{(2)}(\mu, \text{axial}) \\ C_{\text{axial}}^{(2)\mu} &= \frac{2}{5}\mathcal{A}_2^{(2)*}(\mu, \text{axial})\mathcal{A}_2^{(2)}(\mu, \text{axial}) \end{aligned} \right\} \quad (77)$$

Note that the degenerate solutions for $\Psi_{\pm\nu}$ given in equation (50) reduce the number of unique eigenvalues for axial diffusion from five to three. Therefore, a two-fold degeneracy factor is introduced into equation (77) to address this feature. In this axial case, the degeneracy is 1 for $\nu = 0$, and 2 for $\nu = 1$ or 2.

7.2.1.1 Axially Symmetric Dipolar Interaction. This case was treated in the early seminal work of Woessner¹ for dipole-dipole spectral densities, and is commonly encountered in many molecular systems. Expressions for $A_{\text{axial}}^{(2)\text{dd}}$, $B_{\text{axial}}^{(2)\text{dd}}$, and $C_{\text{axial}}^{(2)\text{dd}}$ may be obtained from Table 6, and are given as follows:

$$\left. \begin{aligned} A_{\text{axial}}^{(2)\text{dd}} &= \frac{1}{20}(3n_Z^2 - 1)^2\mathcal{F}_0^{(2)}(\text{dd})^2 \\ B_{\text{axial}}^{(2)\text{dd}} &= \frac{3}{5}n_Z^2(l_Z^2 + m_Z^2)\mathcal{F}_0^{(2)}(\text{dd})^2 \\ C_{\text{axial}}^{(2)\text{dd}} &= \frac{3}{20}(l_Z^2 + m_Z^2)^2\mathcal{F}_0^{(2)}(\text{dd})^2 \end{aligned} \right\} \quad (78)$$

where l_Z , m_Z , and n_Z are the directional cosines relating the Z axis of the interaction PAF to the x , y , and z axes, respectively, in the rotational diffusion frame. The expressions in equation (78) are sufficiently general that they would also apply to an autocorrelated axially symmetric chemical shift anisotropy case by substituting $\mathcal{F}_0^{(2)}(\text{csa})$ for $\mathcal{F}_0^{(2)}(\text{dd})$ in equation (78). Values for these principal values are given in Table 3.

7.2.1.2 Asymmetric Chemical Shift Interaction. The autocorrelated relaxation encountered when chemical shift anisotropy affects the relaxation is covered by this example. With the use of higher magnetic fields, this type of asymmetric interaction is becoming increasingly more common. The thesis of Smith⁶ provides an extensive coverage of this chemical shift anisotropy case. The expressions are

$$A_{\text{axial}}^{(2)\text{csa}} = \frac{1}{20}(3n_Z^2 - 1)^2 \mathcal{F}_0^{(2)}(\text{csa})^2 + \frac{3}{10}(n_X^2 - n_Y^2)^2 \mathcal{F}_{\pm 2}^{(2)}(\text{csa})^2 + \frac{1}{10}\sqrt{6}(3n_Z^2 - 1)(n_X^2 - n_Y^2) \mathcal{F}_0^{(2)}(\text{csa}) \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \quad (79a)$$

$$B_{\text{axial}}^{(2)\text{csa}} = \frac{3}{5}n_Z^2(l_Z^2 + m_Z^2) \mathcal{F}_0^{(2)}(\text{csa})^2 + \frac{2}{5}[(l_X n_X - l_Y n_Y)^2 + (m_X n_X - m_Y n_Y)^2] \mathcal{F}_{\pm 2}^{(2)}(\text{csa})^2 + \frac{2}{5}\sqrt{6}n_Z[l_Z(l_X n_X - l_Y n_Y) + m_Z(m_X n_X - m_Y n_Y)] \mathcal{F}_0^{(2)}(\text{csa}) \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \quad (79b)$$

$$C_{\text{axial}}^{(2)\text{csa}} = \frac{3}{20}(l_Z^2 + m_Z^2)^2 \mathcal{F}_0^{(2)}(\text{csa})^2 + \frac{1}{10}[(l_X^2 - l_Y^2 + m_Y^2 - m_X^2)^2 + 4(l_X m_X - l_Y m_Y)^2] \mathcal{F}_{\pm 2}^{(2)}(\text{csa})^2 + \frac{1}{10}\sqrt{6}[(l_Z^2 - m_Z^2)(l_X^2 - l_Y^2 + m_Y^2 - m_X^2) + 4m_Z l_Z(l_X m_X - l_Y m_Y)] \mathcal{F}_0^{(2)}(\text{csa}) \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \quad (79c)$$

7.2.2 Cross-Correlated Spectral Densities

This cross-correlated case retains a similar Lorentzian form to the spectral density given in equation (73):

$$\begin{aligned} \mathcal{K}_{2m}^{\mu\mu'}(\omega_{\kappa\lambda}, \text{axial diff}) &= A_{\text{axial}}^{(2)\mu\mu'} \frac{6R_{\perp}}{(6R_{\perp})^2 + \omega_{\kappa\lambda}^2} \\ &+ B_{\text{axial}}^{(2)\mu\mu'} \frac{5R_{\perp} + R_{\parallel}}{(5R_{\perp} + R_{\parallel})^2 + \omega_{\kappa\lambda}^2} \\ &+ C_{\text{axial}}^{(2)\mu\mu'} \frac{2R_{\perp} + 4R_{\parallel}}{(2R_{\perp} + 4R_{\parallel})^2 + \omega_{\kappa\lambda}^2} \end{aligned} \quad (80)$$

but differs in the forms of the coefficients: $A_{\text{axial}}^{(2)\mu\mu'}$, $B_{\text{axial}}^{(2)\mu\mu'}$, and $C_{\text{axial}}^{(2)\mu\mu'}$. These are given by

$$\left. \begin{aligned} A_{\text{axial}}^{(2)\mu\mu} &= \frac{1}{5}[\mathcal{A}_0^{(2)*}(\mu, \text{axial})\mathcal{A}_0^{(2)}(\mu', \text{axial}) + \mathcal{A}_0^{(2)*}(\mu', \text{axial})\mathcal{A}_0^{(2)}(\mu, \text{axial})] \\ B_{\text{axial}}^{(2)\mu\mu} &= \frac{2}{5}[\mathcal{A}_1^{(2)*}(\mu, \text{axial})\mathcal{A}_1^{(2)}(\mu', \text{axial}) + \mathcal{A}_1^{(2)*}(\mu', \text{axial})\mathcal{A}_1^{(2)}(\mu, \text{axial})] \\ C_{\text{axial}}^{(2)\mu\mu} &= \frac{2}{5}[\mathcal{A}_2^{(2)*}(\mu, \text{axial})\mathcal{A}_2^{(2)}(\mu', \text{axial}) + \mathcal{A}_2^{(2)*}(\mu', \text{axial})\mathcal{A}_2^{(2)}(\mu, \text{axial})] \end{aligned} \right\} \quad (81)$$

Cross-correlated dipolar interactions between more than two spins in coupled-relaxation studies were observed early,³⁰ and more recently cross terms between chemical shift and dipolar interactions have been found as relaxation work has moved to higher magnetic fields^{31,32} (for a more extensive list of references, see Grant et al.¹¹). Cross terms reveal a dependence upon the angles relating the principal axes of the two interacting tensors. These cross-correlated spectral densities also provides critical information on the asymmetry of motion. Without the spatial complexity of cross terms, it is more difficult to obtain information on anisotropic motional diffusion constants (i.e., R_{xx} , R_{yy} , and R_{zz}) with high sensitivity.

7.2.2.1 Two Pairs of Axial Dipolar Tensors. Again, we turn to dipolar interactions to illustrate this cross-correlation case. The dipolar $A_{\text{axial}}^{(2)\mu\mu'}$, $B_{\text{axial}}^{(2)\mu\mu'}$, and $C_{\text{axial}}^{(2)\mu\mu'}$ constants of equation (81) become

$$\left. \begin{aligned} A_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{1}{10}(3n_{Z,a}^2 - 1)(3n_{Z,b}^2 - 1) \mathcal{F}_0^{(2)}(\text{dd}_a) \mathcal{F}_0^{(2)}(\text{dd}_b) \\ B_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{6}{5}n_{Z,a}n_{Z,b}(l_{Z,a}l_{Z,b} + m_{Z,a}m_{Z,b}) \times \mathcal{F}_0^{(2)}(\text{dd}_a) \mathcal{F}_0^{(2)}(\text{dd}_b) \\ C_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{3}{10}[(l_{Z,a}l_{Z,b} + m_{Z,a}m_{Z,b})^2 - (l_{Z,a}m_{Z,b} - m_{Z,a}l_{Z,b})^2] \times \mathcal{F}_0^{(2)}(\text{dd}_a) \mathcal{F}_0^{(2)}(\text{dd}_b) \end{aligned} \right\} \quad (82)$$

Two different dipolar pairs interacting in a cross term give a cross correlated spectral density that is directly proportional to the subtended angle between their associated internuclear vectors.

7.2.2.2 Asymmetric csa and Axial Dipolar Cross Term. The cross term between the axially symmetric dipolar and asymmetric chemical shift interactions is discussed briefly for this final axial diffusion case. The equations governing such cross terms are

$$\begin{aligned} A_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{1}{10}(3n_{Z,d}^2 - 1)(3n_{Z,cs}^2 - 1) \mathcal{F}_0^{(2)}(\text{dd}) \mathcal{F}_0^{(2)}(\text{csa}) \\ &+ \frac{1}{10}\sqrt{6}(3n_{Z,d}^2 - 1)(n_{X,cs}^2 - n_{Y,cs}^2) \mathcal{F}_0^{(2)}(\text{dd}) \times \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \end{aligned} \quad (83a)$$

$$\begin{aligned} B_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{6}{5}n_{Z,d}n_{Z,cs}(l_{Z,d}l_{Z,cs} + m_{Z,d}m_{Z,cs}) \mathcal{F}_0^{(2)}(\text{dd}) \mathcal{F}_0^{(2)}(\text{csa}) \\ &+ \frac{1}{5}\sqrt{6}[l_{Z,d}n_{Z,d}(l_{X,cs}n_{X,cs} - l_{Y,cs}n_{Y,cs}) + m_{Z,d}n_{Z,d}(m_{X,cs}n_{X,cs} - m_{Y,cs}n_{Y,cs})] \times \mathcal{F}_0^{(2)}(\text{dd}) \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \end{aligned} \quad (83b)$$

$$\begin{aligned} C_{\text{axial}}^{(2)\text{d},\text{csa}} &= \frac{3}{10}[(l_{Z,d}l_{Z,cs} + m_{Z,d}m_{Z,cs})^2 - (l_{Z,d}m_{Z,cs} - m_{Z,d}l_{Z,cs})^2] \mathcal{F}_0^{(2)}(\text{dd}) \mathcal{F}_0^{(2)}(\text{csa}) \\ &+ \frac{1}{10}\sqrt{6}[(l_{Z,d}^2 - m_{Z,d}^2)(l_{X,cs}^2 - l_{Y,cs}^2 + m_{Y,cs}^2 - m_{X,cs}^2) + 4l_{Z,d}m_{Z,d}(l_{X,cs}m_{X,cs} - l_{Y,cs}m_{Y,cs})] \mathcal{F}_0^{(2)}(\text{dd}) \times \mathcal{F}_{\pm 2}^{(2)}(\text{csa}) \end{aligned} \quad (83c)$$

This case is unique because it mixes symmetric and asymmetric interaction tensors together. The effect of this mixed

symmetry is to destroy certain symmetries in the relaxing coupled multiplet, e.g., triplets, quartets, etc. The symmetric and asymmetric transient line intensities of these multiplets are coupled during the relaxation process, indicating the presence of this cross term. While magnetic field strengths were too low to observe these types of cross-correlated spectral densities until the past decade, theoretical considerations predicted their existence over two decades ago.^{33–36} Inevitably, this case will acquire greater significance in the future as magnetic fields continue to increase.

7.3 Asymmetric Rotational Diffusion Model

Using equations (63) and (64), the second-rank spectral densities arising from asymmetric rotational diffusion have five terms, with the explicit forms

$$\left. \begin{aligned} \mathcal{J}_{2m}^{\mu}(\omega_{\kappa\lambda}, \text{asym diff}) &= \frac{1}{5} \sum_{v=-2}^2 \mathcal{A}_v^{(2)*}(\mu, \text{asym}) \\ &\quad \times \mathcal{A}_v^{(2)}(\mu, \text{asym}) \\ &\quad \times \frac{b_v^{(2)}(\text{asym})}{b_v^{(2)2}(\text{asym}) + \omega_{\kappa\lambda}^2} \\ \mathcal{K}_{2m}^{\mu\mu'}(\omega_{\kappa\lambda}, \text{asym diff}) &= \frac{1}{5} \sum_{v=-2}^2 \left\{ \begin{aligned} &\mathcal{A}_v^{(2)*}(\mu, \text{asym}) \\ &\mathcal{A}_v^{(2)}(\mu', \text{asym}) + \\ &\mathcal{A}_v^{(2)*}(\mu', \text{asym}) \\ &\mathcal{A}_v^{(2)}(\mu, \text{asym}) \end{aligned} \right\} \\ &\quad \times \frac{b_v^{(2)}(\text{asym})}{b_v^{(2)2}(\text{asym}) + \omega_{\kappa\lambda}^2} \end{aligned} \right\} \quad (84)$$

Values of the asymmetric motional eigenvalues $b_v^{(2)}(\text{asym})$, are found in Table 1, and may be used with the asymmetric motional parameters $\mathcal{A}_v^{(2)}(\mu, \text{asym})$ given in either Table 5 or Table 6. Expressions for asymmetric diffusion with an axially symmetric interaction tensor has the same form as equation (84) and is easily obtained by setting $\mathcal{F}_{\pm 2}^{(2)}(\mu_{\text{PAF}}) = 0$ in the various $\mathcal{A}_v^{(2)}(\mu, \text{asym})$ of Tables 5 and 6. Likewise, the equations for a centrosymmetric tensor may be obtained, as before, by setting $\mathcal{F}_0^{(2)}(\mu_{\text{PAF}}) = 0$. Explicit expressions for asymmetric diffusional motion are obtained in the same manner as the axial diffusion examples found in Section 7.2. These expressions are sufficiently extensive, however, that they should be constructed only as needed.

7.4 Extreme Narrowing Limit

Equations (73), (76), and (84) lend themselves to a further simplification when the so-called extreme narrowing limit, i.e., $\omega_{\kappa\lambda}^2 \ll b_0^{(l)2}$, obtains. The Lorentzian form then becomes

$$\frac{b_v^{(l)}}{b_v^{(l)2} + \omega_{\kappa\lambda}^2} \approx \frac{1}{b_v^{(l)}} \quad (85)$$

7.5 Use of Spectral Densities in Relaxation Rate Expressions

Equations (73)–(84) illustrate the methods used for obtaining both autocorrelated, $\mathcal{J}_{lm}^{\mu}(\omega_{\kappa\lambda})$, and cross correlated,

$\mathcal{K}_{lm}^{\mu\mu'}(\omega_{\kappa\lambda})$, spectral densities. Explicit spectral densities have been expressed here for a few illustrative models, and other spectral densities may be assembled in the same manner. These spectral densities, along with the respective auto- and cross-correlated spin matrices S_{lm}^{μ} and $S_{lm}^{\mu\mu'}$ defined in equation (16) combine in equation (18) to provide expressions for the several relaxation rates $\hat{K}_{\kappa'\lambda'\kappa\lambda}(\omega_{\kappa\lambda})$. These rates, when introduced into equation (3), yield values for the Redfield relaxation matrix $R_{\kappa'\lambda'\kappa\lambda}$, which then completes the development of the master relaxation equation given in equation (1). Fitting of these relaxation parameters with a number of different pulse experiments yields values for the rotational diffusion constants expressed in Tables 1 and 2, and approximates many of the critical constants contained in Table 3. The fitting process, as might be expected, is enhanced considerably when molecular symmetry provides independent information on the geometrical constants that relate the various interaction and motional diffusion frames outlined in Figure 1. Other NMR studies usually provide more accurate information on dipole–dipole constants and chemical shift anisotropy than can be obtained from relaxation data. This is especially beneficial in analyzing relaxation data, since these more reliable spectral parameters, when available from other sources, make it possible for the relaxation data to be used exclusively in fitting the molecular diffusion parameters.

1 INTRODUCTION

Metal ions play a vital role in a large number of biological processes. For this reason, there is widespread interest in NMR of the spin- $\frac{3}{2}$ nuclei ^7Li , ^{23}Na , ^{39}K , and ^{87}Rb , the spin- $\frac{5}{2}$ nuclei ^{25}Mg and ^{85}Rb , and the spin- $\frac{7}{2}$ nuclei ^{43}Ca and ^{133}Cs . In particular, ^{23}Na is one of the most widely studied of all quadrupolar nuclei, especially in vivo. Even in the most heterogeneous biological tissues, however, the NMR spectra of these metal ions usually exhibit only a single resonance at a chemical shift that is characteristic of the aqueous ion. This apparent lack of structure in the spectra is compensated for by the wealth of information about the environment of the ions yielded by the spin relaxation parameters.

It has long been known that both the transverse and longitudinal relaxation of spin $S \geq \frac{3}{2}$ nuclei are multiexponential if the extreme-narrowing condition is not fulfilled.¹ For example, the transverse relaxation of spin- $\frac{3}{2}$ nuclei is described by two distinct relaxation rates, $R_f^{(1)}$ and $R_s^{(1)}$ [the superscript (1) denotes relaxation of single quantum coherences, $p = \pm 1$], if the product of the Larmor frequency ω_0 and correlation time τ_c is unity or greater, $\omega_0\tau_c \gtrsim 1$. As a result of this biexponential relaxation, the NMR spectrum of slowly tumbling spin- $\frac{3}{2}$ nuclei is a superposition of two Lorentzian lines with full widths (in Hz) at halfheight of $R_f^{(1)}/\pi$ and $R_s^{(1)}/\pi$. Figure 1 shows the normal free induction decay and the corresponding spectrum of sodium ions in an agarose gel. The ^{23}Na lineshape can be seen to be bi-Lorentzian, with 60% of the total intensity in the broader component and 40% in the narrower component. Full analysis of the spectrum of a spin- $\frac{3}{2}$ nucleus requires measurement of both the fast, $R_f^{(1)}$, and slow,

Figure 1 Magnitude mode free induction decay (a) and ^{23}Na spectrum (b) of 2 M NaCl in an agarose gel. Acquisition parameters: 2500 Hz spectral width, 48 transients coadded, 105.8 MHz Larmor frequency, 256 points in (a) zero filled to 1024 in (b)

$R_s^{(1)}$, transverse relaxation rates. This is a difficult task, especially if (a) the two relaxation rates are very similar or (b) the relaxation rate $R_f^{(1)}$ is so fast that the broader of the two lines cannot be observed.

In 1986, both Pekar and Leigh² and Jaccard et al.³ showed that multiple quantum coherences could be excited in isolated spin $S \geq \frac{3}{2}$ nuclei in liquids if, but only if, their relaxation was multiexponential. This discovery helped overturn the orthodox view that excitation of multiple quantum coherence required the presence of splittings due to scalar, dipolar, or quadrupolar couplings, and so could not be achieved in a spectrum that consisted of only a single resonance. The aim of this article is to show how multiple quantum NMR is currently being used to measure the relaxation parameters of spin $S \geq \frac{3}{2}$ nuclei in liquid environments. This article will concentrate on spin- $\frac{3}{2}$ nuclei, while multiple quantum NMR of the much less important spin- $\frac{5}{2}$ and spin- $\frac{7}{2}$ nuclei will be mentioned briefly in Section 7.

2 TENSOR OPERATOR DESCRIPTION OF SPIN- $\frac{3}{2}$ QUADRUPOLAR RELAXATION

Jaccard et al.³ have shown that a tensor operator description of multiexponential quadrupolar relaxation is particularly convenient for discussing multiple quantum NMR experiments. In this formulation, the density operator $\sigma(t)$ is expanded as a linear combination of tensor operators:

$$\sigma(t) = \sum_{l=0}^{2S} \sum_{p=-l}^l b_{l,p}(t) T_{l,p} \quad (1)$$

where $T_{l,p}$ is an irreducible spherical tensor operator of rank l and order p . These two concepts have clear meanings in this usage. For example, an operator $T_{1,-1}$ represents an in-phase coherence of order $p = -1$ (i.e., one of the two components of in-phase single quantum coherence), $T_{3,+1}$ represents a doubly

antiphase coherence of order $p = +1$, $T_{3,-2}$ represents a singly antiphase coherence of order $p = -2$ (i.e., a singly antiphase double quantum coherence), and so on. The fact that the rank and coherence order of each term in the expansion of equation (1) are readily identifiable is a major asset in the description of multiple quantum NMR experiments.

A 90°_y pulse applied to a system of spin- $\frac{3}{2}$ nuclei at thermal equilibrium creates in-phase single quantum coherence. If a number of uninteresting constants are ignored, this initial state can be written in tensor form as

$$\sigma(t=0) = T_{1,-1} - T_{1,+1} \quad (2)$$

Jaccard et al.³ have shown that if the time evolution of the density operator occurs solely as a result of biexponential transverse relaxation then the new density operator $\sigma(t)$ is given in tensor operator form by

$$\sigma(t) = f_{11}^{(1)}(t)(T_{1,-1} - T_{1,+1}) + f_{31}^{(1)}(t)(T_{3,-1} - T_{3,+1}) \quad (3)$$

where

$$f_{11}^{(1)}(t) = \frac{1}{5}[3 \exp(-R_f^{(1)}t) + 2 \exp(-R_s^{(1)}t)] \quad (4a)$$

$$f_{31}^{(1)}(t) = \frac{1}{5}\sqrt{6}[\exp(-R_f^{(1)}t) - \exp(-R_s^{(1)}t)] \quad (4b)$$

For pure quadrupolar relaxation in the absence of exchange, the fast and slow transverse relaxation rates can be calculated as

$$R_f^{(1)} = C(J_0 + J_1) \quad (5a)$$

$$R_s^{(1)} = C(J_1 + J_2) \quad (5b)$$

where the spectral densities J_n and the constant C are given by

$$J_n = \frac{2\tau_c}{1 + n^2\omega_0^2\tau_c^2} \quad (6)$$

$$C = \frac{1}{40}(e^2qQ/\hbar)^2(1 + \frac{1}{3}\eta^2) \quad (7)$$

In the extreme-narrowing limit, $\omega_0\tau_c \ll 1$, the two relaxation rates are equal, $R_f^{(1)} = R_s^{(1)} = 4C\tau_c$; hence, the function $f_{31}^{(1)}(t)$ is zero at all times, and spin- $\frac{3}{2}$ transverse relaxation is monoexponential. However, when the ions are tumbling slowly, $\omega_0\tau_c \gtrsim 1$, the two rates are unequal, with $R_f^{(1)} \gg R_s^{(1)}$, and both the biexponential functions $f_{11}^{(1)}(t)$ and $f_{31}^{(1)}(t)$ are needed for a full description of transverse relaxation.

The function $f_{11}^{(1)}(t)$ in equations (3), (4a), and (4b) describes the biexponential decay of in-phase single quantum coherence, $T_{1,\pm 1}$, with the two components having relative intensities of 60% and 40%. As mentioned in Section 1, this behavior has been known for a long time, and the tensor operator description has here revealed nothing new. Equations (3), (4a), and (4b) also show, however, the biexponential growth and decay of doubly antiphase single quantum coherence, $T_{3,\pm 1}$, according to the function $f_{31}^{(1)}(t)$. Only coherences described by the tensor operator $T_{1,-1}$ give rise to magnetization that is observable as a free induction decay, so these third-rank single quantum coherences cannot

be detected directly.³ It will be shown in the next section, however, that the function $f_{31}^{(1)}(t)$ can be measured using multiple quantum filtration.

The tensor operator description of spin- $\frac{3}{2}$ longitudinal relaxation is broadly similar to that of transverse relaxation.³ If a 180° pulse is applied to a system of spin- $\frac{3}{2}$ nuclei at thermal equilibrium, the resulting deviation from thermal equilibrium can be written in tensor operator form [normalized to equation (2)] as

$$\sigma(t=0) - \sigma^{\text{eq}} = -2\sqrt{2}T_{1,0} \quad (8)$$

If biexponential longitudinal relaxation occurs for a time t , then the new density operator $\sigma(t)$ is given by

$$\sigma(t) - \sigma^{\text{eq}} = -2\sqrt{2}[T_{1,0}f_{11}^{(0)}(t) + T_{3,0}f_{31}^{(0)}(t)] \quad (9)$$

where

$$f_{11}^{(0)}(t) = \frac{1}{5}[\exp(-R_f^{(0)}t) + 4 \exp(-R_s^{(0)}t)] \quad (10a)$$

$$f_{31}^{(0)}(t) = \frac{2}{5}[\exp(-R_f^{(0)}t) - \exp(-R_s^{(0)}t)] \quad (10b)$$

The fast and slow longitudinal relaxation rates for pure quadrupolar relaxation are given by [the superscript (0) denotes relaxation of spin populations, $p = 0$]

$$R_f^{(0)} = 2CJ_1 \quad (11a)$$

$$R_s^{(0)} = 2CJ_2 \quad (11b)$$

As with transverse relaxation, equations (9)–(11b) show that in the extreme-narrowing limit, $R_f^{(0)} = R_s^{(0)} = 4C\tau_c$, so that longitudinal relaxation is monoexponential. Outside this limit, the relaxation is again biexponential, with $R_f^{(0)} \gg R_s^{(0)}$. Multiple quantum filtration experiments that allow the function $f_{31}^{(0)}(t)$ to be measured will be discussed in the next section.

3 MULTIPLE QUANTUM FILTRATION EXPERIMENTS FOR SPIN- $\frac{3}{2}$ NUCLEI

A tensor operator $T_{l,p}$ transforms under a radiofrequency pulse of flip angle β and phase ϕ according to

$$T_{l,p} \xrightarrow{\beta(\hat{I}_y \cos \phi - \hat{I}_x \sin \phi)} \sum_{p'=-l}^l T_{l,p'} d_{p',p}^l(\beta) \exp(-i\Delta p \phi) \quad (12)$$

where p' is the new coherence order, and $\Delta p = p' - p$ is the change in coherence order under the pulse.³ The amplitude of the transfer $T_{l,p} \rightarrow T_{l,p'}$ is given by the reduced rotation matrix element $d_{p',p}^l(\beta)$. These elements are defined to be real; hence, the phase ϕ represents a positive excursion with respect to the rotating frame y axis (i.e., $\phi = 0^\circ$ for a y pulse, $\phi = 90^\circ$ for a $-x$ pulse, and so on).

The important feature revealed by equation (12) is that a pulse cannot change the rank l of a tensor operator (or the coherence it represents), but will, in general, produce operators of all possible coherence orders p . Thus, while the $T_{1,\pm 1}$ terms

in equation (3) cannot be transformed by a pulse into multiple quantum coherences ($|p| \geq 2$), the $T_{3,\pm 1}$ terms that appear as a result of biexponential spin- $\frac{3}{2}$ transverse relaxation can be transformed into triple quantum coherences, $T_{3,\pm 3}$, and antiphase double quantum coherences, $T_{3,\pm 2}$. Therefore, it is the appearance of the third-rank terms in equations (3) and (9) that makes the excitation of multiple quantum coherence possible.

Figure 2 shows two pulse sequences for multiple quantum filtration of spin- $\frac{3}{2}$ nuclei and their corresponding coherence pathway diagrams.⁴ The standard multiple quantum filtration experiment in Figure 2(a) allows the transverse relaxation function $f_{31}^{(1)}(t)$ to be measured.^{2,3} At the end of the τ_e evolution interval, both $T_{1,\pm 1}$ and $T_{3,\pm 1}$ operators will be present as result of biexponential transverse relaxation (the 180° pulse merely refocuses any offsets). Depending on its phase ϕ' , the $\beta = 90^\circ$ pulse then converts the $T_{3,\pm 1}$ coherences into either double ($T_{3,\pm 2}$) or triple ($T_{3,\pm 3}$) quantum coherences, which can be selected by an appropriate phase cycling of the receiver and the pulse phase ϕ . The final $\beta' = 90^\circ$ pulse then reconverts these multiple quantum coherences into a single quantum coherence, $T_{3,\pm 1}$, at the start of acquisition of the free induction decay. As mentioned

above, this third-rank single quantum coherence is not directly observable. However, further biexponential transverse relaxation during the free induction decay will convert the $T_{3,-1}$ coherence into an observable $T_{1,-1}$ coherence. The function that describes this conversion can be written as $f_{13}^{(1)}(t)$ in analogy to equation (3), and it is easily shown that $f_{13}^{(1)}(t) = f_{31}^{(1)}(t)$. Using equations (3) and (12), the observable components of the density operators produced by the double and triple quantum filters in Figure 2(a) can be calculated as³

$$\sigma^{\text{DQF}}(t_2) = \frac{10}{16} T_{1,-1} f_{31}^{(1)}(\tau_e) f_{31}^{(1)}(t_2) \cos 2\phi \quad (13a)$$

$$\sigma^{\text{TQF}}(t_2) = \frac{15}{16} T_{1,-1} f_{31}^{(1)}(\tau_e) f_{31}^{(1)}(t_2) i \sin 3\phi \quad (13b)$$

where evolution solely as a result of transverse relaxation has been assumed. The dependence on the pulse phase ϕ in equations (13a) and (13b) is the basis for selection of these components by phase cycling. Note that either double or triple quantum filtration can be used to measure the function $f_{31}^{(1)}(t)$, either as a function of the evolution interval τ_e or in ‘real time’ as the envelope of the free induction decay. The only difference between the results of the two experiments is that the spin- $\frac{3}{2}$ triple quantum filter is 50% more sensitive than the double quantum filter.⁵

The pulse sequence in Figure 2(b) can be viewed as a multiple quantum filtered inversion–recovery experiment, and allows the longitudinal relaxation function $f_{31}^{(0)}(t)$ to be measured.³ Again, either double (with $\beta = 54.7^\circ$) or triple (with $\beta = 90^\circ$) quantum filtration are possible. Using equations (9) and (12), the observable component of the density operator for each alternative can be written as

$$\sigma^{\text{DQF}}(t_2) = \frac{5}{6} \sqrt{2} T_{1,-1} f_{31}^{(0)}(\tau_e) f_{13}^{(1)}(t_2) \cos 2\phi \quad (14a)$$

$$\sigma^{\text{TQF}}(t_2) = \frac{5}{8} \sqrt{6} T_{1,-1} f_{31}^{(0)}(\tau_e) f_{13}^{(1)}(t_2) i \sin 3\phi. \quad (14b)$$

Thus, either double or triple quantum filtration can be used to measure $f_{31}^{(0)}(t)$ as a function of the evolution interval τ_e . The envelope of the free induction decay is again described by the transverse biexponential function $f_{31}^{(1)}(t)$.

4 MEASUREMENT OF SPIN- $\frac{3}{2}$ RELAXATION PARAMETERS

The free induction decay produced by the triple quantum filter of Figure 2(a) from sodium ions in an agarose gel is shown in Figure 3(a). As predicted, the envelope of the free induction decay is the difference of two exponentials, and corresponds to the function $f_{31}^{(1)}(t_2)$. Fourier transformation of this free induction decay in the normal way yields the triple quantum filtered ^{23}Na spectrum in Figure 3(b). This spectrum corresponds to a function $F_{31}^{(1)}(\omega)$, the Fourier transform of $f_{31}^{(1)}(t)$, and is the difference of two Lorentzian lines with widths $R_f^{(1)}/\pi$ and $R_s^{(1)}/\pi$.

The experimental results in Figure 3(a) and (b) are described by exactly the same two relaxation rates, $R_f^{(1)}$ and $R_s^{(1)}$, as the results in Figure 1. However, the use of multiple quantum filtration has conferred a number of advantages. First, the very fact that a multiple quantum filtered spectrum can be recorded

Figure 2 Pulse sequences and coherence pathway diagrams for multiple quantum filtration of spin- $\frac{3}{2}$ nuclei. Sequence (a) is used to study biexponential transverse relaxation, while sequence (b) is used to study longitudinal relaxation. The pulse phase ϕ in (a) and (b) is stepped through the values 0° , 90° , 180° , and 270° for double quantum filtration (dashed coherence pathways), and through 30° , 90° , 150° , 210° , 270° , and 330° for triple quantum filtration (solid pathways), while the receiver phase alternates between 0° and 180° . The pulse phase ϕ' in (a) is 0° for double quantum and 90° for triple quantum filtration. Maximum sensitivity is achieved with flip angles $\beta = \beta' = 90^\circ$, except for the double quantum filtration version of (b), where $\beta = 54.7^\circ$. The interval τ_m is a few microseconds to allow for phase shifting of the pulses, unless multiple quantum relaxation rates are being measured. The double quantum filtration version of (a) can be used selectively to observe spin- $\frac{3}{2}$ nuclei in ordered environments if $\beta = \beta' = 54.7^\circ$.

Figure 3 Magnitude mode free induction decay (a) and ^{23}Na spectrum (b) of 2 M NaCl in an agarose gel recorded with the triple quantum filter of Figure 2(a). The amplitudes of ^{23}Na spectra recorded with the triple quantum filter of Figure 2(a) are plotted in (c) as a function of the evolution interval τ_e (triangles represent 100 amplitudes between $\tau_e = 0$ and 99 ms). Computer fitting (dashed line) of the points in (c) yielded the relaxation rates $R(1)/f = 409 \text{ s}^{-1}$ and $R(1)/s = 30.7 \text{ s}^{-1}$. Similarly, the amplitudes of ^{23}Na spectra recorded with the triple quantum filter of Figure 2(b) are plotted in (d) as a function of τ_e (triangles represent 30 amplitudes between $\tau_e = 0$ and 116 ms). Computer fitting (dashed line) of the points in (c) yielded the relaxation rates $R(0)/f = 38.5 \text{ s}^{-1}$ and $R(0)/s = 29.7 \text{ s}^{-1}$. Acquisition parameters for all spectra: 2500 Hz spectral width, 48 transients co-added, 105.8 MHz Larmor frequency, 256 points acquired and zero filled to 1024

is significant, since it constitutes unambiguous proof that the ^{23}Na nuclei are tumbling outside the extreme-narrowing limit. Second, both the conventional and multiple quantum filtered data are now available for computer fitting, and this should result in increased accuracy. Third, it is believed that, owing to its greater number of turning points, the $F_{31}^{(1)}(\omega)$ lineshape should yield more reliable fittings than the conventional

lineshape $F_{11}^{(1)}(\omega)$, especially when the two relaxation rates are similar. And finally, because the first point of the free induction decay is zero, the multiple quantum filtered spectrum shows less baseline distortion than the conventional spectrum.

The use of multiple quantum filtration is particularly favorable when the broad component of the spin- $\frac{3}{2}$ lineshape cannot be observed because it has relaxed completely in the 'dead time' between the end of the last pulse and the start of data acquisition. Clearly, this 'visibility' problem will be the same in both conventional and multiple quantum filtered spectra. Equations (13a) and (13b) show, however, that the function $f_{31}^{(1)}(t)$ can also be measured by recording the intensity of the filtered spectrum as a function of the evolution interval τ_e . This measurement suffers from no dead time problems, and, in addition, the presence of the 180° pulse means that the effects of B_0 inhomogeneity are refocused. Figure 3(c) shows the experimental function $f_{31}^{(1)}(t)$ measured in this way for the gel sample used previously. The computer fitting of these points yielded the ^{23}Na relaxation rates $R_f^{(1)} = 409 \text{ s}^{-1}$ and $R_s^{(1)} = 30.7 \text{ s}^{-1}$.

The longitudinal relaxation function $f_{31}^{(0)}(t)$ can be measured as a function of the τ_e interval in the experiment of Figure 2(b) in much the same way as the transverse function.³ Figure 3(d) shows a computer fitting of results from the agarose gel that yielded the ^{23}Na relaxation rates $R_f^{(0)} = 38.5 \text{ s}^{-1}$ and $R_s^{(0)} = 29.7 \text{ s}^{-1}$. In general, however, the longitudinal triple quantum filter is much less sensitive and informative than the transverse experiment, and has not attained the same widespread popularity in spin- $\frac{3}{2}$ NMR.

In addition to the methods discussed so far, it is also possible to measure the spin- $\frac{3}{2}$ multiple quantum relaxation rates using a minor modification of the pulse sequence of Figure 2(a).^{3,6} The decays of $T_{3,\pm 2}$ and $T_{3,\pm 3}$ are monoexponential and can be measured as functions of the τ_m interval (previously assumed to be of negligible duration) in the double and triple quantum filtration experiments, respectively. A 180° refocusing pulse can be inserted into the middle of the τ_m interval if required.

A full discussion of the analysis of spin- $\frac{3}{2}$ relaxation rates measured using multiple quantum filtration experiments is beyond the scope of this article, and only a brief summary can be given here. The relaxation rates given in equations (5a), (5b), (11a), and (11b) were derived on the assumption that relaxation is purely quadrupolar and is described by a single correlation time τ_c . In this case, the correlation time τ_c and the constant C can be easily extracted from the ratio of any two of the measured relaxation rates. In systems where rapid chemical exchange is occurring, however, the assumption of a single correlation time is clearly invalid. This applies to spin- $\frac{3}{2}$ ions in agarose gels, in aqueous solutions of proteins, and in both intra- and extracellular environments in cell suspensions and tissues.⁷⁻⁹ In 1972, Bull¹⁰ proposed a two-site exchange model for spin- $\frac{3}{2}$ nuclei in such systems. In this model, an observed relaxation rate is the weighted sum of the relaxation rate of ions bound to macromolecules and of those in free solution, the weights being the probabilities of the ions being found in each environment. The Bull model is attractive, since the free relaxation rates can easily be estimated and the free site probability can be taken as approximately unity. Thus, the bound relaxation rates can be easily derived and then treated according to the single correlation time model. Unfortunately,

in spite of its elegance, the Bull model does not seem to be very successful in explaining the majority of experimental data. If, using the full range of experimental techniques available, the six possible relaxation rates are measured for a spin- $\frac{3}{2}$ nucleus in, say, a protein solution then it is usually found that the value of τ_c calculated by taking the ratio of a pair of relaxation rates can differ by an order of magnitude according to which pair is chosen.^{7,8} For example, using $R_{\text{free}} = 25 \text{ s}^{-1}$, a Bull analysis of the rates $R_f^{(1)}$ and $R_s^{(1)}$ measured in Figure 3(c) yields $\omega_0\tau_c = 9.1$, while the analysis of $R_f^{(0)}$ and $R_s^{(0)}$ measured in Figure 3(d) yields $\omega_0\tau_c = 1.3$. Although the error on the latter figure may be very large because of the closeness of $R_f^{(0)}$ and $R_s^{(0)}$, the failure of the two-site Bull model is clear. Attempts to extend the Bull model to include multisite exchange would seem to be futile, since (a) the number of parameters would soon become too large for any meaningful fitting, and (b) it is unlikely that monovalent metal ions bind in any discrete manner to the majority of macromolecules. In a more promising development, however, Rooney and Springer^{7,8} have successfully fitted ^{23}Na relaxation data from both protein solutions and cell suspensions by using a model that allowed for a continuous distribution of correlation times.

5 DISCRIMINATION OF INTRA- AND EXTRACELLULAR SPIN- $\frac{3}{2}$ NUCLEI

As mentioned in Section 1, the ^{23}Na or ^{39}K NMR spectra of heterogeneous biological tissues or cell suspensions, either in vivo or in vitro, exhibit only a single resonance at a chemical shift characteristic of the aqueous ion. This is unfortunate, since a key aim of such studies is to determine selectively the relaxation parameters of the ions in the individual tissue compartments. One solution to this problem involves the use of lanthanide shift reagents,^{11,12} such as $\text{Dy}(\text{PPP})_2^{7-}$ or TmDOTP^{5-} . These are too large to cross the cell membrane, and so produce a paramagnetic shift of only the extracellular resonance. The main disadvantage of shift reagents is their toxicity. Nevertheless, they have proved popular for in vitro work and have occasionally been used in vivo, although never, of course, for studies on humans.

In 1987, Pekar et al.¹³ suggested that multiple quantum filtration could be used to observe selectively the resonance from intracellular spin- $\frac{3}{2}$ metal ions. The idea was that the intracellular ions would be slowly tumbling and would thus exhibit biexponential transverse relaxation, while the extracellular ions would be in the extreme-narrowing limit. A double or triple quantum filter would, therefore, fail to excite any multiple quantum coherences in the extracellular nuclei, and only signal from the intracellular ions would appear in the spectrum. This technique has proved only a partial success, however, since it has been found that, in general, the extracellular ions also exhibit biexponential relaxation.^{14,15} In spite of this, the relaxation behavior of spin- $\frac{3}{2}$ nuclei does differ widely between the various tissue compartments, and multiple quantum filters have been used to achieve partial discrimination between compartments in situations where shift reagents are not appropriate.

As an example of the degree of discrimination achieved, Figure 4(a) and (b) show the conventional and triple quantum filtered ^{23}Na NMR spectra of packed human red blood

Figure 4 Conventional, (a) and (c), and triple quantum filtered, (b) and (d), ^{23}Na spectra of human red blood cells. Packed cells were used in (a) and (b), and cells suspended in a solution of 50 mM NaCl, 100 mM choline chloride, and 6 mM DyTTHA^{3-} were used in (c) and (d). The pulse sequence of Figure 2(a) was used in (b) and (d). Acquisition parameters: 2500 Hz spectral width, 240 transients coadded for (a) and (c), 2400 transients coadded for (b) and (d), 105.8 MHz Larmor frequency, 128 points acquired and zero filled to 512, 5 ms evolution interval τ_e in (b) and (d). Fresh blood was drawn from the author on the day of the experiments

cells, while Figure 4(c) and (d) show the corresponding spectra of human red blood cells suspended in a solution containing 50 mM NaCl, 100 mM choline chloride, and 6 mM DyTTHA^{3-} . The triple quantum filtered lineshape of the intracellular ions in Figure 4(d) corresponds closely to that of Figure 4(b), while the intensity of the extracellular resonance relative to the intracellular resonance is clearly much reduced in Figure 4(d) compared with Figure 4(c).

6 RESIDUAL SPIN- $\frac{3}{2}$ QUADROPOLAR SPLITTINGS

The discussion in this article of the use of multiple quantum filtration in the study of spin- $\frac{3}{2}$ quadrupolar relaxation has so far assumed that the ions occur in purely isotropic, liquid-type environments; hence, their spectra exhibit no quadrupolar splittings. In 1986, however, Jaccard et al.³ noted that if residual quadrupolar splittings were present but were

not apparent in the lineshape then these would provide an alternative pathway for the excitation of multiple quantum coherence. If, starting from the initial state of equation (2), free precession occurs solely as a result of the residual quadrupolar splitting $2\omega_Q$ for a time t then the new density operator is given by

$$\sigma(t) = g_{11}^{(1)}(t)(T_{1,-1} - T_{1,+1}) + g_{21}^{(1)}(t)(T_{2,-1} + T_{2,+1}) + g_{31}^{(1)}(t)(T_{3,-1} - T_{3,+1}) \quad (15)$$

where

$$g_{11}^{(1)}(t) = \frac{1}{5}(2 + 3 \cos 2\omega_Q t) \quad (16a)$$

$$g_{21}^{(1)}(t) = i\sqrt{\frac{3}{5}} \sin 2\omega_Q t \quad (16b)$$

$$g_{31}^{(1)}(t) = -\frac{1}{5}\sqrt{6}(1 - \cos 2\omega_Q t) \quad (16c)$$

The functions $g_{ll'}^{(1)}(t)$ in equations (15)–(16c) describe the evolution of in-phase single quantum coherence, $T_{1,\pm 1}$, into antiphase single quantum coherence, $T_{2,\pm 1}$, and doubly antiphase single quantum coherence, $T_{3,\pm 1}$. The major difference between evolution as a result of biexponential relaxation and residual quadrupolar splittings, therefore, is that only in the latter case do singly antiphase coherences, $T_{2,\pm 1}$, appear.

The appearance of the operator $T_{2,\pm 1}$ as a result of a quadrupolar splitting forms the basis of a method of distinguishing this effect from biexponential relaxation. If the double quantum filter of Figure 2(a) is performed on a system that exhibits a residual quadrupolar splitting then both in-phase double quantum coherence, $T_{2,\pm 2}$, and antiphase double quantum coherence, $T_{3,\pm 2}$, will be selected. This does not achieve the desired discrimination, since $T_{3,\pm 2}$ coherence arising as a result of pure transverse relaxation will also be selected by the filter. Jaccard et al.³ and Eliav et al.¹⁶ have shown, however, that if either or both of the flip angles β or β' in the double quantum filter is set to 54.7° then third-rank coherences are suppressed and only second-rank coherences will appear. Thus, the resulting spectrum will feature only those ^{23}Na nuclei that exhibit a residual quadrupolar splitting. The Jeener–Broekaert experiment can be used to achieve the same result with slightly higher sensitivity.¹⁷

Figure 5(a) shows the double quantum filtered ^{23}Na spectrum (with $\beta = \beta' = 90^\circ$) of the suspension of human red blood cells used in Figure 4(c) and (d). If biexponential relaxation were solely responsible for this spectrum then equations (13a) and (13b) show that these lineshapes would be identical to those in the triple quantum filtered spectrum in Figure 4(d). Clearly, however, both intra- and extracellular lineshapes are very different, and this is because those in Figure 5(a) contain a $T_{2,-1}$ component that has arisen from residual quadrupolar splittings hidden within the linewidth. Figure 5(b) shows the result of using the double quantum filter of Figure 2(a) with $\beta = \beta' = 54.7^\circ$ to record a spectrum arising solely from ^{23}Na nuclei that exhibit residual quadrupolar splittings (presumably those associated with the cell membrane^{18,19}). The lineshapes here consist of antiphase spin- $\frac{3}{2}$ powder patterns, except that, using the same phasing parameters as in Figure 5(a), they appear in dispersive mode.^{16,17}

Figure 5 Double quantum filtered ^{23}Na spectra of the red blood cell suspension used in Figure 4(c) and (d). The experiment of Figure 2(a) was used with $\beta = \beta' = 90^\circ$ (a) and $\beta = \beta' = 54.7^\circ$ (b). Acquisition parameters: 2500 Hz spectral width, 2400 transients coadded, 105.8 MHz Larmor frequency, 128 points acquired and zero filled to 512, 5 ms evolution interval τ_e

7 DISCUSSION AND SUMMARY

This article has concentrated on spin- $\frac{3}{2}$ nuclei. This is inevitable, since nuclei such as ^7Li , ^{39}K , ^{87}Rb , and, in particular, ^{23}Na are studied very frequently, while higher spin nuclei such as ^{25}Mg , ^{43}Ca , ^{85}Rb , and ^{133}Cs have less favorable NMR parameters and are only rarely studied. Multiple quantum filtration has been used, however, in ^{25}Mg NMR of MgCl in bovine albumin solutions.^{20,21} The relaxation of spin- $\frac{5}{2}$ nuclei is triexponential outside the extreme narrowing limit, and is described by transverse and longitudinal functions of the type $f_{11}^{(n)}(t)$, $f_{31}^{(n)}(t)$, and $f_{51}^{(n)}(t)$. Thus, excitation of multiple quantum coherences up to $p = \pm 5$ is possible. The most straightforward method of determining the relaxation parameters of spin- $\frac{5}{2}$ nuclei is probably measurement of the four- and five-quantum relaxation rates in an analogous way to which the double and triple quantum relaxation rates can be measured for spin- $\frac{3}{2}$ nuclei.²¹

In summary, since being introduced only in 1986, multiple quantum filtration studies of quadrupolar relaxation have proved highly rewarding, especially in biological systems. Multiple quantum filters allow the biexponential relaxation of spin- $\frac{3}{2}$ nuclei to be measured with great accuracy, and have also been used to obtain partial discrimination of sodium and potassium ions in the various compartments of tissues and cell suspensions. A relatively new application of multiple quantum filtration has been the selective observation and study of spin- $\frac{3}{2}$ nuclei that exhibit residual quadrupolar splittings as a result of their association with ordered structures in cells and tissues. In addition to the applications discussed here, multiple quantum filters have also been used as a method of reversing contrast in ^{23}Na magnetic resonance imaging^{22–24} and as a method of accurately measuring spin- $\frac{3}{2}$ dynamic shifts.²⁵ It seems likely that interest in all these areas will continue to grow in the next few years.

1 INTRODUCTION

Several excellent articles on Redfield relaxation theory are presented elsewhere in this Encyclopedia (see, e.g., *Relaxation Theory: Density Matrix Formulation*), and the applications given here are based on that work. The theory is not only simple and elegant, it is also a very powerful and useful tool for the experimental NMR spectroscopist. As shown below, NMR relaxation time measurements of coupled spin systems provide a wealth of information about molecular structure and molecular dynamics in solution that is available in no other way. Such studies are especially important, since a large fraction of chemistry takes place in solution or at interfaces where molecules are still mobile.

For an isolated spin system consisting of two spins of $\frac{1}{2}$ (e.g., C–H, P–H, C–F, P–F, etc.) at low magnetic fields (2.3 T or lower) where only dipolar relaxation is important, the NMR relaxation in a nonviscous fluid sample can be characterized by a single parameter, R_1 , the spin–lattice relaxation rate, since in this case the longitudinal relaxation, R_1 , and the transverse relaxation, R_2 , are equal. That is, all four spectral lines (two for each nucleus) have the same relaxation rate. For magnetic fields of 4.7 T (200 MHz for protons) and higher, most nuclei other than hydrogen are relaxed by both the dipolar and by the chemical shift anisotropy (CSA) mechanisms. In this event, for a coupled system, the observed relaxation rate cannot be described as the sum of the relaxation rates of the contributing mechanisms, that is, $R_{\text{total}} \neq R_{\text{dipolar}} + R_{\text{CSA}}$. Furthermore, four parameters are required to describe the transverse relaxation (each of the four lines has a different R_2 value);^{1–9} and for longitudinal relaxation, each line relaxes as a triple exponential.^{6–12}

A clear understanding of such relaxation processes is essential, since it has recently been shown that in coherence transfer experiments on large molecules (with long correlation times), anomalous peaks may arise in 2D multiple quantum filtered correlation spectra owing to the presence of such multiple relaxation processes.¹⁰ Differential relaxation can also affect two-dimensional correlation (COSY) experiments.^{13,14}

The experiments in an aqueous solution of Na₂PHO₃ discussed below provide insight into these differential longitudinal and transverse relaxation processes.

For the general case of two coupled spins of $\frac{1}{2}$, A and K, the parameters that affect the longitudinal and the transverse relaxation are the CSA values of spin A and spin K, the A–K bond distance, the molecular correlation time, and the random field terms. The simultaneous determination of all these parameters at a given temperature presents the opportunity to measure their temperature dependence, a situation that is not possible when relaxation is due to a single relaxation mechanism¹⁵ or when one of the two spins is decoupled. In addition, in the coupled experiments described here, the temperature dependence of the random field terms provides information about the molecular motion of those solvent molecules that are in close proximity to the spin pair.

2 REDFIELD THEORY AND TRANSVERSE RELAXATION

The theory of spin–lattice relaxation in coupled spin systems has been treated thoroughly by a number of authors,^{1–12} and is not repeated in detail here. For the most general case, the time evolution of the density matrix σ is given by

$$\frac{d\sigma}{dt} = \mathbf{R}[\sigma - \sigma(\infty)] \quad (1)$$

This equation can in most cases be greatly simplified. If the basis functions for the density matrix are eigenstates of the Hamiltonian then the diagonal elements σ_{ii} of the density matrix represent the populations of the energy levels, and are related to the longitudinal (T_1) relaxation. Furthermore, in this eigenbasis representation, if the eigenstates are not degenerate, the density matrix elements σ_{ij} are not connected via the relaxation superoperator to any other matrix elements, and the time evolution of these states is given by

$$\frac{d\sigma_{ij}}{dt} = -R_{ijij}[\sigma_{ij} - \sigma_{ij}(\infty)] \quad (2)$$

Given the boundary condition that the transverse magnetization at time $t = 0$ is $\sigma_{ij}(\text{max})$, the solution of the above differential equation is

$$\sigma_{ij}(t) = \sigma_{ij}(\text{max}) \exp(-t/T_2) \quad (3)$$

Equation (3) tells us that the free induction decay (FID) signal for the coherence σ_{ij} will decay as a single exponential with a time constant T_2 . The Fourier transform of this FID is consequently a Lorentzian line with a linewidth, $\pi \Delta\nu_{1/2}(i \rightarrow j) = R_{ijij}$ (see Figure 1). The matrix elements R_{ijij} are then related in a simple fashion to the linewidths of the six transverse coherences for the two-spin system. There are four single quantum coherences: R_{1212} and R_{3434} , the low- and high-frequency lines, respectively, in the carbon spectrum (for a carbon–hydrogen spin pair), and R_{1313} and R_{2424} , the low- and high-frequency lines, respectively, in the proton spectrum (a similar situation would hold, of course, for a proton–phosphorus spin pair or a fluorine–phosphorus spin

Figure 1 The energy level diagram for PHO_3^{2-} . The labeled wavefunctions correspond to the weak coupling limit. The transitions are as follows: $1 \rightarrow 3$ and $2 \rightarrow 4$ correspond to the low- and high-frequency proton peaks, $1 \rightarrow 2$ and $3 \rightarrow 4$ correspond to the low- and high-frequency phosphorus peaks, $2 \rightarrow 3$ corresponds to the zero quantum transition, and $1 \rightarrow 4$ corresponds to the double quantum transition

pair). We may indirectly measure the zero quantum coherence rate constant R_{2323} and the double quantum coherence rate constant R_{1414} . These relaxation matrix elements are related in a straightforward fashion to the dipolar parameter p , the two chemical shift anisotropies $\Delta\sigma_I = \delta_I$ and $\Delta\sigma_S = \delta_S$, the molecular correlation time, τ_c , and random field terms as indicated in Table 1.

This is, in principle, an attractive way to obtain a wealth of information about molecular structure and molecular dynamics, since it would appear that one need only measure six relaxation rates. As mentioned above, in a completely homogeneous magnetic field, the rate constant is related to the spectral linewidth:

$$R_{ijij} = (1/T_2)_{(i \rightarrow j)} = \pi \Delta\nu_{1/2}(i \rightarrow j) \quad (4)$$

where $\Delta\nu_{1/2}(i \rightarrow j)$ is the full width at halfheight of a peak with Lorentzian lineshape.

In practice, accurate values of the transverse relaxation time may be obtained using the experimental linewidth only when the relaxation time is short. In this event, the linewidth is usually very large compared with any magnetic field inhomogeneities. In principle, accurate values for the linewidth may be obtained by a spin echo experiment, which circumvents the errors arising from pulse imperfections and self-diffusion through an inhomogeneous field. One popular and often used version of the spin echo experiment is the one proposed by Meiboom and Gill.¹⁶ This experiment uses the pulse sequence

$$90_x^\circ - (\tau - 180_y^\circ - \tau)_n \quad (5)$$

This is a variation of the Carr–Purcell pulse sequence.¹⁷ This experiment is, in principle, quite straightforward. In practice, it is very difficult to obtain accurate, meaningful results in the laboratory. If done with great care, however, this experiment is capable of providing accurate results. Vold et al.¹⁸ used numerical analysis of the Bloch equations to evaluate the effects of several experimental conditions. To obtain an accuracy of 1–2% in CPMG experiments, they suggested that the following conditions be satisfied.

Table 1 Relaxation Matrix Elements for a Weakly Coupled System of Two Spins of $\frac{1}{2}$ in the Population Basis; the Y_{ijij} and Z_{ijij} Random Field Terms Include the Longitudinal Random Field Terms A and B

Longitudinal	
$R_{1111} = -3(p - \delta_I)^2 k_I - 3(p - \delta_S)^2 k_S - 12p^2 k_+ - \frac{1}{2}(A + B)$	
$R_{1122} = 3(p - \delta_S)^2 k_S + \frac{1}{2}A$	
$R_{1133} = 3(p - \delta_I)^2 k_I + \frac{1}{2}B$	
$R_{1144} = 12p^2 k_+$	
$R_{2222} = -3(p + \delta_I)^2 k_I - 3(p - \delta_S)^2 k_S - 2p^2 k_- - \frac{1}{2}(A + B)$	
$R_{2233} = 2p^2 k_-$	
$R_{2244} = 3(p + \delta_I)^2 k_I + \frac{1}{2}B$	
$R_{3333} = -3(p - \delta_I)^2 k_I - 3(p + \delta_S)^2 k_S - 2p^2 k_- - \frac{1}{2}(A + B)$	
$R_{3344} = 3(p + \delta_S)^2 k_S + \frac{1}{2}A$	
$R_{4444} = -3(p + \delta_I)^2 k_I - 3(p + \delta_S)^2 k_S - 12p^2 k_+ - \frac{1}{2}(A + B)$	
Transverse	
$R_{1212} = -3(p^2 + \delta_I^2) k_I - 3(p - \delta_S)^2 k_S - 4(p - \delta_S)^2 k_0 - 6p^2 k_+ - p^2 k_- - Y_{1212}$	
$R_{1313} = -3(p^2 + \delta_S^2) k_S - 3(p - \delta_I)^2 k_I - 4(p - \delta_I)^2 k_0 - 6p^2 k_+ - p^2 k_- - Z_{1313}$	
$R_{2424} = -3(p^2 + \delta_S^2) k_S - 3(p + \delta_I)^2 k_I - 4(p + \delta_I)^2 k_0 - 6p^2 k_+ - p^2 k_- - Z_{2424}$	
$R_{3434} = -3(p^2 + \delta_I^2) k_I - 3(p + \delta_S)^2 k_S - 4(p + \delta_S)^2 k_0 - 6p^2 k_+ - p^2 k_- - Y_{3434}$	
Zero/multiple quantum	
$R_{2323} = -3(p^2 + \delta_I^2) k_I - 3(p^2 + \delta_S^2) k_S - 4(\delta_I - \delta_S)^2 k_0 - 2p^2 k_- - X_{2323}$	
$R_{1414} = -3(p^2 + \delta_I^2) k_I - 3(p^2 + \delta_S^2) k_S - 4(\delta_I + \delta_S)^2 k_0 - 12p^2 k_+ - X_{1414}$	
$p = \gamma_I \gamma_S \mu \hbar / 8\pi r_{IS}^3$	
$\delta = \frac{1}{3} \gamma B_0 [\sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22})]$	
$k_0 = \frac{1}{5} \tau_c$	
$k_i = \tau_c / 5(1 + \omega_i^2 \tau_c^2)$	
$\omega_+ = \omega_I + \omega_S$	
$\omega_- = \omega_I - \omega_S$	

1. Pulse widths must be calibrated and accurate to within about 5% of ideal.
2. Data from the first part of the relaxation curve should not be used in the least-squares fit.
3. The transmitter should be as close to on resonance as possible to eliminate off-resonance effects.
4. Amplitudes of the spin echoes must be calculated relative to an experimentally determined steady-state value.
5. The sample should remain static so that the gradients in the magnetic field are not time-dependent.
6. Refocusing pulse spacings should be less than approximately 100 ms so that diffusion effects are eliminated.

Another method of measuring relaxation in the transverse plane is the spin locking experiment,^{19,20} in which one employs a continuous B_1 field in lieu of the sequence of 180° pulses used in spin echo experiments. This field locks the magnetization along the applied axis in the transverse plane. By varying the duration of the spin locking period, one may fit the peak intensity versus time to a decaying exponential and obtain the spin-lattice relaxation time in the rotating frame, $T_{1\rho}$. For most liquid samples, $T_{1\rho}$ is essentially equivalent to T_2 .^{19,21}

To obtain information about the relaxation rates for zero and multiple quantum coherences, a number of different pulse sequences have been proposed.²² For heteronuclear spin systems, the following pulse sequence may be used to generate double quantum coherences:²³

$$\left. \begin{array}{l} I : 90_y^\circ - \frac{1}{2}\tau - 180^\circ - \frac{1}{2}\tau - 90_x^\circ - t_1 - \text{acquire} \\ S : 180^\circ - \frac{1}{2}\tau - 90^\circ - t_1 \end{array} \right\} \quad (6)$$

where $\tau = \pi/2J$. The purpose of the 180° pulses is to refocus the dephasing of the magnetization due to magnetic field inhomogeneities and chemical shifts and suppress the dependence of the transmitter offset frequency. Yang et al.²⁴ proposed using a similar pulse sequence with explicit pulse phasings to separate the zero and double quantum coherences. This sequence is as follows:

$$\left. \begin{array}{l} I : 90_1^\circ - \frac{1}{2}\tau - 180_y^\circ - \frac{1}{2}\tau/2 \quad 180_x^\circ - \frac{1}{2}t_1 - 90_2^\circ \\ S : 180_y^\circ - \frac{1}{2}\tau - 90_y^\circ - \frac{1}{2}t_1 - 180_x^\circ - \frac{1}{2}t_1 - \text{acquire}_3 \end{array} \right\} \quad (7)$$

To obtain purely zero quantum coherence, the relative phasing of the pulses is

$$\left. \begin{array}{l} (1) \ x \ x \ -x \ -x \\ (2) \ x \ y \ x \ y \\ (3) \ x \ y \ -x \ -y \end{array} \right\} \quad (8)$$

which is arranged to eliminate any magnetization from the S spin. The recovery curve may then be fit to the following equation to obtain the zero quantum relaxation time T_{ZQ} :

$$\begin{aligned} I(t_1) &= I(\infty) + B'e^{-t_1/T_{ZQ}} \sin(\pi J \tau) \\ &= A + B'e^{-t_1/T_{ZQ}} \end{aligned} \quad (9)$$

To obtain purely double quantum coherence, the relative phasing of the pulses is

$$\left. \begin{array}{l} (1) \ x \ x \ -x \ -x \\ (2) \ x \ -y \ x \ -y \\ (3) \ x \ y \ -x \ -y \end{array} \right\} \quad (10)$$

The recovery curve may then be fit to an equation similar to that for a zero quantum coherence to obtain the double quantum relaxation time T_{DQ} .

3 APPLICATION TO MOLECULAR STRUCTURE AND DYNAMICS IN Na_2PHO_3

It is important to test the development of a new theory by carrying out experiments on a sample for which one knows the experimental results. All of the pertinent NMR parameters for a sample of Na_2PHO_3 have been measured by a number of independent methods. We therefore decided to carry out a set of transverse relaxation experiments with a solution of sodium phosphite, Na_2PHO_3 , dissolved in a 60%/40% mixture of ethylene glycol- d_6 and methanol- d_4 . They were performed at -25.4°C , a temperature slightly higher than the temperature of the proton-decoupled T_1 minimum of the phosphorus nuclei at a field of 4.7 T. Figure 2 shows the ^{31}P NMR spectra of the sample in a field of 11.5 T. The upper trace was recorded at 300 K, the middle trace at 250 K, and the bottom trace at 225 K. At 225 K, the low-frequency line has become so broad that it has disappeared into the baseline noise.

Fitting the data to equation (1) produced the following best fit parameters: the P-H bond length $r = 150.4$ pm, the proton chemical shift anisotropy $\Delta\sigma_H = 5.3$ ppm, the phosphorus chemical shift anisotropy $\Delta\sigma_P = -137.5$ ppm, the rotational correlation time, assuming a Lorentzian spectral density function, $\tau_c = 818$ ps, the phosphorus intermolecular term $A = 0.27\text{ s}^{-1}$, and the proton intermolecular term $B = 0.22\text{ s}^{-1}$. The theoretical transverse relaxation times may be calculated using these molecular parameters and the equations given in Table 1. Independent values for the P-H bond length were obtained from X-ray and neutron diffraction experiments.²⁵ Independent values for the phosphorus and proton chemical shift anisotropies were obtained from NMR

Figure 2 The ^{31}P NMR spectra of a sample of Na_2PHO_3 in a magnetic field of 11.5 T (202 MHz resonance frequency for phosphorus). The upper trace was recorded at 300 K, the middle trace at 250 K, and the bottom trace at 225 K. At 225 K, $\omega_0\tau_c \sim 1$, and the low-frequency line has become so broad that it has disappeared into the baseline noise

experiments on a solid sample of Na_2PHO_3 (T. C. Farrar, unpublished results).

These results show clearly that the two lines in the phosphorus spectrum will have different widths and the two lines in the proton spectrum will have different widths. The width of the $(1 \rightarrow 2)$ phosphorus line in PHO_3^{2-} must be broad, since the sign of the phosphorus CSA is negative and R_{1212} contains terms with the difference between δ_P and p . Similarly, the width of the $(3 \rightarrow 4)$ phosphorus line must be narrow, since R_{3434} contains terms with the sum of the CSA and dipolar terms. In the phosphorus spectra shown in Figure 2, the low-frequency line is broad; consequently, the sign of the phosphorus–proton coupling constant $J(\text{P,H})$ must be positive. The equations for R_{ijij} above also show that the greatest differential line broadening will occur at that field for which the CSA and the dipolar parameters are approximately equal, and under those sample conditions for which $\omega\tau_c \sim 1$. This is exactly what we have found experimentally.

The theory clearly tells us what to expect, but it is always a bit more satisfying if one can obtain a simple physical picture of what is happening. Consider, then, a single crystal of Na_2PHO_3 with the various orientations shown in Figure 3(a). The resonance frequency for the phosphorus nuclei that are bonded to protons will change as a function of Θ in the following manner:

$$f_\alpha = f_0 - \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) \quad (11)$$

$$f_\beta = f_0 + \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) \quad (12)$$

where f_α and f_β are the two frequencies in the phosphorus spectrum, Θ is the angle between the P–H internuclear vector and the magnetic field $\mathbf{B}_0$, and r is the P–H bond length. The other constants are defined in Table 1. Note that the f_α line arises from that half of the molecules in which the phosphorus is bonded to a proton nucleus in the α spin state (i.e., those proton nuclei that have their spins aligned parallel with the magnetic field $\mathbf{B}_0$), and the f_β line arises from that half of the molecules in which the phosphorus is bonded to a proton nucleus in the β spin state. If the chemical shift of the phosphorus is isotropic ($\delta_P = 0$), there will be a maximum splitting of $2p$ (about 15 kHz) for the two lines at a value of $\Theta = 0$. For $\Theta = 54.7^\circ$ (the ‘magic angle’), the two lines will coalesce, and at $\Theta = 90^\circ$ the splitting is p (about 7.5 kHz, see the definition of p in Table 1). The spectra for these orientations are depicted in Figure 3(a). The hatched lines below the spectra show the total variation in the magnetic field at the phosphorus nuclei as Θ varies.

If the phosphorus and/or proton chemical shifts are anisotropic (which they are for PHO_3^{2-}) then the local field experienced by the phosphorus nuclei will be very different. Figure 3(b) shows the single crystal spectra for the phosphorus for the same orientations as in Figure 3(a). The frequencies of the two lines are now given by

$$f_\alpha = f_0 - \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) + \delta_P (3 \cos^2 \Theta - 1) \quad (13)$$

$$f_\beta = f_0 + \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) + \delta_P (3 \cos^2 \Theta - 1) \quad (14)$$

Figure 3 (a) ^{31}P NMR spectra for a single crystal of Na_2PHO_3 at three different orientations of Θ , the angle between the P–H internuclear vector and the magnetic field direction, assuming a phosphorus CSA of zero. (b) As (a), but with a phosphorus CSA value of -140 ppm

If the magnitudes of the phosphorus dipolar and CSA terms are about equal then one of the lines in the single crystal spectrum will experience almost no change in frequency as a function of Θ , since any change in the local field due to the dipolar term will be canceled by the CSA term. The other line will experience a change almost twice as great, since local fields generated by the dipolar and CSA terms add constructively. For PHO_3^{2-} , the phosphorus CSA, $\delta_P = (\sigma_{\parallel} - \sigma_{\perp})_P = -125$ ppm.^{6,7} In this case, the total range of magnetic fields experienced as a function of Θ is very small for the P_β nuclei, the phosphorus nuclei spin-coupled to proton nuclei in the β spin state. At a magnetic field of about 6.3 T, the local magnetic field for the P_β nuclei is almost independent of orientation. For the P_α nuclei, the local field changes over a range almost twice as great as that expected for the dipolar interaction. In other words, the dipolar field fluctuations at the P_β nuclei due to changes in orientation are largely canceled by field changes of the opposite sign due to the CSA. The hatched bars below the spectra in Figure 3(b) show schematically this very small range in the local field for the P_β nuclei and the twofold greater-than-normal dipolar range in the dipolar field for the P_α nuclei.

When the molecules begin to move, the magnetic fields at the P_α and P_β nuclei are modulated by the molecular motion. And it is the magnitude of this motion-induced magnetic field modulation [represented by the hatched bars in Figure 3(a) and (b)] that couples the precessional motion of the nuclear spins to the molecular motion and brings about relaxation of the nuclear spin system. When the CSA and dipolar interactions are comparable, as they are in the present case, relatively little magnetic field modulation occurs at the P_β nuclei. Consequently, they will have a very long relaxation time, even for slow molecular motions where $\omega_P \tau_c \sim 1$. The P_α nuclei, however, will experience much larger than normal magnetic field fluctuations, and as a result will have short relaxation times.

Normally, one cannot determine which of the lines in a high-resolution NMR spectrum are associated with the transitions between the various energy levels. For example, in a spectrum such as that in Figure 2, it is not usually possible to determine whether the high-frequency phosphorus line arises from the transition between energy levels 1 and 2 or between levels 3 and 4. However, when differential line broadening is present, one can easily determine which line is associated with the transitions between the energy levels. As pointed out above, since we know from solid state NMR experiments that the phosphorus CSA is negative and since we know from the spectrum that it is the low-frequency phosphorus line that is broad, by looking at the expression for R_{1212} above, we know that the broad line must be associated with the R_{1212} transition. Consequently, the absolute sign of the phosphorus–hydrogen spin coupling constant, $J(\text{P,H})$ must be positive; in this case, $J(\text{P,H}) = +565$ Hz. In a similar fashion, we have shown that the absolute sign of directly bonded carbon–hydrogen spin coupling is positive.⁸

The transverse relaxation times for all four lines were measured using the CPMG sequence [see equation (5)] and $T_{1\rho}$ experiments. The experiments were performed on resonance at the same temperature as the longitudinal relaxation experiments. The sample was static, and field/frequency locking was not used. A three-parameter fit to an equation similar to equation (9) gives the transverse relaxation time. For the $R_{1\rho}$ experiments, the spin locking fields γB_1 were 340 and 746 s^{-1} , respectively, for the proton and phosphorus nuclei. Table 2 shows a comparison of the results from these experiments.

4 DISCUSSION

Examining Table 2, one sees that the experimentally determined transverse relaxation times do not agree with the theoretical relaxation times calculated from the bond length, the two CSAs, and the correlation time obtained from the longitudinal relaxation studies. The calculated T_{ij} values are appreciably longer than the experimentally determined values. The differences are due to several factors. The largest source of the differences probably arises from the intermolecular, random field terms. These terms account for relaxation mechanisms of rank one, such as scalar relaxation, spin rotation, chemical exchange, and relaxation due to the presence of paramagnetic species. Since the experiments were done at low temperature, spin rotation can be ruled out. Very careful sample preparation allows one also to rule out paramagnetic impurities. Since the random field terms for

the longitudinal relaxation also contribute to the transverse relaxation, and have been included in the Y_{ijj} and Z_{ijj} terms in the calculated values, the difference must arise from additional random field terms that are unique to the transverse relaxation. Such terms would include those due to chemical exchange and other relatively slow random dynamic processes. Neglect of these terms will result in calculated values for the transverse relaxation rates that are smaller (and calculated relaxation times that are longer) than the experimentally measured values.

If one assumes that the additional intermolecular contribution is the same for both single quantum coherences of a given nucleus, one may subtract the relaxation rates and get a relation independent of the intermolecular interactions:

$$\Delta_P = R_{1212} - R_{3434} = 12p\delta_P k_P + 16p\delta_P k_0 \quad (15)$$

$$\Delta_H = R_{1313} - R_{2424} = 12p\delta_H k_H + 16p\delta_H k_0 \quad (16)$$

where k_i and k_0 are defined in Table 1. Comparing the experimentally obtained values of these parameters with those calculated from T_1 data, the results still do not agree, implying either that these additional intermolecular terms are not the sole factor causing the difference or that there are still additional random field terms operating that do not equally affect the two different coherences for a given nucleus. This suggests, for example, that Y_{1212} and Y_{3434} (see Table 1) are not equal.

Another factor that may lead to the discrepancies seen between the theoretical relaxation rates and the experimentally determined rates is the form of the spectral density function. Longitudinal relaxation depends on rapidly fluctuating fields near the Larmor frequency γB_0 . Transverse relaxation times depend on fluctuating fields near the Larmor frequency as well as slowly fluctuating fields described by k_0 . The Lorentzian spectral density function may not be valid for this range of molecular motions. Finally, the experiments may not be measuring the true transverse or zero/multiple quantum relaxation rates.

5 SUMMARY

In principle, transverse relaxation studies, including zero and multiple quantum coherences, can provide structural and dynamic information. They complement longitudinal relaxation studies in that they provide information concerning low-frequency motions and cross-correlation functions. Preliminary work comparing longitudinal and transverse relaxation results obtained for PHO_3^{2-} in solution indicates that great caution

Table 2 Theoretical and Experimental Results of Transverse Relaxation Studies on PHO_3^{2-}

^aThe values for p , $\Delta\sigma_P$, $\Delta\sigma_H$, τ_c , and the random field terms A and B were taken from longitudinal NMR experiments, solid state NMR experiments, and neutron diffraction work, and were used in the equations for the R_{ijj} matrix elements given in Table 1.

should be used in using the transverse experiments to obtain structural and dynamic information. This is in part due to the difficulty in executing accurate, meaningful CPMG and $T_{1\rho}$ experiments. It may also be due to the fact that a single spectral density function is not a faithful representation of the molecular motions over the entire range of motion.

Given the six equations for the six different coherences and the up to 10 unknown parameters (δ_H , δ_P , p , and τ_c , and the six transverse random field terms; see Table 1), a measurement of the six coherences is not enough information to give one accurate, uniquely determined values for all of those parameters. In addition, as we have seen in the example presented above, there are experimental problems, since it is very difficult indeed to measure linewidths (coherences) accurately, especially for very narrow lines. In our experience, neither linewidth measurements nor Carr–Purcell–Meiboom–Gill spin echo experiments give highly reliable results, especially at the higher temperatures where some of the linewidths are relatively narrow. $T_{1\rho}$ experiments, if done carefully, give reasonably good results.

The most fundamental difficulty is that one has 6 equations and there are probably 10 unknown parameters. This would seem to indicate that experimental information about the transverse relaxation must be complemented by additional data from longitudinal relaxation experiments. In practice, a better way to obtain information about the molecular parameters is to carry out longitudinal relaxation time experiments. Although the data analysis is considerably more difficult, the experiments are easier to execute, and give more reliable and more reproducible results.^{6–8}

1 INTRODUCTION

Whenever molecular motions effectively average the spatially anisotropic couplings between a nuclear spin and the extranuclear environment, NMR relaxation parameters can be described using standard second-order time-dependent perturbation theory.¹ Because of the quadratic relationship between interaction strength and relaxation rate, if several couplings are responsible for effecting nuclear spin relaxation, relaxation rates identified with each distinct coupling are not additive unless all bilinear cross products vanish.

Although symmetry arguments require that these cross products vanish in certain instances, generally these terms are nonzero. It is important to recognize that each cross term must be modified by a factor that describes the degree of correlated fluctuation between the competing relaxation pathways. Fundamentally different *cross* correlation and *autocorrelation* times are needed to describe the perturbation response characteristics of spins influenced by competitive relaxation pathways.

The distinction between autocorrelation and cross correlation is more than arithmetic. Autocorrelation is instrumental in thermalization/dissipation processes, and can be associated with measurements of T_1 , T_2 , $T_{1\rho}$, or cross relaxation. In contrast, cross correlation initiates polarization and coherence transfer, and is manifest in higher forms of transient spin order. The roles played by autocorrelation and cross correlation are complementary.

The study of relaxation-induced multispin order probes temporal spin correlation in a manner similar to a multidimensional NMR probe of residual spin correlation. Indeed, most contemporary NMR techniques utilize polarization transfer, and if the relaxation process selectively dissipates certain forms of spin order then failure to consider such relaxation

effects can damage the credibility of the most elementary 2D experiment. From a practitioner's perspective, utilization of cross correlation yields much finer detail of molecular structure and dynamics than conventional relaxation parameters, and should be the method of choice, whenever possible, for the contemporary molecular scientist who wishes to exploit nuclear spin relaxation to its fullest.

Two established reviews, by Werbelow and Grant² and by Vold and Vold³, discuss relaxation-induced magnetization transfer and coherence transfer, respectively. Three reviews by Canet,⁴ Grant et al.,⁵ and Werbelow,⁶ provide valuable discussions of numerous other features associated with cross correlation and nuclear spin relaxation in multispin systems.

2 SEMICLASSICAL THEORY OF NUCLEAR SPIN RELAXATION

In the absence of applied rf fields, the interaction between a nuclear spin and the extranuclear environment can be written as $\hat{H}(t) = \hat{E} + \hat{F}(t)$ where $\hat{E} = \langle \hat{H}(t) \rangle$ and $\hat{F}(t) = \hat{H}(t) - \hat{E}$. The term associated with nuclear spin relaxation, $\hat{F}(t)$, can be cast in the form

$$\hat{F}(t) = \sum_{\eta} \hat{F}_{\eta} = \sum_{\eta} \xi_{\eta} \sum_k (-1)^k \hat{T}_{\eta}^k V_{\eta}^{-k}(t) \quad (1)$$

The Hamiltonian $\hat{F}(t)$ is composed of a number of distinct couplings or relaxation pathways (η). Each interaction has been partitioned into a symmetrized product of classical lattice functions V , characteristic interaction coupling constants ξ , and spin operators $\hat{T}$. The simple decomposition implicit in equation (1) obtains for interactions with axial symmetry.

If motional narrowing obtains, the time evolution of individual matrix elements of a thermally normed, reduced spin density operator $\hat{\chi}(t)$ are described by a simple set of linearly coupled first-order equations¹

$$\begin{aligned} \frac{d}{dt} \chi_{\alpha\alpha'}(t) = & -i\omega_{\alpha\alpha'} + \sum_{\alpha''} \sum_{\alpha'''} \mathcal{R}_{\alpha\alpha'\alpha''\alpha'''} \chi_{\alpha''\alpha'''}(t) \\ & \times \exp[i(\omega_{\alpha\alpha'} - \omega_{\alpha''\alpha'''})t] \end{aligned} \quad (2)$$

$$\begin{aligned} \mathcal{R}_{\alpha\alpha'\alpha''\alpha'''} = & \sum_k \sum_{\eta} \sum_{\eta'} [J_k^{\eta\eta'}(\omega_{\alpha\alpha'}) + J_k^{\eta\eta'}(\omega_{\alpha''\alpha'''})] \\ & \times (T_{\eta}^k)_{\alpha\alpha''} (T_{\eta'}^{-k})_{\alpha'''\alpha'} \\ & - \delta_{\alpha\alpha''} \sum_{\beta} J_k^{\eta\eta'}(\omega_{\alpha''\beta}) (T_{\eta}^k)_{\alpha\beta} (T_{\eta'}^{-k})_{\beta\alpha'} \\ & - \delta_{\alpha'''\alpha'} \sum_{\beta} J_k^{\eta\eta'}(\omega_{\beta\alpha''}) (T_{\eta}^k)_{\alpha\beta} (T_{\eta'}^{-k})_{\beta\alpha''} \end{aligned} \quad (3)$$

The spectral density $J_k^{\eta\eta'}$ is derived from the correlation function $\langle V_{\eta}^{-k}(t - \tau) V_{\eta'}^k(t) \rangle$ via a one-sided Fourier transformation:

$$J_k^{\eta\eta'}(\omega) = \xi_{\eta} \xi_{\eta'} \text{Re} \int_0^{\infty} \langle V_{\eta}^{-k}(t - \tau) V_{\eta'}^k(t) \rangle \exp(-i\omega\tau) d\tau \quad (4)$$

In this discussion, the imaginary component of the spectral density, identified with a second-order frequency shift, is ignored. The abbreviated matrix elements introduced in equations (2) and (3) are defined by $\chi_{\alpha\beta} = \langle \alpha | \hat{\chi} | \beta \rangle$, $(T_\eta^k)_{\alpha\beta} = \langle \alpha | \hat{T}_\eta^k | \beta \rangle$, and $\omega_{\alpha\beta} = \langle \alpha | \hat{\mathcal{E}} | \alpha \rangle - \langle \beta | \hat{\mathcal{E}} | \beta \rangle$. If appropriate caution is exercised, one may invoke the secular approximation¹ and replace $\exp[i(\omega_{\alpha\alpha'} - \omega_{\alpha''\alpha'''})t]$ with $\delta[i(\omega_{\alpha\alpha'} - \omega_{\alpha''\alpha'''})]$.

3 ‘MAGNETIZATIONS’ AND COHERENCES

Although equation (2) provides a convenient framework for computation, it imparts little insight into the inherent kinetic symmetries of spin relaxation. Furthermore, many observables in the relaxation experiment do not identify with individual elements of the reduced density operator, and the correspondence between theory and experiment is unclear. However, certain inadequacies of equation (2) are avoided upon transformation to a more useful operator basis^{2,7}

$$\hat{v}_i = \sum_j Q_{ij} \chi_j \quad (5)$$

$$-\Gamma_{ij} = \sum_{m,m'} Q_{im} \mathcal{R}_{mm'} Q_{m'j} \quad (6)$$

where the summation indices j , m and m' designate sums over all distinct pairs of states ($\alpha\alpha'$). The negative sign is introduced as a matter of convention. Various linear combinations of diagonal elements of the density operator correspond to magnetization or polarization modes, whereas combinations of various off-diagonal elements are identified as coherence modes. In general, each mode is characterized by a well-defined order or rank L and parity (under spin inversion). Most importantly, each mode can be brought into direct correspondence with a measurable of the system. The operator basis most suitable for discussion of relaxation effects is not necessarily the most appropriate for discussion of pulse effects or evolution under $\hat{\mathcal{E}}$.

Obviously, $\hat{\chi}$ could be expanded initially in a complete set of orthogonal basis operators, $\hat{\chi} = \sum_i c_i \hat{v}_i$, followed by the development of an operator equivalent to equation (2):^{8,9}

$$\begin{aligned} \frac{d}{dt} \langle \hat{v}_i(t) \rangle &= i[\hat{v}_i, \hat{\mathcal{E}}] + \sum_{k,\eta,\eta'} J_k^{\eta\eta'}(\omega_k) \text{Tr}\{\hat{\chi}(t)[[\hat{v}_i, \hat{T}_\eta^k], \hat{T}_{\eta'}^{-k}]\} \\ &= i[\hat{v}_i, \hat{\mathcal{E}}] - \sum_j \Gamma_{ij} \langle \hat{v}_j(t) \rangle \end{aligned} \quad (7)$$

A computational framework can be built around the evaluation of spin matrix elements or an evaluation of composite spin commutators. In certain situations, utilizing equation (2) may provide certain advantages, both in terms of insight and computation, over equation (7), whereas in other situations, the opposite argument could be made.

4 THE CROSS-CORRELATION SPECTRAL DENSITY

Looking at either equation (3) or equation (7), it is apparent that the time evolutions of various coherence and magnetization modes are influenced by both autocorrelation ($\eta = \eta'$) and

cross correlation ($\eta \neq \eta'$) spectral densities. Cross correlation is quenched only if the correlation function $\langle V_\eta^{-k}(t - \tau) V_{\eta'}^k(t) \rangle$ vanishes. In the context of those interactions commonly encountered, one must consider the following nonvanishing interferences: random fields operative at different nuclear sites, interferences between interactions where the lattice variables transform as first-rank spherical harmonics, and those interferences where the lattice variables transform as second-rank spherical harmonics.

The most *useful* interferences encountered in practice occur between mechanisms that probe rotational dynamics via the rank-2 spherical harmonic angular correlation function. These interactions include dipole–dipole (direct and indirect), electric quadrupolar and anisotropic shielding. Detailed formulas for rank-2 spherical harmonic angular correlation functions applicable for studies in isotropic fluids² and anisotropic fluids¹⁰ are available, as are expressions applicable for nonaxially symmetric rank-2 interactions.¹¹ For illustrative purposes, a suitable correlation function loses little versatility if it is assumed that motions can be modeled as diffusive and the fluid is spherically symmetric (i.e., isotropic), $\langle V_\eta^k \rangle = 0$, in which instance the k dependence of the spectral density can be suppressed. However, the assumption of isotropic molecular reorientation is too restrictive, whereas equations for general asymmetric reorientation are too unwieldy. An acceptable compromise is provided by the symmetric top rotator, which encompasses the essential element of model-free reorientation. For a symmetric top rotator, the reduced spectral density $J^{\eta\eta'}(\omega)/\xi^\eta \xi^{\eta'}$ of a second-rank spherical harmonic angular correlation function is defined as

$$\begin{aligned} \frac{J^{\eta\eta'}(\omega)}{\xi^\eta \xi^{\eta'}} &= \text{Re} \int_0^\infty \langle Y_2^{-k}(\Omega_\eta(t)) Y_2^k(\Omega_{\eta'}(0)) \rangle \exp(-i\omega t) dt \\ &= \frac{1}{16\pi} \left[\frac{(3 \cos^2 \theta_\eta - 1)(3 \cos^2 \theta_{\eta'} - 1) \tau_{20}}{1 + (\omega \tau_{20})^2} \right. \\ &\quad + \frac{12 \cos \theta_\eta \cos \theta_{\eta'} \sin \theta_\eta \sin \theta_{\eta'} \cos(\phi_\eta - \phi_{\eta'}) \tau_{21}}{1 + (\omega \tau_{21})^2} \\ &\quad \left. + \frac{3 \sin^2 \theta_\eta \sin^2 \theta_{\eta'} \cos(2\phi_\eta - 2\phi_{\eta'}) \tau_{22}}{1 + (\omega \tau_{22})^2} \right] \end{aligned} \quad (8)$$

where $1/\tau_{Ln} = L(L+1)D_\perp + n^2(D_\parallel - D_\perp)$. $D_\parallel$ is the unique component of the diagonalized diffusion tensor and $D_\perp$ is the doubly degenerate component.

In the limit of isotropic reorientation ($\tau_{20} = \tau_{21} = \tau_{22} = \tau_2$) and extreme narrowing ($\omega \tau_2 \ll 1$), this expression reduces to $\tau_2/4\pi$ for autocorrelation terms ($\eta = \eta'$) and $\tau_2(3 \cos^2 \Theta - 1)/8\pi$ for cross correlation terms ($\eta \neq \eta'$). The angle Θ is defined as the angle between the principal axes of the two correlated interactions. In the subsequent development, the autocorrelation spectral densities $J^{\eta,\eta=\eta}$ $\sum J^\eta$ are explicitly distinguished from the cross-correlation spectral densities $J^{\eta,\eta' \neq \eta} \sum K^{\eta\eta'}$.

Unlike autocorrelation spectral densities, a cross-correlation spectral density can be either positive or negative, and often the measurement of sign rather than magnitude provides crucial information. Furthermore, cross correlation is *extremely* sensitive to rotational anisotropy. In Figure 1, the angular cross correlation factor $K^{\eta\eta'}/[J^{\eta\eta}(\omega)J^{\eta'\eta'}(\omega)]^{1/2}$ is plotted as a function of $D_\parallel/D_\perp$ for various values of $\omega \tau_{20}$. This plot

Figure 1 Plot of the angular cross correlation factor $K^{\eta\eta'}(\omega)/[J^\eta(\omega)J^{\eta'}(\omega)]^{1/2}$ versus motional anisotropy $D_{\parallel}/D_{\perp}$, for $\omega\tau_{20} = 0, 1, 2$, and 10 . This plot is generated from equation 8 using the geometric factors $\cos \theta_{\eta} = \cos \theta_{\eta'} = \frac{1}{3}$ and $\phi_{\eta} - \phi_{\eta'} = \frac{2}{3}\pi$. It is assumed that $\xi_{\eta}\xi_{\eta'} > 0$

is generated from equation (8) using a geometry relevant for methyl relaxation; $\theta_{\eta} = \theta_{\eta'} = \cos^{-1} \frac{1}{3}$ and $\phi_{\eta} - \phi_{\eta'} = \frac{2}{3}\pi$. For isotropic motions, intrinsic rank-2 spherical harmonic angular cross correlation factors reduce to the ubiquitous factor $\frac{1}{2}(3 \cos^2 \Theta - 1) = -\frac{1}{3}$, noted earlier. As illustrated in Figure 1, this is independent of whether or not extreme narrowing obtains.

Although cross-correlation factors for different geometric arrangements have unique dependences on motional anisotropy, representative features are portrayed in Figure 1. Obviously, large motional anisotropies do not guarantee strong cross correlation. Furthermore, interference (cross correlation) vanishes for certain motional anisotropies, and the influence of anisotropic motions on cross-correlation changes dramatically if slow motions are present. Indeed, for a given motional anisotropy, the *sign* of the cross-correlation spectral density may be opposite for high- and low-field studies. Conversely, if the degree of motional anisotropy is temperature-dependent, variable temperature studies performed at one field strength may produce similar behavior. In Figure 2, this behavior is demonstrated more clearly, with the cross-correlation factor plotted as a function of $\omega\tau_{20}$ for two fixed values of $D_{\parallel}/D_{\perp}$.

As mentioned, the cross-correlation spectral density can be positive, negative or zero for dynamical reasons. The preceding argument presumes the two interaction constants are like-signed: $\xi_{\eta}\xi_{\eta'} > 0$. If these interaction constants are

Figure 2 Plot of the angular cross-correlation factor $K^{\eta\eta'}(\omega)/[J^\eta(\omega)J^{\eta'}(\omega)]^{1/2}$ versus $\omega\tau_{20}$ for $D_{\parallel}/D_{\perp} = 10$ and 20 . This plot is generated from equation 8 using the geometric factors $\cos \theta_{\eta} = \cos \theta_{\eta'} = \frac{1}{3}$ and $\phi_{\eta} - \phi_{\eta'} = \frac{2}{3}\pi$. It is assumed that $\xi_{\eta}\xi_{\eta'} > 0$

oppositely signed then the cross-correlation spectral density is intrinsically negative in the limit of complete (positive) correlation. Generally, NMR observables are immune to relative signs of interaction strengths. Most definitely, this is not true when cross-correlation effects are the subject of discussion.

5 EFFECTS OF CROSS-CORRELATION IN SIMPLE, SCALAR-COUPLED SPIN- $\frac{1}{2}$ SYSTEMS

Many basic features of cross correlation are illustrated nicely by consideration of the spin grouping of scalar-coupled, distinguishable, spin- $\frac{1}{2}$ nuclei. The magnetization/coherence modes for all nondegenerate first-order systems composed of N spin- $\frac{1}{2}$ nuclei are provided by the direct product operators $\Pi_{i=1}^N (\hat{\mathcal{E}}^i + \hat{I}_z^i + \hat{I}_+^i + \hat{I}_-^i)$. Since $\chi_{\alpha\alpha'} = (\chi_{\alpha'\alpha})^*$, the unrestricted decays of $\hat{I}_x$, $\hat{I}_y$, $\hat{I}_+$, or $\hat{I}_-$ are indistinguishable. Therefore, although the dimensionality of the density matrix for this system is 2^{2N} , the decay of athermal magnetization (polarization) is characterized by $2^N - 1$ unique relaxation rates. $N(2^N - 1)$ rate constants are associated with the dissipation of single quantum coherence. The remaining $2^{N-1}(2^N - 1 - N)$ rate constants quantify the relaxation of other forms of multispin/multiquantum order. Only for $N = 1$ will two time constants (T_1 and T_2) completely describe the relaxation characteristics (in the absence of applied rf fields) of the N -spin system.

For a spin system composed of N -spin- $\frac{1}{2}$ nuclei, $\hat{I}^{(1)}$, $\hat{I}^{(2)}$, $\dots$, $\hat{I}^{(N)}$, with each spin relaxed through anisotropic shielding (SA) and mutual dipole–dipole (D) interactions, the interconversion/dissipation rates of the various polarizations are described succinctly by the following expressions:

$$\left. \begin{aligned} \hat{I}_z^{(i)} &\Leftarrow \sum_{j \neq i} \rho_{ij} + 4J^{\text{SA}_i}(\omega_i) \Rightarrow \hat{I}_z^{(i)} \\ \hat{I}_z^{(i)} &\Leftarrow \sigma_{ij} \Rightarrow \hat{I}_z^{(j)} \\ \hat{I}_z^{(i)} &\Leftarrow -4K^{\text{D}_{ij}, \text{SA}_i}(\omega_i) \Rightarrow 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} \\ \hat{I}_z^{(i)} &\Leftarrow 2K^{\text{D}_{ij}, \text{D}_{ik}}(\omega_i) \Rightarrow 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} &\Leftarrow \sum_{k \neq i, j} \rho_{ik} + \sum_{k \neq i, j} \rho_{jk} + \Delta_{ij} + 4J^{\text{SA}_i}(\omega_i) \\ &\quad + 4J^{\text{SA}_j}(\omega_j) \Rightarrow 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} \\ 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} &\Leftarrow \sigma_{jk} + 2K^{\text{D}_{ij}, \text{D}_{ik}}(\omega_i) \Rightarrow 2\hat{I}_z^{(i)}\hat{I}_z^{(k)} \\ 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} &\Leftarrow -4K^{\text{D}_{ik}, \text{SA}_i}(\omega_i) - 4K^{\text{D}_{jk}, \text{SA}_j}(\omega_j) \\ &\quad \Rightarrow 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} &\Leftarrow \sum_{l \neq i, j, k} \rho_{il} + \sum_{l \neq i, j, k} \rho_{jl} + \sum_{l \neq i, j, k} \rho_{kl} \\ &\quad + \Delta_{ij} + \Delta_{ik} + \Delta_{jk} + 4J^{\text{SA}_i}(\omega_i) \\ &\quad + 4J^{\text{SA}_j}(\omega_j) + 4J^{\text{SA}_k}(\omega_k) \Rightarrow 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} &\Leftarrow \sigma_{kl} + 2K^{\text{D}_{ik}, \text{D}_{il}}(\omega_i) + 2K^{\text{D}_{jk}, \text{D}_{jl}}(\omega_j) \\ &\quad \Rightarrow 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(l)} \\ 2\hat{I}_z^{(i)}\hat{I}_z^{(j)} &\Leftarrow 0 \Rightarrow 2\hat{I}_z^{(i)}\hat{I}_z^{(l)} \\ \hat{I}_z^{(i)} &\Leftarrow 0 \Rightarrow 2\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ 4\hat{I}_z^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} &\Leftarrow 0 \Rightarrow 4\hat{I}_z^{(i)}\hat{I}_z^{(l)}\hat{I}_z^{(m)} \end{aligned} \right\} \quad (9)$$

where

$$\left. \begin{aligned} \rho_{ij} &= \frac{1}{3}J_0^{\text{D}_{ij}}(\omega_i - \omega_j) + J_1^{\text{D}_{ij}}(\omega_i) + 2J_2^{\text{D}_{ij}}(\omega_i + \omega_j) \\ \sigma_{ij} &= -\frac{1}{3}J_0^{\text{D}_{ij}}(\omega_i - \omega_j) + 2J_2^{\text{D}_{ij}}(\omega_i + \omega_j) \\ \Delta_{ij} &= J_1^{\text{D}_{ij}}(\omega_i) + J_1^{\text{D}_{ij}}(\omega_j) \end{aligned} \right\} \quad (10)$$

Of course, the individual rates introduced in equation (9) are specific elements of the (super)operator $\hat{\hat{H}}$ introduced earlier [see equation (7)]. Shielding anisotropy and dipole–dipole interactions are defined in terms of gyromagnetic ratios γ_i , internuclear distances r_{ij} , shielding anisotropies $\Delta\sigma_i$ and magnetic field strength B_0 : $\xi_{\text{D}_{ij}} = (\frac{6}{5}\pi)^{1/2}\gamma_i\gamma_j\hbar r_{ij}^{-3}$, $\xi_{\text{SA}_i} = (\frac{2}{15}\pi)^{1/2}\Delta\sigma_i\gamma_i B_0$.

These expressions clearly demonstrate that cross correlation results in polarization transfer. Interferences between SA and dipole–dipole interconvert even and odd spin orders, whereas dipole–dipole interferences interconvert various forms of spin order with similar parity under spin inversion symmetry. Equation (9) only list mutual couplings between one- two-, and three-spin order. If higher forms of spin order are considered, the appropriate polarization transfer selection rules

are summarized by the expressions

$$\left. \begin{aligned} 2^{k-1}\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k)} &\Leftarrow \sum_{i=1}^k 4K^{\text{D}_{i,k+1}, \text{SA}_{k+1}}(\omega_{k+1}) \\ &\quad \Rightarrow 2^k(\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k)})\hat{I}_z^{(k+1)} \\ 2^{k-1}\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k)} &\Leftarrow \sum_{i=1}^k 2K^{\text{D}_{i,k+1}, \text{D}_{i,k+2}}(\omega_{k+1}) \\ &\quad \Rightarrow 2^{k+1}(\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k)})\hat{I}_z^{(k+1)}\hat{I}_z^{(k+2)} \end{aligned} \right\} \quad (11)$$

These restrictions limit the overall changes in spin order to ± 1 (SA–D interference) or ± 2 (D–D interference) and are a direct consequence of the commutator relations embedded in equation (7). Dipole–dipole cross correlation can induce polarization transfer between spin orders of similar rank, for spin orders greater than one, the same as cross relaxation, σ_{ij} :

$$\begin{aligned} 2^{k-1}\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k)} &\Leftarrow \sum_{i=1}^{k-1} \sigma_{k,k+1} + 2K^{\text{D}_{i,k}, \text{D}_{i,k+1}}(\omega_i) \\ &\quad \Rightarrow 2^{k-1}(\hat{I}_z^{(1)}\hat{I}_z^{(2)}\dots\hat{I}_z^{(k-1)})\hat{I}_z^{(k+1)} \end{aligned} \quad (12)$$

These same considerations are equally helpful in descriptions of single quantum (1Q) or multiple quantum coherence (MQC). For example, consider the dynamic transformations of spin-‘ i ’ single quantum coherence:

$$\left. \begin{aligned} \hat{I}_+^{(i)} &\Leftarrow (1/T_2)_i \Rightarrow \hat{I}_+^{(i)} \\ 2\hat{I}_+^{(i)}\hat{I}_z^{(j)} &\Leftarrow (1/T_2)_i \Rightarrow 2\hat{I}_+^{(i)}\hat{I}_z^{(j)} \\ 4\hat{I}_+^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} &\Leftarrow (1/T_2)_i \Rightarrow 4\hat{I}_+^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ \hat{I}_+^{(i)} &\Leftarrow 0 \Rightarrow \hat{I}_+^{(j)} \\ \hat{I}_+^{(i)} &\Leftarrow -\frac{8}{3}K^{\text{D}_{ij}, \text{SA}_i}(0) - 2K^{\text{D}_{ij}, \text{SA}_i}(\omega_i) \\ &\quad \Rightarrow 2\hat{I}_+^{(i)}\hat{I}_z^{(j)} \\ 2\hat{I}_+^{(i)}\hat{I}_z^{(k)} &\Leftarrow -\frac{8}{3}K^{\text{D}_{ij}, \text{SA}_i}(0) - 2K^{\text{D}_{ij}, \text{SA}_i}(\omega_i) \\ &\quad \Rightarrow 4\hat{I}_+^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ \hat{I}_+^{(i)} &\Leftarrow \frac{1}{2}\sigma_{jk} + \frac{4}{3}K^{\text{D}_{ij}, \text{D}_{ik}}(0) + K^{\text{D}_{ij}, \text{D}_{ik}}(\omega_i) \\ &\quad \Rightarrow 4\hat{I}_+^{(i)}\hat{I}_z^{(j)}\hat{I}_z^{(k)} \\ 2\hat{I}_+^{(i)}\hat{I}_z^{(j)} &\Leftarrow \frac{1}{2}\sigma_{jk} + \frac{4}{3}K^{\text{D}_{ij}, \text{D}_{ik}}(0) + K^{\text{D}_{ij}, \text{D}_{ik}}(\omega_i) \\ &\quad \Rightarrow 2\hat{I}_+^{(i)}\hat{I}_z^{(k)} \end{aligned} \right\} \quad (13)$$

Permutation of nuclear labels will generate expressions for the relevant 1QCs of other spins. The parameter $(1/T_2)_i$ is defined as

$$\begin{aligned} (1/T_2)_i &= \sum_{j \neq i} \frac{2}{3}J^{\text{D}_{ij}}(0) + \frac{1}{2} \left[\sum_{j < k} \rho_{jk} + J^{\text{D}_{jk}}(\omega_k) \right] \\ &\quad + \frac{8}{3}J^{\text{SA}_i}(0) + 2J^{\text{SA}_i}(\omega_i) \end{aligned} \quad (14)$$

The subtle differences between descriptions of the evolution of populations and single quantum coherences are due to

the ‘simple line’ approximation, which suppresses secular couplings and transverse cross relaxation.

The informational content of these expressions is illustrated clearly by consideration of the simple AMX spin system. Each member of the A quartet can be associated with its own fictitious spin:

$$\left. \begin{aligned} \hat{I}_z^{\alpha\alpha} &= \frac{1}{4}(\hat{I}_z^{(A)} + 2\hat{I}_z^{(A)}\hat{I}_z^{(M)} + 2\hat{I}_z^{(A)}\hat{I}_z^{(X)} + 4\hat{I}_z^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ \hat{I}_z^{\alpha\beta} &= \frac{1}{4}(\hat{I}_z^{(A)} + 2\hat{I}_z^{(A)}\hat{I}_z^{(M)} - 2\hat{I}_z^{(A)}\hat{I}_z^{(X)} - 4\hat{I}_z^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ \hat{I}_z^{\beta\alpha} &= \frac{1}{4}(\hat{I}_z^{(A)} - 2\hat{I}_z^{(A)}\hat{I}_z^{(M)} + 2\hat{I}_z^{(A)}\hat{I}_z^{(X)} - 4\hat{I}_z^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ \hat{I}_z^{\beta\beta} &= \frac{1}{4}(\hat{I}_z^{(A)} - 2\hat{I}_z^{(A)}\hat{I}_z^{(M)} - 2\hat{I}_z^{(A)}\hat{I}_z^{(X)} + 4\hat{I}_z^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \end{aligned} \right\} \quad (15)$$

Assuming an initial perturbation described as the nonselective inversion of the A quartet, the *initial* relaxation rates associated with each member of the quartet are given by

$$\left. \begin{aligned} (1/T_1)_{\alpha\alpha} &= (1/T_1)_A - 4K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad - 4K^{\text{DAX},\text{SA}_A}(\omega_A) + 2K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_1)_{\alpha\beta} &= (1/T_1)_A - 4K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad + 4K^{\text{DAX},\text{SA}_A}(\omega_A) - 2K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_1)_{\beta\alpha} &= (1/T_1)_A + 4K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad - 4K^{\text{DAX},\text{SA}_A}(\omega_A) - 2K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_1)_{\beta\beta} &= (1/T_1)_A + 4K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad + 4K^{\text{DAX},\text{SA}_A}(\omega_A) + 2K^{\text{DAM},\text{DAX}}(\omega_A) \end{aligned} \right\} \quad (16)$$

where $(1/T_1)_A = \rho_{\text{AM}} + \rho_{\text{AX}} + 4J^{\text{SA}_A}(\omega_A)$.

Notice that various sums and differences of initial rates can be identified with unique spectral densities. The combinations of line intensities that isolate each of the four terms are exactly the combinations that result in the product operator description implicit in equation (9). Looking at equation (7), it is apparent that when one specific coherence or magnetization mode $\hat{v}_i$ is selectively perturbed then the initial response of an observed mode $\hat{v}_j$ is completely determined by the coupling Γ_{ij} . In virtually all circumstances, this experiment often provides definitive, accessible, qualitative information. It is equally important to recognize that the initial rate approximation, when applied to the perturbation response of one-spin order, is always independent of cross correlation.

Conversely, if all four members of the quartet are characterized by the same relaxation behavior, no multispin order is generated, and cross correlation is insignificant. Similarly, a nonselective perturbation affecting symmetrically disposed lines within a multiplet does not generate differential relaxation unless anisotropic shielding/dipole–dipole interferences are present.

A parallel description of 1QC utilizes the single transition operators

$$\left. \begin{aligned} I_+^{\alpha\alpha} &= \frac{1}{4}(\hat{I}_+^{(A)} + 2\hat{I}_+^{(A)}\hat{I}_z^{(M)} + 2\hat{I}_+^{(A)}\hat{I}_z^{(X)} + 4\hat{I}_+^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ I_+^{\alpha\beta} &= \frac{1}{4}(\hat{I}_+^{(A)} + 2\hat{I}_+^{(A)}\hat{I}_z^{(M)} - 2\hat{I}_+^{(A)}\hat{I}_z^{(X)} - 4\hat{I}_+^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ I_+^{\beta\alpha} &= \frac{1}{4}(\hat{I}_+^{(A)} - 2\hat{I}_+^{(A)}\hat{I}_z^{(M)} + 2\hat{I}_+^{(A)}\hat{I}_z^{(X)} - 4\hat{I}_+^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \\ I_+^{\beta\beta} &= \frac{1}{4}(\hat{I}_+^{(A)} - 2\hat{I}_+^{(A)}\hat{I}_z^{(M)} - 2\hat{I}_+^{(A)}\hat{I}_z^{(X)} + 4\hat{I}_+^{(A)}\hat{I}_z^{(M)}\hat{I}_z^{(X)}) \end{aligned} \right\} \quad (17)$$

with the associated linewidth parameters

$$\left. \begin{aligned} (1/T_2)_{\alpha\alpha} &= (1/T_2)_A - \frac{8}{3}K^{\text{DAM},\text{SA}_A}(0) - 2K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad - \frac{8}{3}K^{\text{DAX},\text{SA}_A}(0) - 2K^{\text{DAX},\text{SA}_A}(\omega_A) + \frac{1}{2}\sigma_{\text{MX}} \\ &\quad + \frac{4}{3}K^{\text{DAM},\text{DAX}}(0) + K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_2)_{\alpha\beta} &= (1/T_2)_A - \frac{8}{3}K^{\text{DAM},\text{SA}_A}(0) - 2K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad + \frac{8}{3}K^{\text{DAX},\text{SA}_A}(0) + 2K^{\text{DAX},\text{SA}_A}(\omega_A) - \frac{1}{2}\sigma_{\text{MX}} \\ &\quad - \frac{4}{3}K^{\text{DAM},\text{DAX}}(0) - K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_2)_{\beta\alpha} &= (1/T_2)_A + \frac{8}{3}K^{\text{DAM},\text{SA}_A}(0) + 2K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad - \frac{8}{3}K^{\text{DAX},\text{SA}_A}(0) - 2K^{\text{DAX},\text{SA}_A}(\omega_A) - \frac{1}{2}\sigma_{\text{MX}} \\ &\quad - \frac{4}{3}K^{\text{DAM},\text{DAX}}(0) - K^{\text{DAM},\text{DAX}}(\omega_A) \\ (1/T_2)_{\beta\beta} &= (1/T_2)_A + \frac{8}{3}K^{\text{DAM},\text{SA}_A}(0) + 2K^{\text{DAM},\text{SA}_A}(\omega_A) \\ &\quad + \frac{8}{3}K^{\text{DAX},\text{SA}_A}(0) + 2K^{\text{DAX},\text{SA}_A}(\omega_A) + \frac{1}{2}\sigma_{\text{MX}} \\ &\quad + \frac{4}{3}K^{\text{DAM},\text{DAX}}(0) + K^{\text{DAM},\text{DAX}}(\omega_A) \end{aligned} \right\} \quad (18)$$

The various effects of cross correlation are written across each multiplet in a characteristic fashion, and if spectral linewidths accurately reflect homogeneous broadening then appropriate linear combinations of linewidth differentials can be used to isolate cross-correlation spectral densities:

$$\left. \begin{aligned} \frac{1}{4}[(1/T_2)_{\alpha\alpha} + (1/T_2)_{\alpha\beta} + (1/T_2)_{\beta\alpha} + (1/T_2)_{\beta\beta}] &= (1/T_2)_A \\ \frac{1}{2}[(1/T_2)_{\alpha\alpha} - (1/T_2)_{\alpha\beta} - (1/T_2)_{\beta\alpha} + (1/T_2)_{\beta\beta}] &= \sigma_{\text{MX}} + \frac{8}{3}K^{\text{DAM},\text{DAX}}(0) + 2K^{\text{DAM},\text{DAX}}(\omega_A) \\ \frac{1}{4}[(1/T_2)_{\alpha\alpha} + (1/T_2)_{\alpha\beta} - (1/T_2)_{\beta\alpha} - (1/T_2)_{\beta\beta}] &= -\frac{8}{3}K^{\text{DAM},\text{SA}_A}(0) - 2K^{\text{DAM},\text{SA}_A}(\omega_A) \\ \frac{1}{4}[(1/T_2)_{\alpha\alpha} - (1/T_2)_{\alpha\beta} + (1/T_2)_{\beta\alpha} - (1/T_2)_{\beta\beta}] &= -\frac{8}{3}K^{\text{DAX},\text{SA}_A}(0) - 2K^{\text{DAX},\text{SA}_A}(\omega_A) \end{aligned} \right\} \quad (19)$$

In high-field studies of adiabatically broadened lines, differential linewidths are the norm rather than the exception.

6 EFFECTS OF CROSS CORRELATION IN MULTIPLY DEGENERATE SPIN- $\frac{1}{2}$ SYSTEMS

For spin systems containing identical nuclei, the same fundamental principles introduced previously can be applied, and the A_2 , A_3 , AX_2 , AX_3 , and AMX_2 groupings^{2,4,5,12,13} have been discussed extensively.

However, there are some significant differences between degenerate and nondegenerate first-order spin systems. These differences include

1. adiabatic (zero frequency) cross-correlation spectral densities play a role in polarization transfer;
2. secular couplings conflict with the simple line approximation invoked earlier, which results in lineshapes that are non-Lorentzian;
3. polarization transfer can be consummated by interferences between mechanisms that share no nucleus in common;

Figure 3 Theoretical inversion-recovery curves of the A triplet of an AX_2 spin grouping relaxed by dipole-dipole and anisotropic electronic shielding. The lower curve corresponds to a delay on the order of $T_1 = [2\rho_{AX} + 4J_1^{SA_A}(\omega_A)]^{-1}$ and the upper curve corresponds to the equilibrium spectrum (delay $\gg T_1$). For clarity, these two curves have been vertically displaced. Relaxation-induced polarization and coherence transfer results in strongly asymmetric spectral features. See the text for additional details

4. no longer can every mode be brought into correspondence with a conventional observable.

A brief indication of the relaxation behavior expected for a simple degenerate spin system such as AX_2 is shown in Figure 3. This figure is constructed assuming a simple inversion-recovery experiment is performed on spin A. The lower curve corresponds to a recovery time on the order of $(\ln 2)T_1$, where $(1/T_1) = 2\rho_{AX} + 4J_1^{SA_A}(\omega_A)$ and the vertically offset upper curve corresponds to a recovery time much longer than T_1 . These curves are constructed assuming complete equivalence of the two dipolar interactions, D_{AX} and $D_{AX'}$, with $\omega_A\tau_{20} = 10$, $D_{||}/D_{\perp} = 100$, $\theta_{SA_A} = 0^\circ$, $\theta_{D_{AX}} = \theta_{D_{AX'}} = 71^\circ$, $\phi_{D_A} - \phi_{D_{AX'}} = 120^\circ$, and $(\Delta\sigma\gamma_A B_0)/\gamma_i\gamma_j\hbar r_{ij}^{-3} = \zeta = \frac{1}{8}$. This realistic set of parameters is chosen for illustrative purposes, and bears no special significance.

Assuming a positive scalar coupling and positive interaction constants, the homogeneous linewidths of the low-frequency, central, and high-frequency components are in the ratios

$$(1 + \kappa^{DD} + 2\zeta^2 - 4\zeta\kappa^{DSA}) : (1 - \kappa^{DD} + 2\zeta^2) : (1 + \kappa^{DD} + 2\zeta^2 + 4\zeta\kappa^{DSA}) \quad (20)$$

In this motional limit (see Figure 1), the dipole-dipole cross correlation factor κ^{DD} is $\frac{3}{4}$. In this same limit, the cross-correlation factor κ^{DSA} for dipole-anisotropic shielding interference is -1 (see equation (8)). Differential broadening of the outer lines relative to the central line indicates a positive dipole-dipole cross correlation. Broadening of the low-frequency component relative to the high-frequency component indicates dipole-shielding anisotropy cross correlation.

Assuming positive scalar coupling and interaction constants, this cross-correlation spectral density is negative.

Comparison of the two curves also indicates that the athermal ‘magnetization’ of the central component relaxes more rapidly than the outer components. It may seem paradoxical that the component identified with the longest T_2 has the shortest T_1 . However, as noted earlier, it is not uncommon for a cross-correlation spectral density to change sign when sampled at two markedly different frequencies. A detailed discussion of the wealth of molecular information implanted in Figure 3 is beyond the scope of this brief introduction, and the reader is directed to the original literature.^{2,4,5}

In other spin systems containing tightly coupled nuclei (e.g., AB, ABX, ABC, etc.), well-defined relaxation selection rules and simple sets of basis operators cannot be defined so simply. The distinctive roles of cross correlation, autocorrelation, and cross relaxation become blurred.

7 CROSS CORRELATION AND RELAXATION IN THE ROTATING FRAME

As a complement to the study of polarization transfer in the laboratory frame, analogous studies can be applied to selectively spin locked magnetization in the rotating frame.

Consider the N spin- $\frac{1}{2}$ system described earlier. In the presence of a strong spin locking field ($\gamma_i B_1 = \omega_r >$ frequency offset) applied selectively to spin i , modification of equation (9) proves exceptionally simple.¹⁴ For each relevant polarization, $\hat{I}_z^{(i)}$ is replaced by $\hat{I}_{zp}^{(i)}$ ($\hat{I}_z^{(i)}$ in the rotating frame, which is equivalent to $\hat{I}_+^{(i)}$ in the laboratory frame, and the various rate constants are replaced by the following modified expressions:

laboratory frame rate $\Rightarrow$ rotating frame equivalent

$$\left. \begin{aligned} \rho_{ij} &\Rightarrow \frac{1}{2}\rho_{ij} + \frac{2}{3}J^{Dij}(\omega_r \approx 0) + J^{Dij}(\omega_j) \\ \sigma_{ij} &\Rightarrow 0 \\ 2K^{Dij,Dik}(\omega_i) &\Rightarrow \frac{4}{3}K^{Dij,Dik}(\omega_r \approx 0) + K^{Dij,Dik}(\omega_i) \\ 2K^{Dij,Djk}(\omega_j) &\Rightarrow 0 \\ \Delta_{ij} &\Rightarrow \frac{1}{2}\rho_{ij} + \frac{2}{3}J^{Dij}(\omega_r \approx 0) \\ 4J^{SA_i}(\omega_i) &\Rightarrow \frac{8}{3}J^{SA_i}(\omega_r \approx 0) + 2J^{SA_j}(\omega_i) \\ 4K^{Dij,SA_i}(\omega_i) &\Rightarrow \frac{8}{3}K^{Dij,SA_i}(\omega_r \approx 0) + 2K^{Dij,SA_i}(\omega_i) \\ 4K^{Dij,SA_j}(\omega_j) &\Rightarrow 0 \end{aligned} \right\} \quad (21)$$

Except for the appearance of certain secular couplings, these couplings are identical to those first introduced in equation (13).

Equation (21) reveal some interesting traits. If the spin lock field is large compared with the frequency *offset*, cross relaxation between spins i and j is quenched. In this same limit, $\hat{I}_+^{(i)}$ and $2\hat{I}_+^{(i)}\hat{I}_z^{(j)}$ are coupled together by the term $\frac{8}{3}K^{Dij,SA_i}(\omega_r \approx 0) + 2K^{Dij,SA_i}(\omega_i)$. This expression demonstrates that when extreme narrowing fails, cross correlation can replace cross relaxation as the source of homonuclear spin diffusion. Once again, measurement of cross correlation under spin lock conditions has enormous potential, and permits one

to focus on specific elements of $\hat{\Gamma}$ while suppressing other elements that may be an annoyance.¹⁵

8 SUMMARY

Cross-correlation effects, once considered little more than theoretical curiosities, have assumed a central role in contemporary NMR relaxation studies. In multispin systems, cross-correlation features are ubiquitous, and, for high applied field strengths, very modest shielding anisotropies can result in significant polarization transfer. In practice, dipole–dipole interferences have been utilized primarily in studies of molecular dynamics, whereas applications of dipole–shielding anisotropy interferences have provided details of shielding anisotropies. As shielding tensors become better characterized, these archetypal applications will change.

In addition to the most familiar interferences discussed thus far, dipole–quadrupole, quadrupole–quadrupole, and quadrupole–shielding anisotropy interferences can be important in the relaxation of quadrupolar nuclei. These interferences provide unique information, and enable the study of weak interactions in the presence of more dominant interactions. Similarly, random field interferences have received considerable attention in the context of double resonance and multi-quantum studies. Recently, cross-correlation effects between rank-2 interactions and ‘Curie’ spin have received considerable attention, as have interference effects in scalar relaxation.

1 INTRODUCTION

Nuclear magnetic resonance is uniquely capable of revealing structure and dynamics on a molecular level. An understanding of nuclear spin relaxation is fundamental to an understanding of nuclear magnetic resonance in general. The theoretical framework needed to promote this understanding is conveniently constructed in terms of the time evolution of the density operator under the influence of some Hamiltonian as expressed by the Liouville–von Neumann equation. The basic theory needed for what follows may be found in *Liouville Equation of Motion*. It will be presumed that the reader is familiar with the contents of this article.

The emphasis here will be on molecules in liquids, though many of the principles presented are applicable to solids and gases. The experimental observables of NMR are magnetizations induced in a sample as a consequence of subjecting it to various static and time-varying magnetic fields. The quantum mechanical operators corresponding to these observables act only on the nuclear spin degrees of freedom of the system. Furthermore, these operators are proportional to the spin angular momentum operators or products thereof and, hence, can be dealt with using finite basis sets of states or operators. Relaxation, however, is a consequence of interactions between the nuclear spins and the rest of the system, referred to as the ‘lattice’ or ‘bath’. In most cases, the lattice cannot be treated exactly using quantum mechanics, because the density operator and the Hamiltonian cannot be defined in explicit mathematical detail. The strategy generally employed, then, is to treat the effects of the lattice classically as a random time-dependent modulation of the nuclear spin operators while retaining a quantum mechanical description of the nuclear spins themselves. All externally applied magnetic fields are likewise treated classically. Our goal is to derive equations that correctly describe the observed temporal behavior of the experimental observables. This is done by proposing a Hamiltonian for the system under study, solving the Liouville–von Neumann equation for the time evolution of the density operator, computing the expected time evolution of the experimental observables, and comparing the result with measured values of these observables. Secondly, one wants to extract from this temporal behavior of the observables information about the fundamental nature of the system under investigation. For example, bond angles and

rates of molecular reorientation due to Brownian motion dramatically affect the results of an NMR experiment. How can this kind of information be extracted from the behavior of the magnetization in a sample as a function of time? This article will present the time-dependent perturbation theory methods commonly used in NMR to explain observed phenomena, discuss the various mechanisms that influence relaxation in liquids, and present some simulations exemplifying how nuclear spins behave as a consequence of these mechanisms.

This article presumes a basic knowledge of the nuclear magnetic resonance phenomenon, including nuclear spin polarization in an external static magnetic field and interaction of nuclear spins with applied radiofrequency fields. For those not acquainted with these concepts, several basic texts may be consulted.^{1–3} The reader is assumed to have some grasp of basic quantum mechanics and angular momentum theory at the level generally taught in undergraduate physical chemistry courses. Some command of linear algebra and integral and differential calculus is also assumed. All abbreviations and symbols are either defined in the endpapers or are defined in context. Vectors will be distinguished by bold italic type, and the same symbol in normal weight type will denote the magnitude of a vector or, with appropriate subscripts, its components. Quantum mechanical operators will have a hat, for example $\hat{H}$. Liouville space operators or superoperators will have a double hat, for example $\hat{\hat{L}}$.

No experimental data will be presented in this article. The experimental literature on coupled relaxation has been recently reviewed.⁴ Rather, many simulations using the GAMMA magnetic resonance simulation platform⁵ will be used, so that particular aspects of the subject may be illustrated and contrasted without lengthy digressions into experimental detail. While some references to the original literature will be given, most references will be to texts where additional details of the concepts discussed can be found.

1.1 What Is Nuclear Spin Relaxation?

To begin, let us consider nuclear spin relaxation from a phenomenological viewpoint. When a sample containing nuclear spins (e.g., water, which contains ^1H nuclei) is placed in a strong, uniform, static magnetic field $\mathbf{B}_0$, the sample is observed to develop a macroscopic magnetization $\mathbf{M}_0$ parallel to $\mathbf{B}_0$. The direction of $\mathbf{B}_0$ is taken to be the z direction of a laboratory-fixed coordinate system. Certain nuclei, for example ^{15}N , develop magnetization antiparallel to $\mathbf{B}_0$. The magnetization of a sample placed suddenly in a strong field increases with time and asymptotically approaches a steady state value. The magnitude of the steady state magnetization is proportional to the number of magnetic nuclei in the sample and to the strength of $\mathbf{B}_0$ (it depends on temperature also, but constant temperature will be assumed for now). Each nucleus of an isotope having a nonzero nuclear spin contributes an amount of magnetization characteristic of that particular isotope. If one used deuterium oxide rather than normal water, for example, both the rate of approach to the steady state and the steady-state magnetization would be different. If the sample is left in the magnet for a long time so that it has closely approached the steady state, this condition is called *thermal equilibrium*. If the magnetization is perturbed from thermal equilibrium, by a pulse of radiofrequency

field at the appropriate frequency, it will return to thermal equilibrium—again asymptotically. This process that causes the magnetization to approach thermal equilibrium is called *nuclear spin relaxation*. The time needed for a sample to achieve thermal equilibrium is, of course, infinite, since the approach is asymptotic. However, the time needed to reasonably approximate thermal equilibrium is in the range of milliseconds to hundreds of seconds for liquids, depending on the nature of the sample and the nuclei involved.

The rest of this article will consist mainly of a detailed discussion of the behavior of the magnetization as a function of time and how measurement of this behavior can be used to determine the structural and dynamical features of the molecules bearing the magnetic nuclei.

1.2 Classical Treatment: Bloch's Equations

The first investigations of nuclear-spin relaxation were conducted soon after the discovery of NMR.^{6–8} The main results of this work can be summarized by the following equations:

$$\left. \begin{aligned} \frac{dM_x}{dt} &= [M_y(\gamma B_0 - \omega) - M_z\gamma B_y] - \frac{M_x}{T_2} \\ \frac{dM_y}{dt} &= -[M_x(\gamma B_0 - \omega) - M_z\gamma B_x] - \frac{M_y}{T_2} \\ \frac{dM_z}{dt} &= [M_x\gamma B_y - M_y\gamma B_x] - \frac{M_z - M_0}{T_1} \end{aligned} \right\} \quad (1)$$

These phenomenological equations are generally referred to as the Bloch equations and are cast here in terms of a reference frame rotating at an angular frequency ω about the z axis with respect to a laboratory-fixed frame. A particularly lucid discussion of the Bloch equations may be found in the text by Slichter.⁹ This system of coupled linear differential equations with constant coefficients has solutions wherein the magnetization precesses about the effective field in the rotating frame having components $(B_x, B_y, B_0 - \omega/\gamma)$. In order for B_x and B_y to be stationary in the rotating frame, they must be oscillating in the laboratory frame so that their sum rotates at frequency ω . This will be discussed in mathematical detail in Section 2.7. For usual high-resolution experiments with liquids, ω will be of the order of tens or hundreds of megahertz, thus, radiofrequency technology is used to produce B_x and B_y in the laboratory frame.

However, the main interest here is in the terms involving T_1 and T_2 . If $\omega = \gamma B_0$ and $B_x = B_y = 0$ then equation (1) uncouple and yield particularly simple solutions wherein M_x and M_y relax exponentially to zero governed by T_2 while M_z relaxes exponentially toward M_0 governed by T_1 . Specifically, the solution of equation (1) is given by

$$\left. \begin{aligned} M_x(t) &= M_x(0) \exp(-t/T_2) \\ M_y(t) &= M_y(0) \exp(-t/T_2) \\ M_z(t) &= M_0 + [M_z(0) - M_0] \exp(-t/T_1) \end{aligned} \right\} \quad (2)$$

where $M(0)$ is the magnetization at time zero. These equations accurately describe the evolution of the macroscopic magnetization whenever the system under study may be regarded as an ensemble of spins interacting only with the lattice and not

with each other. The relaxation of a surprisingly large number of materials that have been studied is satisfactorily explained by equation (2).

The fact that the magnetization changes with time implies that the nuclei are undergoing transitions among the available quantum mechanical states. Just as the magnetization may be manipulated by inducing transitions with externally applied rf pulses, any natural phenomenon that produces a time-varying field at a nucleus can induce transitions. The effect of all of these natural phenomena is to drive the macroscopic magnetization toward the thermal equilibrium value. See Section 3 for a discussion of specific examples of natural phenomena that can be mechanisms of spin relaxation. The decay of M_x and M_y involves exchange of energy among the spins, whereas the evolution of M_z toward its steady state value involves transfer of energy between the spins and the lattice.

1.3 When There Are Two or More Coupled Spins

When two or more spins are coupled by some sort of interaction, equation (1) may not be sufficient to explain the observed evolution of the magnetization. Consider, for example, a ^{13}C – ^1H moiety such as might be found in the formate ion.¹⁰ In a conceptually simple experiment, the ^1H magnetization is inverted, and then the ^1H and ^{13}C magnetizations are followed as a function of time. Additional details of this experiment can be found in Section 4.1.1. If there were no interaction between ^1H and ^{13}C then each of the spins could be treated separately according to equation (1), and the resulting evolution would be as shown in Figure 1(a). The ^1H magnetization recovers to thermal equilibrium exponentially as expected, and the ^{13}C magnetization remains unperturbed; however, when one actually performs this experiment, the results are as shown in Figure 1(b). The ^{13}C magnetization grows beyond thermal equilibrium, and then decays back to thermal equilibrium. Apparently, magnetization is flowing from the ^1H to the ^{13}C nuclei; this behavior cannot be predicted by equation (1). The mechanism that has been introduced to produce this effect is dipole–dipole (DD) coupling between the two nuclei. This is an example of cross relaxation. The theory of which this is a simple example will be the subject of the rest of this article.

2 TIME-DEPENDENT PERTURBATION THEORY

The theoretical model generally adopted for high-resolution NMR of liquids is that of a molecule bearing the spin system of interest immersed in a solvent. The concentration of such molecules is sufficiently low that intermolecular interactions among the spins of interest need not be considered. Because of the short range and random nature of the interactions involved, this assumption is adequately met even at fairly high concentrations. The macroscopic sample may then be considered as an ensemble of isolated systems each consisting of a single spin system of interest immersed in a bath or lattice the exact state of which is of no interest. The terms ‘bath’ and ‘lattice’ will be used interchangeably to refer to all the degrees of freedom of one member of the ensemble not directly associated with the nuclear spins in which we

Figure 1 Simulation of relaxation of a two-spin (^{13}C – ^1H) system after a proton π nonselective pulse: (a) relaxed only by external random fields ($T_1 = 1.6$ s, $J = 140$ Hz); (b) relaxed also by dipole–dipole coupling between the two spins (internuclear distance 0.109 nm, spherical top, correlation time 10 ps). The intensity is scaled so that the total ^{13}C magnetization at thermal equilibrium is unity, and that of ^1H is then greater by a factor $\gamma_{\text{H}}/\gamma_{\text{C}}$, or about four. See Section 4.1.1 for a more detailed discussion of the experiment

are interested. For example, the translational, rotational, and vibrational states of the molecule bearing the spin system of interest as well as the states of any nuclear or electron spins in solvent molecules would be in this category. The number of degrees of freedom of the lattice is so great as to be effectively infinite, with essentially a continuum of energy eigenstates. Using the terms somewhat loosely, the ‘heat capacity’ of the lattice is assumed to be so much greater than that of the nuclear spins that no interaction between

the two can change the ‘temperature’ of the lattice. The nuclear spins also interact with externally applied magnetic fields, which are treated classically. In this discussion, the external magnetic field will be only the usual static field $\mathbf{B}_0$, the direction of which is taken to be the z axis of our laboratory coordinate system. Pulses will be treated as instantaneous rotations. A more general treatment of pulses and time-dependent external fields in general has been given by Smith et al.^{11–13}

To begin our theoretical development, the Hamiltonian for one member of our ensemble can be expressed as a combination of terms acting on the spin system $\hat{\mathcal{H}}_s$, terms acting on the bath $\hat{\mathcal{H}}_b$, and terms for the interaction between the two $\hat{\mathcal{H}}_I$:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_s + \hat{\mathcal{H}}_b + \hat{\mathcal{H}}_I \quad (3)$$

The density operator $\hat{\rho}(t)$ encompasses both spin system and bath. The Liouvillian $\hat{\mathcal{L}}$ is a commutation or derivation superoperator relating to the Hamiltonian according to

$$\hat{\mathcal{L}} = \hat{\mathcal{H}} \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}} \quad (4)$$

For a discussion of superoperators and their relationship to operators see Section 5 of *Liouville Equation of Motion*. The Hamiltonian for a spin system $\hat{\mathcal{H}}_s$ interacting only with $\mathbf{B}_0$ contains terms from Zeeman interactions, chemical shieldings, scalar couplings, etc. A detailed discussion of high-resolution NMR Hamiltonians may be found in the first of the series of articles by Smith et al.¹¹ Some of these interactions involve terms that are dependent upon spin system orientation relative to $\mathbf{B}_0$, in which case interaction terms involving the rotational state of the molecule will be of interest. Such terms are of principal interest for spin relaxation studies in liquids, since molecules in liquids are rotating rapidly and changing rotational state frequently owing to collisions. Because of this, it is useful to express individual terms of the Hamiltonian in a general spherical tensor format. The Hamiltonian may be expressed as¹¹

$$\hat{\mathcal{H}} = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} \hat{F}_{-m}^{\mu} \quad (5)$$

These tensors can be easily rotated from one coordinate system to another.¹⁴ Here the $\hat{T}_m^{\mu}$ are spin operators acting on the system of interest, the $\hat{F}_{-m}^{\mu}$ are operators on the lattice states or functions relating to the externally applied magnetic fields, and ξ_{μ} are interaction constants, which will vary depending upon the nature of the interaction. The index μ is used to label a particular interaction, and each interaction has one or more associated values of the rank l . For each l , one must sum over the projection index m as shown. All of the terms in this sum can be assigned to one of the three Hamiltonians on the right-hand side of equation (3). Terms involving $l = 0$ and $m = 0$ for the spin operators are bath terms. Those involving $l = 0$ and $m = 0$ for the lattice operators as well as those depending only on the applied external field are spin terms. All others are interaction terms.

Both $\hat{T}_m^{\mu}$ and $\hat{F}_{-m}^{\mu}$ transform like spherical harmonics under rotations,¹⁴ and are related to their adjoints as follows:

$$\left. \begin{aligned} (\hat{F}_m^{\mu})^{\dagger} &= (-1)^m \hat{F}_{-m}^{\mu} \\ (\hat{T}_m^{\mu})^{\dagger} &= (-1)^m \hat{T}_{-m}^{\mu} \end{aligned} \right\} \quad (6)$$

The superscript $\dagger$ indicates the adjoint or Hermitian conjugate of the operator. When the operator is represented in Liouville space using some operator basis, this means transpose the vector and take the complex conjugate of each element.

The Liouville equation in the Schrödinger representation is

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}} |\hat{\rho}(t)\rangle \quad (7)$$

(For a more detailed development of this type of equation, see Section 5 of *Liouville Equation of Motion*). It defines the time evolution of the density operator for the entire system, spins and lattice, in terms of the Liouvillian of equation (4). In this representation, the density superket is time-dependent whereas the Liouvillian is not. This implies, as mentioned above, that no time-varying magnetic fields are applied. Unfortunately, equation (7) is completely intractable, because the lattice and interaction Hamiltonians $\hat{\mathcal{H}}_b$ and $\hat{\mathcal{H}}_I$ cannot be clearly defined and the dimension of the Liouville space of the lattice would be far too large for meaningful calculations to be performed. Hence, we are forced to seek an approximate method for solving the Liouville equation. Nuclear spins relax very slowly compared with most events on a molecular scale, so it is reasonable to suppose that the interaction $\hat{\mathcal{H}}_I$ is very weak. Further, collisions between the molecule of interest and solvent molecules should be treatable as a random process amenable to statistical methods. These two facts lead one to attempt a solution of equation (7) using perturbation theory and statistical mechanics.

2.1 The Interaction Representation

We begin the application of time-dependent perturbation theory by making use of the interaction picture of the problem to permit focusing on the small interaction terms. If we transform all the operators in the Liouville equation into an interaction representation based on the combined bath and spin system Hamiltonians, we can effectively ‘remove’ the pure bath and pure spin system contributions, a procedure that simplifies equation (7) and, it is to be hoped, facilitates its integration:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}'_I(t) |\hat{\rho}'(t)\rangle \quad (8)$$

(for a discussion of interaction representations and transformations, see Section 4.1 of *Liouville Equation of Motion*). Operators (superkets) and superoperators in the interaction representation are indicated by a prime. These relate to the Schrödinger representation via

$$\left. \begin{aligned} \hat{\mathcal{L}}_0 &= \hat{\mathcal{L}}_s + \hat{\mathcal{L}}_b \\ |\hat{\rho}'(t)\rangle &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{\rho}(t)\rangle \\ \hat{\mathcal{L}}'_I(t) &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \hat{\mathcal{L}}_I \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \end{aligned} \right\} \quad (9)$$

2.2 Second-Order Perturbation Theory

Because of the inherently complex interaction between bath and spin system, as embodied in the superoperator $\hat{\mathcal{L}}'_I(t)$, the equation of motion must be solved using some sort of approximation technique. One approach is to use

a Dyson expansion of the integral. The initial steps are trivial—equation (8) is integrated formally from an arbitrary starting time t_0 to some later time t :

$$\left. \begin{aligned} \int_{t_0}^t d|\hat{\rho}'(t_1)\rangle &= -\frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_1)\rangle \\ |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_1)\rangle \end{aligned} \right\} \quad (10)$$

We can now make a change of variable in equation (10),

$$|\hat{\rho}'(t_1)\rangle = |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \quad (11)$$

and substitute back into the integrand of equation (10) to produce

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) \left[|\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \right] \\ &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \end{aligned} \quad (12)$$

This process is iterated, substituting equation (11), with the appropriate change of variable for $|\hat{\rho}'(t_2)\rangle$, into equation (12). With each iteration, the lower order integrals involve only the initial density superket. Continuing the iterations and assuming that the series eventually converges so that the last term involving $|\hat{\rho}'(t_n)\rangle$ may be ignored produces the Dyson series

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle + \sum_{n=1}^{\infty} \left(-\frac{i}{\hbar} \right)^n \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \\ &\quad \times \int_{t_0}^{t_{n-1}} dt_n \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) \cdots \hat{\mathcal{L}}'_1(t_n) |\hat{\rho}'(t_0)\rangle \end{aligned} \quad (13)$$

If it could be shown that the interaction Liouvillians at different times commute then the time ordering would be inconsequential, and equation (12) would be equivalent to a Taylor series for an exponential:

$$|\hat{\rho}'(t)\rangle = \exp \left[-\frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) \right] |\hat{\rho}'(t_0)\rangle \quad (14)$$

If the interaction Liouvillian (in the interaction representation) were time-independent then the integral would be trivial and the solution in the interaction representation would be

$$|\hat{\rho}'(t)\rangle = \exp \left[-\frac{i}{\hbar} \hat{\mathcal{L}}'_1(t - t_0) \right] |\hat{\rho}'(t_0)\rangle \quad (15)$$

We shall assume that the Liouvillians at different times do not commute, but that terms higher than second order are negligible, i.e., that *second-order perturbation theory* is

adequate to describe the system. The equation of motion is then approximated by

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_0)\rangle \end{aligned} \quad (16)$$

2.3 Application of the Wangness–Bloch–Redfield Assumptions

Equation (16) is still not in a form that can be handled either analytically or numerically for useful systems. We therefore apply several additional approximations that will eventually lead to a manageable expression. Recognizing that the first integral term in equation (16) is nondissipative, it can at most add a constant term to the density matrix. Furthermore, we shall shortly deal with an ensemble of spin systems, and the average effect of the interaction Liouvillian at any point in time is zero for an isotropic liquid. This is true for a bath interacting in an essentially random fashion with the system of interest. Therefore the first integral term in equation (16) may be ignored, giving

$$|\hat{\rho}'(t)\rangle = |\hat{\rho}'(t_0)\rangle - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_0)\rangle \quad (17)$$

If the integrand is continuous over the integration range then we can differentiate equation (17) to obtain a differential equation again:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \quad (18)$$

It is assumed that the integral really only depends upon the difference $\tau = t - t_1$, so that the variable of integration may be changed as follows:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_{t_0}^t d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t_0)\rangle \quad (19)$$

It is further assumed that the density superket does not change rapidly over the range of the integral, so that replacing $|\hat{\rho}'(t_0)\rangle$ with $|\hat{\rho}'(t)\rangle$ does not introduce significant error. This yields

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_0^t d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t)\rangle \quad (20)$$

A final assumption is that t will be long enough that the integrand will have decayed to zero and no error will be introduced by extending the limit of integration to infinity. Then we have

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t)\rangle \quad (21)$$

2.4 The Semiclassical Liouville Equation

At this point, it is essential to depart from the treatment of the entire system of spins and bath and focus only on the smaller system of interest, namely, the spin system. The total system density operator can always be represented as a tensor product of two density operators, one spanning the spin system subspace and one spanning the lattice subspace:

$$|\hat{\rho}(t)\rangle = |\hat{\sigma}(t)\rangle |\hat{\rho}_b(t)\rangle \quad (22)$$

Keep in mind that it is the smaller spin system represented by the reduced density operator $|\hat{\sigma}(t)\rangle$ that is of interest, not the entire system $|\hat{\rho}(t)\rangle$. The latter resides in a Liouville space of unmanageable dimensionality whereas the dimension of the former is normally small enough that its evolution in time can be mathematically detailed with some precision. One can define a superket $|\hat{\rho}_s(t)\rangle$ that resides in the full Liouville space of the spin system and bath, and yet contains only the information regarding the spin system of interest:

$$\left. \begin{aligned} |\hat{\rho}_s(t)\rangle &= \hat{P}|\hat{\rho}(t)\rangle = \hat{E}_s \otimes (|\hat{\rho}_b(t)\rangle \otimes \langle \hat{E}_b|) \\ |\hat{\sigma}(t)\rangle &= (\hat{E}_s \otimes \langle \hat{E}_b|) |\hat{\rho}_s(t)\rangle = (\hat{E}_s \otimes \langle \hat{E}_b|) \hat{P}|\hat{\rho}(t)\rangle \\ &= (\hat{E}_s \otimes \langle \hat{E}_b|) \hat{E}_s \otimes (|\hat{\rho}_b(t)\rangle \otimes \langle \hat{E}_b|) \end{aligned} \right\} \quad (23)$$

The equation of motion for $|\hat{\rho}_s(t)\rangle$ is obtained by use of the projection superoperator $\hat{P}$ in the approximate equation of motion:

$$\frac{d|\hat{\rho}_s'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \hat{\mathcal{L}}_1'(t-\tau) \hat{P}|\hat{\rho}_s'(t)\rangle \quad (24)$$

Back-transformation into the Schrödinger representation produces

$$\begin{aligned} \frac{d|\hat{\rho}_s'(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\rho}_s(t)\rangle - \frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ &\quad \times \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \end{aligned} \quad (25)$$

This equation is general for any system interacting with a large bath, so long as the constraints outlined in Section 2.3 are fulfilled. The Liouvillians $\hat{\mathcal{L}}_s$ and $\hat{\mathcal{L}}_b$ commute, and $\hat{\mathcal{L}}_b$ cannot operate on $|\hat{\rho}_s(t)\rangle$, so that $\exp(-i\hbar^{-1}\hat{\mathcal{L}}_0\tau)\hat{P} = \exp(-i\hbar^{-1}\hat{\mathcal{L}}_s\tau)\hat{P}$. Then,

$$\begin{aligned} \frac{d|\hat{\rho}_s(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\rho}_s(t)\rangle - \frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ &\quad \times \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \end{aligned} \quad (26)$$

It is beyond the scope of this article to show that the net result of continued manipulations produces

$$\begin{aligned} &\hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \\ &= \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times \hat{P}|\hat{\rho}_s'(t) - \hat{\rho}_s'(\infty)\rangle \end{aligned} \quad (27)$$

Further details of this step may be found in an article by Szymanski et al.¹⁵ The projection operators allow us now to work exclusively with the reduced density operator and place all operators into the corresponding reduced space. Switching to the difference (reduced) density operator $\Delta\hat{\sigma}$, we now perform an ensemble average over all the spin systems in the sample to yield

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \\ &\quad \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times |\hat{\sigma}(t) - \hat{\sigma}(\infty)\rangle \\ &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \\ &\quad \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (28)$$

As in the Hilbert space formulation of Wangness–Bloch–Redfield theory, it remains to isolate the time dependence in the integral function in order to formulate spectral densities.

2.5 The Spin and Interaction Hamiltonians

The lattice Hamiltonian $\hat{\mathcal{H}}_b$ now influences the equation of motion only in that the system relaxes toward thermal equilibrium at the temperature of the bath $|\hat{\sigma}(\infty)\rangle$. We must now define in detail the form of the spin and interaction Hamiltonians. The principal influence of the lattice is to reorient the spin system. Equation (5) can then be interpreted as follows to account for both the spin system and its interaction with the lattice:

$$\hat{\mathcal{H}}_s + \hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (29)$$

The lattice operators are now manifested as random functions of time that reorient the spin system. This is referred to as the *semiclassical model* for the Hamiltonian; the interaction terms of the Hamiltonian are time-dependent through the lattice functions $F_{-m}^{\mu}(t)$, but the operators that act on the spin system are independent of time. Invoking the ergodic hypothesis, the ensemble average can be replaced by a time average, and, if all orientations are equally probable (an isotropic liquid), many of the interactions average to zero in first order. The isotropic terms, $l = m = 0$, in equation (29) are independent of spin system orientation, and, hence, do not need to be time-averaged. These terms yield for a system of n spins the isotropic Hamiltonian commonly found in texts on high-resolution NMR:

$$\hat{\mathcal{H}}_s = \hat{\mathcal{H}}_0 = -\sum_{i=1}^n \hbar \omega_i \hat{I}_{iz} + 2\pi \hbar \sum_{i=2}^n \sum_{j=1}^{i-1} J_{ij} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \quad (30)$$

The symbol J is widely used in the literature for both scalar couplings and spectral densities, which will be introduced in equation (41). We prefer to retain this notation in both cases, trusting that the reader will be able to discern from the context which is meant in a given case. Other Hamiltonian components that are orientation-dependent and, therefore, time-dependent will be categorized in the interaction Hamiltonian term of equation (29):

$$\hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (31)$$

Although it is not explicit, note that the sum over μ in equation (29) includes the rotationally invariant components, whereas the sum in equation (31) does not include them. Furthermore, since the lattice operators are now simply functions, the adjoint used in equation (6) is replaced by a complex conjugate, so that $[F_m^{\mu}(t)]^* = (-1)^m F_{-m}^{\mu}(t)$. The equation of motion is then

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}\rangle - \frac{1}{\hbar^2} \int_0^{\infty} d\tau \hat{\mathcal{L}}_1 \\ & \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{\mathcal{L}}_1 \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) |\Delta\hat{\sigma}\rangle \end{aligned} \quad (32)$$

2.6 The Relaxation Superoperator

Making use of the semiclassical interaction model for $\hat{\mathcal{H}}_I$ given in equation (29), the interaction Liouvillian can be constructed:

$$\begin{aligned} \hat{\mathcal{L}}_I(t) = & \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m (\hat{T}_m^{\mu} \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{\mu}) F_{-m}^{\mu}(t) \\ = & \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{\Gamma}_m^{\mu} F_{-m}^{\mu}(t) \end{aligned} \quad (33)$$

Substitution of this relationship into equation (32) produces

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \hat{\Gamma}_m^{\mu} \\ & \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ & \times \hat{\Gamma}_{m'}^{\mu'} \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) |\Delta\hat{\sigma}\rangle \end{aligned} \quad (34)$$

Our objective is to separate quantities that depend on the time variable τ from the spin operators, which do not. The spherical spin tensor operator components $\hat{T}_m^{\mu}$ generally will not commute with $\hat{\mathcal{H}}_0$ and, hence, will not commute with $\hat{\mathcal{L}}_0$ either, so one cannot isolate the exponentials involving τ .

One can express the spherical tensor operators in a basis comprising the eigenoperators of the static Hamiltonian superoperator $\hat{\mathcal{L}}_0$:

$$\left. \begin{aligned} |\hat{T}_m^{\mu}\rangle &= \sum_p |\hat{T}_{m,p}^{\mu}\rangle \\ |\hat{T}_m^{\mu}(t)\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{T}_m^{\mu}\rangle \\ &= \sum_p \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{T}_{m,p}^{\mu}\rangle = \sum_p e^{-i\Omega_p t} |\hat{T}_{m,p}^{\mu}\rangle \end{aligned} \right\} \quad (35)$$

The Ω_p are the transition frequencies in the laboratory frame, eigenvalues of the Liouvillian $\hat{\mathcal{L}}_0$. The range of p is from 1 to the dimension of the spin system Liouville space. For a system of n spin- $\frac{1}{2}$ nuclei, this would be 2^{2n} . Such a treatment is equivalent to expanding the spin operators in terms of a basis consisting of the eigenfunctions of the static Hamiltonian $\hat{\mathcal{H}}_0$, as is done in the usual Hilbert space development of the Redfield equation.^{9,16} Using these relations, the equation of motion now becomes

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \\ & \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p \hat{\Gamma}_{m',p}^{\mu'} e^{-i\Omega_p \tau} |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (36)$$

This expansion uses the close relationship between a similarity transformation superoperator and the exponential of a commutation superoperator. The commutation superoperator of the isotropic spin system Hamiltonian is given by

$$\hat{\mathcal{L}}_0 = \hat{\mathcal{H}}_0 \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}}_0 \quad (37)$$

The similarity transformation superoperator will, in this instance, be given by

$$\begin{aligned} \hat{G} |\hat{T}_m^{\mu}\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \otimes \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) |\hat{T}_m^{\mu}\rangle \\ &= \left| \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \hat{T}_m^{\mu} \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \right\rangle = |\hat{T}_m^{\mu}(t)\rangle \end{aligned} \quad (38)$$

The two superoperators are related by

$$\hat{G} = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \quad (39)$$

The exponential term in τ can now be grouped with the rest of the variables involving τ , and the desired separation of spin operators and τ -dependent lattice functions is thus achieved:

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \\ & \times \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{m',p}^{\mu'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} e^{-i\Omega_p \tau} |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (40)$$

The integral is defined as the spectral density function by

$$\mathcal{J}_{mm'}^{\mu\mu'}(\Omega) = \int_0^\infty d\tau \overline{F_{-m}^\mu(t) F_{-m'}^{\mu'}(t-\tau)} e^{-i\Omega\tau} \quad (41)$$

The spherical tensor properties of the $F_{-m}^\mu(t)$ guarantee that the integrand averaged over all orientations with equal probability will be nonzero only when $m' = -m$ and the result will be independent of m . Thus, one can write equation (41) in terms of a reduced spectral density $J^{\mu\mu'}$:

$$\mathcal{J}_{mm'}^{\mu\mu'}(\Omega) = (-1)^m \delta_{-mm'} J^{\mu\mu'}(\Omega) \quad (42)$$

Furthermore, it is presumed that the lattice functions are stationary random variables, i.e., that the result of a time average does not depend on the time at which the averaging process is started, and we may set $t = 0$ in the integrand of equation (41). The reduced spectral density is then

$$J^{\mu\mu'}(\Omega) = \int_0^\infty d\tau \overline{F_{-m}^\mu(0) F_{-m'}^{\mu'}(\tau)} e^{-i\Omega\tau} \quad (43)$$

A detailed discussion of spectral densities and how they relate to the dynamical and geometrical parameters of the spin system is found in *Relaxation of Coupled Spins from Rotational Diffusion*.

The relaxation superoperator is defined by

$$\hat{\Gamma} = \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l (-1)^m \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{-m,p}^{\mu'} J^{\mu\mu'}(\Omega_p) \quad (44)$$

The equation of motion for the density superket may be written very compactly using these definitions:

$$\frac{d|\hat{\sigma}(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \hat{\Gamma} |\Delta\hat{\sigma}(t)\rangle \quad (45)$$

The relaxation superoperator may be written as a sum of terms of the form

$$\hat{\Gamma} = - \sum_{\mu} \sum_{\mu'} \hat{\Gamma}^{\mu\mu'} \quad (46)$$

with the individual terms defined by

$$\hat{\Gamma}^{\mu\mu'} = \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l (-1)^m \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{-m,p}^{\mu'} J^{\mu\mu'}(\Omega_p) \quad (47)$$

The $\hat{\Gamma}^{\mu\mu'}$ terms express how the various interactions characterizing the spin system correlate with one another to produce relaxation. If $\mu = \mu'$, the relaxation is termed *autocorrelated*; otherwise, it is called *cross correlated*. This latter term must not be confused with *cross relaxation*, which is simply the flow of magnetization from one nucleus to another rather than from a nucleus to the lattice. Cross relaxation may involve either autocorrelated or cross-correlated relaxation mechanisms. This concept will be discussed further in Section 3.

2.7 The Rotating Frame

It is common practice in NMR to work in a rotating frame, or simultaneously in multiple rotating frames. One use of the rotating frame is to remove Zeeman contributions to the Hamiltonian by rotating about the field axis at or near the Larmor frequency of a spin. Although not of significance in rendering a formal solution to the Liouville equation in the case presented here, in numerical solutions of the equation of motion this avoids computational roundoff, which can occur in mixing frequencies on a megahertz scale (from the static magnetic field) with those on a hertz scale (from chemical shifts and scalar couplings).

Transformation into a rotating frame about the static magnetic field axis, the z axis, is accomplished using the rotation operator

$$\hat{R}_z(\theta) = \exp\left(-\frac{i}{\hbar} \hat{F}_z \theta\right) \quad (48)$$

In this case, the angle of rotation is written as $\theta = \Omega t$, where Ω is the angular frequency of the rotation. The form of the Liouville equation in the rotating frame is only a slight modification of that in the laboratory frame. In the frame rotating about the z axis at angular frequency Ω ,

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar} \left[\hat{\mathcal{L}}(t) + \hat{\Gamma}_z(\Omega) \right] |\hat{\rho}(t)\rangle \quad (49)$$

The superoperator $\hat{\Gamma}_z(\Omega)$ is formed as the commutator of $\Omega \hat{F}_z$. Superkets and superoperators in the rotating frame are indicated by an underscore and relate to the laboratory frame via the rotation superoperator

$$\hat{\hat{R}}_z(\Omega t) = \hat{R}_z(\Omega t) \otimes \hat{R}_z^*(\Omega t) \quad (50)$$

The transformations have the form

$$\left. \begin{aligned} |\hat{\hat{Q}}(t)\rangle &= \hat{\hat{R}}_z(\Omega t) |\hat{Q}\rangle \\ \hat{\hat{\mathcal{L}}}(t) &= \hat{\hat{R}}_z(\Omega t) \hat{\mathcal{L}} \hat{\hat{R}}_z^{-1}(\Omega t) \end{aligned} \right\} \quad (51)$$

That equations (49) and (7) are equivalent is shown by carrying out the differentiation as follows, making the indicated substitutions:

$$\begin{aligned} \frac{d|\hat{\hat{\rho}}(t)\rangle}{dt} &= \frac{d}{dt} \left[\hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \right] \\ &= \frac{d}{dt} \left[\hat{\hat{R}}_z(\Omega t) \right] |\hat{\rho}(t)\rangle + \hat{\hat{R}}_z(\Omega t) \frac{d|\hat{\rho}(t)\rangle}{dt} \\ &= -\frac{i}{\hbar} \hat{\hat{\Gamma}}_z(\Omega) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle + \hat{\hat{R}}_z(\Omega t) \frac{d|\hat{\rho}(t)\rangle}{dt} \\ &= -\frac{i}{\hbar} \hat{\hat{\Gamma}}_z(\Omega) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \\ &\quad - \frac{i}{\hbar} \hat{\hat{R}}_z(\Omega t) \hat{\mathcal{L}} \hat{\hat{R}}_z^{-1}(\Omega t) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \\ &= -\frac{i}{\hbar} \left[\hat{\hat{\mathcal{L}}}(t) + \hat{\hat{\Gamma}}_z(\Omega) \right] |\hat{\hat{\rho}}(t)\rangle \end{aligned} \quad (52)$$

From spherical tensor arguments, we know that the static Hamiltonian $\hat{\mathcal{H}}_0$ is isotropic and rotationally invariant. Thus, it is left unaffected by transformation into the rotating frame, as we might suspect since $[\hat{\mathcal{H}}_0, \hat{F}_z] = 0$, and from equation (30), we can write

$$\hat{\mathcal{H}}_0 = \hat{\mathcal{H}}_0 = \sum_{i=1}^n \hbar \omega_i \hat{I}_{iz} + 2\pi \hbar \sum_{i=1}^n \sum_{j=1}^{i-1} J_{ij} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \quad (53)$$

The interaction Hamiltonian as given by equation (31) will become as follows in the rotating frame:

$$\hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (54)$$

The bath variables are functions of time in this semiclassical treatment, and are unaffected by the rotation operator, which acts only on spin operators.

The question now is how the solution of equation (49) differs from that already presented in the laboratory frame. The form of the rotating frame Liouville equation is very similar to that in the laboratory frame, and the approach to a solution is the same. We define an effective Hamiltonian according to

$$\hat{\mathcal{H}}_{\text{eff}} = \hat{\mathcal{H}}_0 + \Omega \hat{F}_z \quad (55)$$

and transform into an interaction representation based on $\hat{\mathcal{H}}_{\text{eff}}$ rather than $\hat{\mathcal{H}}_0$ to remove the static components of the rotating frame Hamiltonian from our differential equation. It is of some interest to note that this particular $\hat{\mathcal{H}}_{\text{eff}}$ is time-independent both in the frame rotating about the z axis and in the laboratory frame. The new equation of motion has exactly the same form as equation (8), but all quantities have been transformed into the rotating frame:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}'_I(t) |\hat{\rho}'(t)\rangle \quad (56)$$

We are still using a prime to signify the interaction representation. Equation (56) is the analog to equation (8), and a modified equation (9) is used to relate the interaction representation to the rotating frame:

$$|\hat{Q}'\rangle = \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle \quad (57)$$

The order in which one alters these reference frames can, in this instance, be switched, because $\hat{\mathcal{H}}_{\text{eff}}$ commutes with $\hat{R}_z$. That is to say, for the effective Hamiltonian of this treatment, the following relations hold:

$$\begin{aligned} |\hat{Q}'\rangle &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle = \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) \\ &\quad \times \exp\left(\frac{i}{\hbar} \hat{F}_z \Omega t\right) |\hat{Q}\rangle \\ &= \exp\left(\frac{i}{\hbar} \hat{F}_z \Omega t\right) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle \end{aligned} \quad (58)$$

The steps taken towards the solution of equation (56) are virtually identical to the treatment performed in the laboratory frame, we simply write the analog to equation (34):

$$\begin{aligned} \frac{d|\hat{Q}\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{Q}\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \hat{T}_m^{\mu} \\ &\quad \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t + \tau)} \\ &\quad \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) \hat{T}_{m'}^{\mu'} \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\Delta \hat{Q}\rangle \end{aligned} \quad (59)$$

The difference is that now we perform the expansion in terms of eigenoperators of the effective Hamiltonian and note that these are still in the rotating frame. Analogs of equation (35) in this treatment are

$$\left. \begin{aligned} |\hat{T}_m^{\mu}\rangle &= \sum_p |\hat{T}_{m,p}^{\mu}\rangle \\ |\hat{T}_m^{\mu}(t)\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\hat{T}_m^{\mu}\rangle \\ &= \sum_p \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\hat{T}_{m,p}^{\mu}\rangle \\ &= \sum_p e^{-i\omega_p \tau} |\hat{T}_{m,p}^{\mu}\rangle \end{aligned} \right\} \quad (60)$$

This choice of representing the interaction Hamiltonian produces an important relationship between the spin operators and the commutator superoperator of $\hat{F}_z$:

$$\hat{F}_z^D |\hat{T}_m^{\mu}\rangle = m |\hat{T}_m^{\mu}\rangle \quad (61)$$

Equation (59) then becomes

$$\begin{aligned} \frac{d|\hat{Q}(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{Q}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ &\quad \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t + \tau)} \\ &\quad \times \hat{T}_m^{\mu} \sum_p e^{-im_p \omega_0 \tau} \hat{T}_{m',p}^{\mu'} e^{i\omega_p \tau} |\Delta \hat{Q}(t)\rangle \end{aligned} \quad (62)$$

In these equations, we are using ω_p for the transition frequencies associated with the effective Hamiltonian $\hat{\mathcal{H}}_{\text{eff}}$ in order to distinguish them from the transition frequencies Ω_p associated with the isotropic Hamiltonian $\hat{\mathcal{H}}_0$. Another, more common, viewpoint is that ω_p are the transition frequencies in the rotating frame whereas Ω_p are the transition frequencies in the laboratory frame.

When we transform the spin tensor superoperator components out of the rotating frame, the rotating frame frequencies disappear from the relaxation matrix in that the spectral densities are always evaluated at laboratory frame frequencies as

follows:

$$\begin{aligned} \frac{d|\hat{\underline{\sigma}}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{\underline{\sigma}}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ & \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t+\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p e^{-im_p \Omega_0 \tau} \hat{\Gamma}_{m',p}^{\mu'} e^{i\omega_p \tau} |\Delta \hat{\underline{\sigma}}(t)\rangle \end{aligned} \quad (63)$$

$$\begin{aligned} \frac{d|\hat{\underline{\sigma}}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{\underline{\sigma}}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ & \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t+\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p \hat{\Gamma}_{m',p}^{\mu'} e^{i\Omega_p \tau} |\Delta \hat{\underline{\sigma}}(t)\rangle \end{aligned} \quad (64)$$

The end result is that the relaxation matrix is unaffected by rotation about the z axis. The solution in the rotating frame—highly preferred over that in the laboratory frame in computation—is often used as is; i.e., no transformation is performed to place the density matrix back into the laboratory frame after the solution of $|\hat{\underline{\sigma}}(t)\rangle$ is obtained.

A word of caution is in order. Although the transformation into a single rotating frame about the static field axis does not affect the relaxation matrix, this is not true for a transformation into a multiple rotating frame. Multiple rotating frames are particularly useful in dealing with heteronuclear spin systems, but in such cases a secular approximation must be applied. Fortunately, the nonsecular terms will be oscillating at frequencies that are on the order of the difference between the isotope Larmor frequencies. For the vast majority of cases, these will be at least several megahertz at common field strengths. At low field strengths or in the event that two isotopes have very similar Larmor frequencies, only a single rotating frame can be used, but will typically suffice to place all transition frequencies on a reasonable scale for accurate computation.

3 RELAXATION MECHANISMS AND CROSS CORRELATION

We have shown that spin system relaxation is dictated by the superoperator $\hat{\Gamma}$, and, according to equation (46), it is a sum over products of superoperators corresponding to the active interactions as indexed by symbols μ and μ' . Using this equation, we can proceed to formulate superoperators for individual relaxation mechanisms. To complete the formulation of $\hat{\Gamma}$, it is only necessary to give explicit form to equation (31) for each of the relaxation mechanisms active in the spin system under study. In this section, such will be done for several of the mechanisms most frequently encountered in liquid samples.

3.1 Intramolecular Dipole–Dipole Coupling

Relaxation by dipolar interactions is the most commonly treated relaxation mechanism in NMR. As such, we shall begin our specific relaxation discussions with the dipolar interaction and the dipole–dipole relaxation mechanism. The dipolar Hamiltonian for a system of n spins is given by

$$\begin{aligned} \hat{\mathcal{H}}^D = & \sum_{i=2}^n \sum_{j=1}^{i-1} \xi_{ij}^D \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(D, \theta_{ij}, \phi_{ij}) \hat{T}_m^{(2)} \\ & \times (D, i, j) \end{aligned} \quad (65)$$

The index μ has been resolved into the label D and a sum over all pairs of spins in the system. The spherical polar coordinates (θ_{ij}, ϕ_{ij}) specify the orientation of the internuclear vector for each pair of spins relative to the laboratory fixed coordinate system, and are implicitly time-dependent through the rotational diffusion of the molecule. Only the $l = 2$ spherical tensor components contribute to this mechanism. The dipolar interaction is symmetric about the internuclear vector, so that only two orientational parameters are required. The two spins interact through space, so that it is immaterial whether they are proximate through chemical bonds or not. The dipolar interaction constant is given by

$$\xi_{ij}^D = -2\sqrt{\frac{6\pi}{5}} \frac{\gamma_i \gamma_j}{r_{ij}^3} \quad (66)$$

The required rank-2 spatial functions are identical to the spherical harmonic functions as given by

$$\left. \begin{aligned} F_0^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_0^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \sqrt{\frac{5}{16\pi}} (3 \cos^2 \theta_{ij} - 1) \\ F_{\pm 1}^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_{\pm 1}^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \mp \sqrt{\frac{15}{8\pi}} (\cos \theta_{ij} \sin \theta_{ij} e^{\pm i\phi_{ij}}) \\ F_{\pm 2}^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_{\pm 2}^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \sqrt{\frac{15}{32\pi}} (\sin^2 \theta_{ij} e^{\pm 2i\phi_{ij}}) \end{aligned} \right\} \quad (67)$$

Since the molecule reorients in a liquid, these angles are time-dependent and contribute to the lattice spectral densities as described in Section 2.6.

The rank-2 spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(D, i, j) &= \sqrt{\frac{1}{6}} (3 \hat{I}_{iz} \hat{I}_{jz} - \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j) \\ \hat{T}_{\pm 1}^{(2)}(D, i, j) &= \mp \frac{1}{2} (\hat{I}_{i\pm} \hat{I}_{jz} + \hat{I}_{iz} \hat{I}_{j\pm}) \\ \hat{T}_{\pm 2}^{(2)}(D, i, j) &= \frac{1}{2} \hat{I}_{i\pm} \hat{I}_{j\pm} \end{aligned} \right\} \quad (68)$$

For a system composed of two spins, both $I = \frac{1}{2}$, the spin operators take on the following matrix representations when

expressed in the product basis $\{|\alpha\alpha\rangle, |\alpha\beta\rangle, |\beta\alpha\rangle, |\beta\beta\rangle\}$:

$$\left. \begin{aligned} \frac{1}{2\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & -1 & 0 \\ 0 & -1 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad \frac{1}{4} \begin{bmatrix} 0 & -1 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix} \\ \frac{1}{2} \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \right\} \quad (69)$$

The commutation superoperators required for equation (44) are formed from the spin tensor components as follows:

$$\hat{\Gamma}_m^{\text{Dij}} = \hat{T}_m^{(2)}(\mathbf{D}, i, j) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(\mathbf{D}, i, j) \quad (70)$$

The dipole-dipole contribution to relaxation is thus given by

$$\begin{aligned} \hat{\Gamma}^{\text{DD}} &= \sum_{i=2}^n \sum_{j=1}^{i-1} \sum_{k=2}^n \sum_{l=1}^{k-1} \xi_{ij}^{\text{D}} \xi_{kl}^{\text{D}} \sum_{m=-2}^2 (-1)^m \\ &\times \sum_p \hat{\Gamma}_m^{\text{Dij}} \hat{\Gamma}_{-m,p}^{\text{Dkl}} J^{\text{DDijkl}}(\Omega_p) \end{aligned} \quad (71)$$

3.2 Chemical Shielding Anisotropy

Another important interaction contributing to relaxation arises from the anisotropic part of the chemical shielding Hamiltonian (SA). Because the energies involved are dependent on the static magnetic field strength, this type of relaxation becomes more important as the spectrometer field strength increases. The Hamiltonian for shielding anisotropy is given by

$$\hat{\mathcal{H}}^{\text{S}} = \sum_{i=1}^n \xi_i^{\text{S}} \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) \hat{T}_m^{(2)}(\mathbf{S}, i) \quad (72)$$

In this case, the index μ has been resolved into the label $\mathbf{S}$ and a sum over all the spins in the system. Only the $l = 2$ tensors are required. The set $\{\theta_i, \phi_i, \chi_i\}$ are the three Euler angles that orient the principal axes of a given shielding tensor into a common coordinate system according to

$$F_m^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) = \sum_{m'=\pm 2} \mathcal{D}_{mm'}^{(2)}(\theta_i, \phi_i, \chi_i) F_{m'}^{(2)}(\mathbf{S}, \text{PAS}_i) \quad (73)$$

If the shielding tensor is symmetric ($\eta = 0$) then the spherical harmonic is sufficient to describe the lattice fluctuations, and equation (73) reduces to

$$F_m^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) = Y_m^{(2)}(\theta_i, \phi_i) \quad (74)$$

Here PAS is used to indicate the principal axis system in which the rank-2 irreducible tensor is diagonal, and $\mathcal{D}_{mm'}^{(2)}$ are the elements of the rank-2 Wigner rotation matrices. We have neglected the $l = 1$ component in equation (72) because it is very small in almost all cases. Although the isotropic

component ($l = 0$) does not vanish for this interaction, as it does for the DD interaction in liquid systems, we have combined it with the Zeeman term in the Hamiltonian to produce the chemical shielding contribution to $\hat{\mathcal{H}}_0$, i.e., these contributions are absorbed into the ω_i of equation (30).

It is important to note that in the treatment of shielding anisotropy, the ‘spin’ tensors are actually ‘spin-space’ tensors in that they contain normalized components of the static magnetic field and are thus dependent upon its spatial orientation. Since this is stationary and oriented along the z axis in the laboratory frame, it is of no concern to the theory presented. However, using this type of formulation, one cannot rotate this tensor in spin space, as conceivably could be done for the dipolar Hamiltonian spin tensor. The shielding interaction constant, spatial functions, and ‘spin-space’ tensor components are given below, the latter having field components that stem from a normalized field vector $\mathbf{B}_n = \mathbf{B}_0/|\mathbf{B}_0| = \mathbf{B}_0/B_0$. The interaction constants are given by

$$\xi_i^{\text{S}} = \sqrt{\frac{6\pi}{5}} \nu_i B_0 \delta_{zz}(i) = \sqrt{\frac{6\pi}{5}} \frac{\gamma_i}{\gamma_{\text{H}}} \Omega_{\text{spec}} \delta_{zz}(i) \quad (75)$$

The SA tensor functions in the PAS are given by

$$\left. \begin{aligned} F_0^{(2)}(\mathbf{S}, \text{PAS}) &= \sqrt{\frac{5}{4\pi}} \\ F_{\pm 1}^{(2)}(\mathbf{S}, \text{PAS}) &= 0 \\ F_{\pm 2}^{(2)}(\mathbf{S}, \text{PAS}) &= \sqrt{\frac{5}{24\pi}} \eta \end{aligned} \right\} \quad (76)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(\mathbf{S}, i) &= \sqrt{\frac{1}{6}} (3\hat{I}_{iz}B_z - \hat{\mathbf{I}}_i \cdot \mathbf{B}_n) \\ \hat{T}_{\pm 1}^{(2)}(\mathbf{S}, i) &= \mp \frac{1}{2} (\hat{I}_{i\pm}B_z + \hat{I}_{iz}B_{\pm}) \\ \hat{T}_{\pm 2}^{(2)}(\mathbf{S}, i) &= \frac{1}{2} \hat{I}_{i\pm}B_{\pm} \end{aligned} \right\} \quad (77)$$

For a treatment of a single spin- $\frac{1}{2}$ particle, the rank-2 shielding ‘spin-space’ tensor components take on the following matrix forms when expressed in the standard spin basis $\{|\alpha\rangle, |\beta\rangle\}$ in the laboratory frame, with the field axis along $+z$:

$$\frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad -\frac{1}{2} \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad (78)$$

Although the shielding Hamiltonian is of rank 2, the $m = 2$ component disappears, and the shift anisotropy-shift anisotropy contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{SS}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^{\text{S}} \xi_j^{\text{S}} \sum_{m=-1}^1 (-1)^m \sum_p \hat{\Gamma}_m^{\text{Si}} \hat{\Gamma}_{-m,p}^{\text{Sj}} J^{\text{SSij}}(\Omega_p) \quad (79)$$

The $\hat{\Gamma}_m^{\text{Si}}$ are commutation superoperators are formed from the spin tensor component for spin i according to

$$\hat{\Gamma}_m^{\text{Si}} = \hat{T}_m^{(2)}(\mathbf{S}, i) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(\mathbf{S}, i) \quad (80)$$

3.3 Quadrupolar Interactions

Spins having spin angular momentum quantum numbers larger than $\frac{1}{2}$, $I \geq 1$, may possess an appreciable electric quadrupole moment, which can provide important relaxation mechanisms. The Hamiltonian for quadrupolar interactions is given by

$$\hat{\mathcal{H}}^Q = \sum_{i=1}^n \xi_i^Q \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(Q, \theta_i, \phi_i, \chi_i) \hat{T}_m^{(2)}(Q, i) \quad (81)$$

As for the Q mechanism, the index μ has been resolved into the label Q and a sum over all the spins in the system. Only the $l = 2$ tensors are required. The set $\{\theta_i, \phi_i, \chi_i\}$ are the three Euler angles that orient the principal axes of the quadrupolar tensor into a common coordinate system according to

$$F_m^{(2)}(Q, \theta_i, \phi_i, \chi_i) = \sum_{m'=\pm 2} \mathcal{D}_{mm'}^{(2)}(\theta_i, \phi_i, \chi_i) F_{m'}^{(2)}(Q, \text{PAS}_i) \quad (82)$$

When the quadrupolar tensor is symmetric ($\eta = 0$), the spherical harmonic is sufficient to describe the lattice fluctuations and equation (82) reduces to

$$F_m^{(2)}(Q, \theta_i, \phi_i, \chi_i) = Y_m^{(2)}(\theta_i, \phi_i) \quad (83)$$

As for the shielding Hamiltonian, three angles are necessary for specification of the spatial tensor orientation. For an axially symmetric quadrupolar tensor, $\eta = 0$, only two angles are necessary, and in that case the spatial functions are equivalent to the rank-2 spherical harmonics given for the dipolar interaction. The quadrupolar interaction constants are given by

$$\begin{aligned} \xi_i^Q &= \hbar \sqrt{\frac{6\pi}{5}} \frac{\delta_{zz}(i)}{2I_i(2I_i - 1)} = \hbar \sqrt{\frac{6\pi}{5}} \frac{\text{QCC}_i}{2I_i(2I_i - 1)} \\ &= \hbar \sqrt{\frac{6\pi}{5}} \frac{2\pi \nu_i^Q}{2I_i(2I_i - 1)} \end{aligned} \quad (84)$$

where QCC is the quadrupolar coupling constant. The lattice interaction functions are given by

$$\left. \begin{aligned} F_0^{(2)}(\text{PAS}) &= \sqrt{\frac{5}{4\pi}} \\ F_{\pm}^{(2)}(\text{PAS}) &= 0 \\ F_{\pm 2}^{(2)}(\text{PAS}) &= \sqrt{\frac{5}{24\pi}} \eta \end{aligned} \right\} \quad (85)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(Q, i) &= \sqrt{\frac{1}{6}} (3\hat{I}_{iz}^2 - \hat{I}_i^2) \\ \hat{T}_{\pm 1}^{(2)}(Q, i) &= \mp \frac{1}{2} (\hat{I}_{i\pm} \hat{I}_{iz} + \hat{I}_{iz} \hat{I}_{i\pm}) \\ \hat{T}_{\pm 2}^{(2)}(Q, i) &= \frac{1}{2} \hat{I}_{i\pm}^2 \end{aligned} \right\} \quad (86)$$

For treatment of a spin-1 particle, the rank-2 quadrupolar spin tensor components are expressed in their matrix form as

$$\begin{aligned} \hat{T}_0^{(2)} & \quad \hat{T}_1^{(2)} = [\hat{T}_{-1}^{(2)}]^\text{T} \quad \hat{T}_2^{(2)} = [\hat{T}_{-2}^{(2)}]^\text{T} \\ \frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \end{aligned} \quad (87)$$

The spin index is implicit and the matrices are in the standard single spin basis $\{|\alpha\rangle, |\beta\rangle, |\gamma\rangle\}$. The quadrupole–quadrupole contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{QQ}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^Q \xi_j^Q \sum_{m=-2}^2 (-1)^m \sum_p \hat{\Gamma}_m^{\text{Qi}} \hat{\Gamma}_{-m,p}^{\text{Qj}} J^{\text{QQij}}(\Omega_p) \quad (88)$$

The superoperator $\hat{\Gamma}_m^{\text{Qi}}$ is formed from the spin tensor operators as follows:

$$\hat{\Gamma}_m^{\text{Qi}} = \hat{T}_m^{(2)}(Q, i) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(Q, i) \quad (89)$$

3.4 External Random Fields

Relaxation by random fields is often used as a ‘catch-all’ in order to account for relaxation that cannot be attributed to other relaxation mechanisms. The origin of the random fields is not precisely specified. They could, for example, arise from DD interactions with paramagnetic species or nuclear spins of solvent molecules. Consider a random field at spin i given by $\mathbf{B}(\mathbf{R}, i, t)$. The time average of the field must be zero, since all constant terms have been absorbed into the static Hamiltonian. However, the time-averaged amplitude of the field irrespective of its direction is nonzero, and this quantity $\mathbf{B}(\mathbf{R}, i) = |\overline{\mathbf{B}(\mathbf{R}, i, t)}|$ will define the interaction strength according to

$$\xi_i^{\text{R}} = \gamma_i B(\mathbf{R}, i) \quad (90)$$

A normalized random field with unit time-averaged amplitude can now be defined as follows:

$$\mathbf{b}(\mathbf{R}, i, t) = \frac{\mathbf{B}(\mathbf{R}, i, t)}{B(\mathbf{R}, i)} \quad (91)$$

The spherical components of this vector are

$$\left. \begin{aligned} b_0^{(1)}(\mathbf{R}, i, t) &= b_z(\mathbf{R}, i, t) \\ b_{\pm 1}^{(1)}(\mathbf{R}, i, t) &= \mp \sqrt{\frac{1}{2}} b_{\pm}(\mathbf{R}, i, t) \end{aligned} \right\} \quad (92)$$

These spherical components of the normalized random field may be identified with the lattice fluctuation functions as follows, and expressed in terms of the spherical harmonics and the time-dependent norm of the scaled random field:

$$F_m^{(1)}(\mathbf{R}, i, t) = b_m^{(1)}(\mathbf{R}, i, t) = |\mathbf{b}(\mathbf{R}, i, t)| Y_m^{(1)}(\theta_i, \phi_i) \quad (93)$$

In contrast to the other interactions we have discussed, all of which have constant amplitude but random orientation, the random field interaction must be assumed to vary randomly in both orientation and amplitude. All the time dependence of the lattice functions then cannot be vested in the spherical harmonics. The Hamiltonian for the random field interaction is

$$\hat{\mathcal{H}}^{\text{R}} = \sum_{i=1}^n \xi_i^{\text{R}} \sum_{m=-1}^1 (-1)^m F_{-m}^{(1)}(\mathbf{R}, i, t) \hat{T}_m^{(1)}(\mathbf{R}, i) \quad (94)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(1)}(\mathbf{R}, i) &= \hat{I}_{iz} \\ \hat{T}_{\pm 1}^{(1)}(\mathbf{R}, i) &= \mp \sqrt{\frac{1}{2}} \hat{I}_{i\pm} \end{aligned} \right\} \quad (95)$$

For a single spin- $\frac{1}{2}$ particle, the random field spin tensor components are

$$\left. \begin{aligned} \hat{T}_0^{(1)} &= \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad \hat{T}_1^{(1)} = -[\hat{T}_{-1}^{(1)}]^T \\ &= \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (96)$$

The random field-random field contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{RR}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^{\text{R}} \xi_j^{\text{R}} \sum_{m=-1}^1 (-1)^m \sum_p \hat{\Gamma}_m^{\text{R}i} \hat{\Gamma}_{-m,p}^{\text{R}j} J^{\text{RR}ij}(\Omega_p) \quad (97)$$

3.5 Cross Correlation Effects

According to equation (47), the relaxation matrix is a sum of terms, each of which involves two interactions. The index μ implicitly contains a spin or spin pair index, the type of interaction, and the interaction rank. Since there is no restriction on the double sum, there are a great many terms involving different spins or spin pairs and different mechanisms. If the value of any of the indices associated with μ' is different from that associated with μ , the term is referred to as a cross-correlation term. Such terms can involve two different spins or spin pairs of the same mechanism, or two different mechanisms. Some of these terms are zero because the interactions involved are not correlated, so the time average over the product of lattice functions yields zero, but many of them are not negligible and contribute dramatically to relaxation, as will be demonstrated in Section 4. Consider the DD mechanism with three or more spins in the system of interest as shown in equation (71). If $i \neq k$ or $j \neq l$ (both of these inequalities can hold if there are four or more spins) then we have an example of cross correlation. Interactions of different ranks will never correlate, but dipolar and shielding anisotropy interactions are both of rank-2, and cross terms like the following will occur in addition to those enumerated previously:

$$\left. \begin{aligned} \hat{\Gamma}^{\text{DS}} &= \sum_{i=2}^n \sum_{j=1}^{i-1} \sum_{k=1}^n \xi_{ij}^{\text{D}} \xi_k^{\text{S}} \sum_{m=-2}^2 (-1)^m \\ &\quad \times \sum_p \hat{\Gamma}_m^{\text{D}ij} \hat{\Gamma}_{-m,p}^{\text{S}k} J^{\text{DS}ijk}(\Omega_p) \\ \hat{\Gamma}^{\text{SD}} &= \sum_{i=1}^n \sum_{j=2}^n \sum_{k=1}^{j-1} \xi_i^{\text{S}} \xi_{jk}^{\text{D}} \sum_{m=-2}^2 (-1)^m \\ &\quad \times \sum_p \hat{\Gamma}_m^{\text{S}i} \hat{\Gamma}_{-m,p}^{\text{D}jk} J^{\text{SD}ijk}(\Omega_p) \end{aligned} \right\} \quad (98)$$

Some simulations showing the effects of cross correlation may be found in Sections 4.2 and 4.4.

4 SOME EXAMPLES

Now that the mathematical tools needed are at our disposal and several relaxation mechanisms have been presented, we can explore their effects using some simple spin systems as examples. This will be done by means of simulations using the GAMMA magnetic resonance simulation platform⁵ so that the various mechanisms can be turned on and off or adjusted at will to illustrate their effects. Most of our attention will be focused on longitudinal relaxation, though some transverse effects will be noted. In addition, the influence of molecular motion and geometry on the results of our ‘experiments’ will be examined. A growing body of experimental results⁴ indicates that the theoretical framework developed above predicts the results of experiments very accurately. Thus, we can proceed with some confidence to predict the results of experiments, though they may not yet be in the literature. The complexity of the relationship between these geometrical and dynamical parameters is such that it is clearly impossible to explore every variable fully here, but selected examples will be used to exhibit the sensitivity of experimental results to various physical parameters.

4.1 Coupled Relaxation Experiments: The AX Spin System

In this section, several experiments will be described that are used for studying longitudinal relaxation in coupled spin systems. Examples of their application to a ^{13}C - ^1H (AX) spin system will be given. Many of the basic principles of coupled relaxation can be illustrated using only this simple spin system. Some other pair of heteronuclei or a homonuclear spin system could be treated equally well.

The return to thermal equilibrium of magnetization that has been perturbed is governed by equation (45). Experiments to study spin relaxation normally consist of

1. preparing the spin system in a nonequilibrium state using rf pulses;
2. allowing the magnetization to relax for a period of time t_1 ;
3. projecting the magnetization of interest onto the observable single quantum coherences, again using rf pulses;
4. observing the resulting FID as a function of the time t_2 ;
5. Fourier transforming the FID to obtain a spectrum exhibiting the partially relaxed magnitudes of the various magnetizations.

This procedure is repeated for various values of t_1 and for various preparations of the nonequilibrium state until a sufficient body of data has been accumulated to elucidate all desired aspects of the relaxation of the system under study. Generally, one acquires enough data to overdetermine the relaxation, and then utilizes nonlinear least-squares fitting techniques to extract the values of the physical parameters of interest from the experimental data. Using the theory given above as implemented in the GAMMA platform, one can numerically simulate all of these steps. To exhibit all aspects of the relaxation behavior, it is generally necessary to perform several experiments, preparing the spin system in various ways. In each case, the relaxation during the evolution time t_1 is governed by equation (45), but the initial condition for the differential equation (i.e., the density operator at the start of the evolution period) is different in each case. Several

Figure 2 The proton hard pulse experiment used to create Figure 1. The wide pulse is a π pulse; the narrow one is a $\frac{1}{2}\pi$ pulse

such experiments are described below. More experimental details can be found in the review by Grant et al.⁴ We shall confine ourselves to exploring the effects of several relaxation mechanisms on some simple spin systems to illustrate the kinds of physical parameters to which spin relaxation is sensitive. Using the ^{13}C – ^1H (AX) spin system as a simple example, several typical experiments for studying coupled relaxation will be presented.

4.1.1 Nonselective Inversion: Hard Pulse

In the introduction (Section 1.3) the concept of cross relaxation due to dipolar coupling between the spins was introduced, and was illustrated in Figure 1. Figure 2 shows the proton hard pulse or nonselective inversion procedure used to create the simulations in Figure 1. This experiment illustrates many of the features of coupled relaxation and many of the effects of the various relaxation mechanisms. The protocol of the experiment is as follows:

1. Preparation: the system is started at thermal equilibrium, then a nonselective π pulse is applied at the proton resonance frequency. All the proton magnetization is now aligned along the negative z axis; the carbon magnetization remains at thermal equilibrium.
2. Evolution: the system is allowed to evolve for a time t_1 . The proton magnetization returns toward thermal equilibrium, with cross relaxation to the carbon.
3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon resonance frequency to project the z components of the carbon magnetization onto the carbon single quantum coherences.
4. Detection: the carbon FID is digitized.
5. The FID is Fourier transformed.

A series of values of t_1 was chosen and the procedure repeated for each value. The resulting spectra are shown in Figure 1. The ^1H spectra shown there were obtained by shifting the projection and observation steps to the proton frequency. Note that the two lines in each doublet evolve identically; this leads naturally to the idea of magnetization modes. More on this subject can be found in **Relaxation Mechanisms: Magnetization Modes**. It is generally more convenient and instructive to plot linear combinations of peak intensities corresponding to these magnetization modes. In Figure 1 note

that the four lines have been designated as C1, C2, H1, and H2. The magnetization modes for this AX system are

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} \\ M_H &= M_{H1} + M_{H2} \\ M_\Delta &= M_{C1} - M_{C2} = M_{H1} - M_{H2} \\ M_T &= \text{sum over all state populations} \end{aligned} \right\} \quad (99)$$

The M_T mode is just the sum of the populations of all the states, which is assumed to be constant, since the number of spins in the sample is constant. This corresponds to using the irreducible spherical tensor operators for two nonidentical spins as basis operators. The procedure for generating these operators is discussed in detail by Wang and Grant.¹⁷ Figure 3 shows the effect of several relaxation mechanisms on the spin system of Figure 1. The dotted line shows evolution under DD relaxation alone; random field effects have been turned off. The system relaxes much more slowly than shown in Figure 1. The addition of SA relaxation results in evolution as shown by the light line. To this point, M_Δ has not been perturbed at all. However, when cross correlation between DD and SA (see Section 3.5) is added, the evolution shown by the heavy lines results. Thus, only the DD–SA cross correlation relaxation couples M_Δ to the other modes. Figure 4 shows expanded views of the lines of the doublet at thermal equilibrium for these same cases. When DD–SA relaxation is considered, the two linewidths, i.e., the T_2 values of the lines, are no longer equal, and the doublet is not symmetric. In this case, lineheights may not be used to follow the evolution of the magnetization modes, but integrated intensities must be used. This has been done in Figure 3.

Figure 3 Magnetization mode evolution plots showing the effect on a ^{13}C – ^1H spin system of DD relaxation (dotted line), the addition of SA on the ^{13}C of 100 ppm (light line), and finally with cross correlation between DD and SA (heavy lines). The spin system is as in Figure 1. The shielding tensor is axially symmetric, with the unique axis along the internuclear vector. A hard pulse perturbation as in Figure 2 is used. There is no random field relaxation. The M_Δ mode is shown only for the last case, since it is always zero in the first two cases

Figure 4 Expanded plots showing thermal equilibrium ^{13}C spectra from the data set of Figure 3. The light line shows only DD relaxation, while the heavy line includes DD-SA cross correlation. The doublet remains symmetric for DD relaxation, but addition of DD-SA cross correlation affects T_2 differentially for the two transitions, yielding an unsymmetrical doublet

Figure 5 The effect of internuclear distance on DD cross relaxation from M_H to M_C . Random field relaxation of $T_1 = 10$ s is also present for both ^{13}C and ^1H . All other aspects of the experiment are the same as for Figure 1

In Figure 1, relaxation following a π ^1H pulse has already been illustrated for a nominal bond distance of 0.109 nm. The DD relaxation mechanism depends on the inverse sixth power of the internuclear separation. Suppose, now, that the proton is more remote. Figure 5 shows a plot of M_C as a function of the proton carbon distance from 0.11 to 0.30 nm. The random field mechanism has been set for a T_1 of 10 s. The internuclear distance has a dramatic effect on the cross relaxation, and one would expect to be able to measure distances quite accurately by studying cross relaxation. However, the rotational diffusion correlation time has a similar effect, as shown in Figure 6. It is only possible to determine the ratio of these two quantities. In a large molecule where a number of internuclear distances are sought, it is often possible to determine at least one internuclear distance a priori, for example, by assuming that one C-H bond has its usual value for similar hybridization

of the carbon; then all other internuclear distances can be calculated. This calculation presumes that nuclei involved all reorient at the same rate, i.e., that the molecule is rigid. As the internuclear distance is increased, the DD mechanism weakens rapidly, but, even at 0.3 nm, the DD mechanism is still evident in that it produces cross relaxation. It is not the weakening of the DD mechanism that imposes this limit, but rather that it becomes weak compared to the combined effect of all other mechanisms.

So far, we have assumed that the molecule under study undergoes rotational diffusion as a spherical top, and the orientation of the internuclear vector with respect to some molecule-fixed coordinate system is irrelevant. If the molecule is diffusing as a symmetric top, this is no longer the case. Let the molecule-fixed coordinate system be that which diagonalizes the rotational diffusion tensor. Then Figure 7 shows the dependence of M_C on the angle θ between the

Figure 6 The effect of rotational correlation time on cross relaxation. A random field relaxation of $T_1 = 10$ s is present for both ^{13}C and ^1H . All other aspects of the experiment are the same as for Figure 5

Figure 7 The effect of motional anisotropy on cross relaxation from M_H to M_C for various angles between the internuclear vector and the unique axis of the rotational diffusion tensor. Curves are given for an oblate and a prolate top as shown. All other aspects of the experiment are the same as for Figure 1

unique axis of the top and the internuclear vector for motional anisotropies $D_{\perp}/D_{\parallel}$ of 0.3 and 3.0. To effect DD relaxation, molecular motion must change the direction of the internuclear vector. Thus, if the C–H vector is oriented parallel to the direction of $D_{\parallel}$ then changing the value of $D_{\parallel}$ has no effect on the relaxation. In Figure 7, $D_{\perp}$ has been kept constant as in Figure 1, and $D_{\parallel}$ has been altered to produce the anisotropies.

4.1.2 Inversion–Recovery

Figure 8 illustrates the inversion–recovery experiment. This procedure is identical to that commonly used for measuring ^{13}C T_1 values under ^1H decoupling, but here no decoupling is applied. The protocol for the experiment is as follows:

1. Preparation: the system is started at thermal equilibrium; then a π pulse is applied at the carbon resonance frequency. All the carbon magnetization is now aligned along the negative z axis; the proton magnetization remains at thermal equilibrium.
2. Evolution: the system is allowed to evolve for a time t_1 . The carbon magnetization returns to thermal equilibrium, with cross relaxation to the protons.
3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon resonance frequency to project the z components of the carbon magnetization onto the carbon single quantum coherences.
4. Detection: the carbon FID is digitized.
5. The FID is Fourier transformed.

Figure 9 shows the resulting simulated spectra for the AX spin system as in Figure 1. As before, the ^1H spectra shown in Figure 9 were obtained by shifting the projection and observation steps to the proton frequency. Note that magnetization flows from the ^{13}C to the ^1H in this case—the reverse of what was observed in Figure 1. For this simulation, only DD relaxation was used, to accentuate the effects of cross relaxation; thus, the relaxation times are substantially longer. Figure 10 shows a plot of M_C taken from the spectra of

Figure 8 The inversion–recovery experiment. The wide pulse is a π pulse; the narrow one is a $\frac{1}{2}\pi$ pulse

Figure 9. The dotted line shows a single exponential with the T_1 adjusted to best fit the actual evolution. The nonexponential behavior indicates that the ^{13}C magnetization is perturbed by the presence of the ^1H , i.e., by cross relaxation to the protons. The departure is slight, and might be overlooked in a real experiment unless careful studies were done with high S/N data. Thus, the hard pulse experiment of the previous section is a much more sensitive measure of the effects of cross relaxation. Again, the M_{Δ} mode is unperturbed.

4.1.3 Selective Inversion: Polarization Transfer

There are several variations of the selective inversion or soft pulse experiment, depending on which of the spectral lines are to be inverted and the method to be used for inversion. A simple low-power ‘soft’ rectangular pulse or a shaped pulse can be used to invert a single line. One member of a doublet can be inverted by adjusting the pulse amplitude so that the on-resonance peak experiences a π nutation while the off-resonance one experiences an effective field producing a 2π precession and is thus unchanged. These methods have been used before the advent of modern spectrometers with sufficient phase agility to accomplish polarization transfer or INEPT-type procedures such as the one described in Figure 11. This latter procedure is now the preferable one in most cases. It proceeds as follows:

1. Preparation: the system is started at thermal equilibrium; then a proton $(\frac{1}{2}\pi)_x$ pulse is applied to orient the two members of the proton doublet along the y axis. Precession due to scalar coupling for a period of $\frac{1}{2}J$ produces antiphase proton magnetization along the x axis that is then rotated back onto the z axis with a $(\frac{1}{2}\pi)_y$ pulse. The simultaneous π pulses in the center of the preparation period cause the evolution due to chemical shift to refocus, but do not affect the evolution due to scalar coupling. The carbon thermal equilibrium magnetization is inverted by the π pulse, and to this is added the antiphase magnetization generated in the proton domain. This yields a 1.5 : –2.5 doublet intensity ratio.
2. Evolution: the system is allowed to evolve for a time t_1 . Both the carbon and proton magnetizations return toward thermal equilibrium.

Figure 9 Simulated spectra resulting from the inversion–recovery experiment described in Figure 8. The spin system is the same as for Figure 1. Only DD relaxation is enabled

Figure 10 The M_C mode taken from the spectra of Figure 9 plotted versus time. The solid line is the actual evolution of the magnetization; the dotted line is the corresponding single exponential evolution

3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon or the proton resonance frequency to project the z components of the corresponding magnetization onto the single quantum coherences.
4. Detection: the carbon or proton FID is digitized.
5. The FID is Fourier transformed.

Figure 12 shows the spectra obtained by applying this sequence to the spin system of Figure 1. Note how proton magnetization is transferred to the ^{13}C in much the same way as happens in an INEPT experiment. In this case, the M_Δ mode is strongly perturbed, but, as shown in Figure 13, it is mono-exponential because this mode is not coupled to any other for an AX system with only DD relaxation. Even though the spectral lines evolve in a more complicated way and evolve differently for the ^1H than for the ^{13}C doublet, the difference of the two lines of the doublet M_Δ evolves identically and

mono-exponentially, whether measured in the ^1H or the ^{13}C spectrum as stated in equation (99). This is a manifestation of the fact that the operator corresponding to M_Δ is identical whether it is measured in the proton spectrum or the carbon spectrum. These two differences of line intensities are just two different views of the same measurable, and this measurable is not coupled to any other mode.

4.2 Angles Between Internuclear Vectors: The AX_2 Spin System

In Section 4.1.3, we observed how cross correlation between DD and SA interactions can influence relaxation. The AX_2 spin system introduces the possibility to have cross correlation between two different DD interactions. There are

Figure 11 Selective inversion of a proton doublet using nonselective pulses. The wide pulses are π ; the narrow ones are $\frac{1}{2}\pi$. The letters under the pulses indicate relative phases. If no phase is indicated, it is arbitrary

Figure 12 Spectra obtained by applying the selective inversion procedure of Figure 11 to the proton spin system described in Figure 1. Only the DD mechanism is enabled

Figure 13 Magnetization modes taken from the spectra of Figure 12 plotted as a function of evolution time. Here the single exponential (dotted) line precisely superimposes on M_{Δ} and is not visible. Compare with Figure 10

three different spin pairs (AX, AX', and XX'), each of which has a DD interaction, and there can be cross correlation among these various interactions (see Section 3.5). Because of the complexity of the way in which these cross correlations are folded into the elements of the relaxation superoperator, it is difficult to show how they influence relaxation in a clear way. However, the AX₂ spin system also introduces the angle between two internuclear vectors as a parameter of interest that is affected by this DD–DD cross-correlation. In Section 4.1.1, it was noted that for an AX spin system, the orientation of the internuclear vector with respect to some molecule-fixed frame is irrelevant for a spherical top. However, Figure 14 shows the influence of the angle between two internuclear vectors on the results of a proton hard pulse experiment. The magnetization

modes of interest here are

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} + M_{C3} \\ M_{+-+} &= M_{C1} - M_{C2} + M_{C3} \end{aligned} \right\} \quad (100)$$

The M_{+-+} mode was not present in the AX spin system, and is coupled to both the total proton and total carbon magnetizations. Both of these modes show dramatic sensitivity to the HCH angle for spherical top diffusion.

4.3 Rotational Anisotropy: The AX₃ Spin System

The prototypical AX₃ spin system is a ¹³C methyl group. If a methyl is attached to a larger molecule, the free rotation

Figure 14 For a ¹H–¹³C–¹H (AX₂) system, the effect of the HCH angle on the cross relaxation of the observable magnetization modes. Only the DD mechanism is enabled in the simulations. The perturbation is a proton hard pulse as in Figure 2. All other conditions are the same as for Figure 1

Figure 15 For a $^{13}\text{C}-^1\text{H}_3$ (AX_3) system, the effect of motional anisotropy (shown as $D_{\perp}/D_{\parallel}$ for the various curves) on the cross relaxation of the M_C and M_{+---+} magnetization modes. Only the DD mechanism is enabled in the simulations. The geometry is tetrahedral, with the threefold axis of the methyl collinear with $D_{\parallel}$. The perturbation is a proton hard pulse as in Figure 2. All other conditions are the same as for Figure 1

about the threefold axis of the methyl combined with the much slower overall tumbling of the molecule as a whole results in high motional anisotropy. This situation is a good case for exploring the effect of motional anisotropy on spin relaxation. The magnetization modes of interest in this case can be written as linear combinations of the four transitions of the carbon quartet:

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} + M_{C3} + M_{C4} \\ M_{+---+} &= 3M_{C1} - M_{C2} - M_{C3} + 3M_{C4} \end{aligned} \right\} \quad (101)$$

Figure 15 shows these ^{13}C magnetization modes as they evolve in a proton hard pulse experiment. Beginning with a spherical top, cross relaxation is observed much as in previous cases; however, as the anisotropy of the reorientation increases, the M_{+---+} mode is very sensitive, even switching to a negative excursion rather than a positive one under highly unsymmetrical reorientation.

4.4 *o*-Dichlorobenzene

The simulation in Figure 16 uses experimental parameters as for the protons of *o*-dichlorobenzene (an $\text{AA}'\text{BB}'$ spin system.) The basic parameters for this simulation were taken from a paper by Stark et al.¹⁸ The lower traces show spectra with full DD relaxation, including both autocorrelation and cross-correlation terms, whereas the upper traces have only autocorrelated DD terms. Under extreme narrowing (the two left traces), there is no apparent difference. When the correlation times are increased by a factor of 10, however, differences in maximum peak heights and linewidths are clearly visible. This simulation includes only dipolar relaxation terms, and uses a rigid asymmetric top as the motional model.

These few examples show the wealth of information available from coupled relaxation studies. Furthermore, many of the

Figure 16 Simulated proton spectra at 220 MHz of *o*-dichlorobenzene with DD relaxation including both autocorrelated and cross-correlated relaxation terms (lower traces) and with only autocorrelated terms (upper traces). The motion was modeled as a rigid asymmetric top with correlation times of 3.4, 5.4, and 1.9 ps (left traces) and 34, 54, and 19 ps (right traces). Artificial line broadening of 0.05 Hz was used for the spectra on the left to suppress truncation artifacts

multidimensional experiments that have become commonplace tools for the chemist and biochemist involve placing coupled spin systems in nonequilibrium states. In many cases, the cross relaxation and cross-correlation effects illustrated here markedly influence the results of such experiments, and due consideration must be given when interpreting these experiments.

The GAMMA platform has been made available to the public by its authors. The source code of the GAMMA-based program that generated all the simulations herein, as well as online simulations of these effects, are available courtesy of the National High Magnetic Field Laboratory at <http://gamma1.magnet.fsu.edu/~gamma/>.

1 INTRODUCTION

This article introduces nuclear spin relaxation primarily in the *weak limit*, by which we mean the kind of relaxation theory that is also called the perturbation limit, or the motionally narrowed limit. This is the most common form of relaxation in NMR.

Generally any theoretical treatment of relaxation divides the equations of motion of the spin system into two parts: first, a static or nearly static part consisting of the Zeeman energy, the spin–spin couplings (usually also including the dipolar energy between spins, and quadrupolar interactions, for rigid solids), and some other terms depending on the system; and second, a randomly time-varying part that produces relaxation. The latter can often be described approximately by two parameters: a size in energy units of $\hbar\omega_i$, and a time τ_c or ‘correlation time’, which is a characteristic time, usually the time that it takes for the random interaction to change by an amount that is unpredictable but is comparable to $\hbar\omega_i$. For example, when two nuclear spins in a molecule in solution relax mainly via the dipolar interaction between each other, ω_i is of the order of 10^5 s^{-1} for vicinal protons, decreasing as the inverse cube of the distance for further neighbors, and τ_c is of the order of the time for the interspin vector to rotationally diffuse by about one radian away from any initial direction. Neither ω_i nor τ_c can be defined precisely for every problem, although for some important problems they can be usefully defined. For large biopolymers, τ_c is of the order of 10^{-8} s , and it is roughly proportional to molecular weight.

The weak limit is almost always valid if $\omega_i\tau_c \ll 1$, but a more useful criterion is that the relaxation rate (such as T_1^{-1} or T_2^{-1}), calculated using the weak limit formulas, be small compared to ω_i . A useful rule of thumb is that transverse relaxation times T_2 are of the order of $\omega_i^2\tau_c$ and longitudinal rates are of the order of $\omega_i^2\tau_c/(1 + \omega^2\tau_c^2)$, where ω is a nuclear

spin frequency, or difference in nuclear spin frequencies, depending on the relaxation process under consideration. It is commonplace that $\omega\tau_c$ be greater than one for moderately large molecules, and it also can happen that $\omega_i\tau_c$ is greater than one, so that T_2 processes cannot be treated using the weak limit, whereas, in the same system, T_1 processes can be. In fact, T_1 processes can almost always be treated by the weak limit, with the exception of experiments, usually field cycling, performed at low field; and for conceptually similar experiments in the rotating frame such as studies of slow motions described in *Ultraslow Motions in Solids*.

In the present article, we shall introduce this topic in as simple a way as possible, in the hope of demystifying it for the inexperienced reader. We do not attempt a thorough review or much discussion of the different classes of relaxation that can occur. Even setting up the main Hamiltonian and the smaller time-dependent Hamiltonian requires many assumptions and some intuition about the system. On the other hand, we shall mention a number of topics not found in general texts. We shall not discuss details of applications since these are treated elsewhere in this Encyclopedia. Fortunately, the list of relaxation interactions is not long: dipolar relaxation already mentioned; similar relaxation due to electron spin–nuclear spin interaction in paramagnetic materials; spin–rotation interaction, especially in gases but also in smaller molecules in solution; and, for nuclei other than spin- $\frac{1}{2}$, the fluctuating electric quadrupolar interaction.

The kind of theory we have been describing is called *semiclassical*, because the time dependence of the perturbing interaction is generally described by classical variables such as distances. Relaxation theories can be, and generally are, also set up completely quantum mechanically. Unfortunately, the character of the time dependences of most relaxation interactions cannot be calculated from first principles, so that most relaxation theories are semiclassical. An exception is relaxation by lattice vibrations in solids or electron spins in metals, although even in these cases theories are likely to be somewhat phenomenological. Quantum relaxation theory also helps to justify some apparently arbitrary assumptions of the semiclassical theory.

2 REVIEW OF THE LITERATURE

The original Bloch equations,¹ containing two relaxation times, hinted at the probable richness of information contained in relaxation theory. T_1^{-1} was the rate at which energy changes would occur, and this more demanding process was expected to be slower than T_2 (line-broadening) processes, which do not require energy transfer in the absence of an rf field. The basic picture of nuclear relaxation was virtually completed with the masterful paper by Bloembergen, Purcell, and Pound (BPP), connecting transition rates between levels with spectral densities, and T_2 processes primarily with spectral densities at zero frequency.² By symmetry, T_1 and T_2 should be equal in the low-field limit and also, since T_2 must be a continuous function of B_0 , $T_1 = T_2$ in the limit of short correlation time, $\omega_0\tau_c \ll 1$ (where ω_0 is the Zeeman frequency γB_0).

In early papers, it was assumed that the relaxation by spin–spin interactions in rigid solids would produce straightforward transverse relaxation, but this view was

incorrect. The dipolar spin–spin interaction has to be treated separately from weak relaxation mechanisms in a rigid solid, and it can participate in a wide variety of interesting phenomena.

The next important development was the introduction of the density matrix to describe the system to be relaxed, and the satisfactory calculation of T_1 and T_2 for a single spin, by Wangness and Bloch. This treatment was then restated and generalized by various workers. Kubo and Tomita provided a theory based on the general theory of irreversible processes; Bloch treated relaxation in the rotating frame, among other things; and the present writer provided a version of the theory that may be useful to the novice reader. During this same period, Solomon was performing his important experiments on the HF molecule, providing a systematic basis for discussion of cross-relaxation theory (NOE) as treated in the papers of Solomon and Bloembergen. The topic has been treated in several texts, reviews, and monographs,^{1–15} of which Abragam's may be the most lucid introduction to the operator version of the formalism.^{3,6,14} In the present article, we use the notation of our own work¹⁵ and of Slichter⁴ as far as possible, while maintaining consistency with the other articles in this Encyclopedia. Excellent reviews of applications of weak and strong relaxation theories can be found in the books edited by Muus and Atkins⁸ and by Tycko.¹¹

A somewhat separate, more sophisticated and general approach has been developed by several theorists, based primarily on the work of Kubo and Tomita, and of Morita.^{8,10,12,13} The reader should be aware that there is only one underlying theory, and that the independent formalisms of various workers mentioned are all valid, and differ only in sophistication and in suitability for different problems.

3 STRONG RELAXATION

Strong relaxation theories are not presented here, but we describe them briefly. Many such theories are generalizations of the early well-known treatment of McConnell and of Slichter in which the chemical shift of a single spin is assumed to change at a random rate between two definite values, as a model for a dynamic change between two major average conformations. Generally, weak mechanisms such as dipolar relaxation are grafted onto such a theory, and the entire spin-dynamic problem can be solved analytically, as described in *Chemical Exchange Effects on Spectra*. Sometimes essentially the same kind of theory is set up with an infinite number of conformational states and shifts. An important example is the simulation of lineshapes for deuterium NMR in membranes and liquid crystals. The type of problem discussed in *Ultralow Motions in Solids* is also in this class.

All such strong relaxation mechanisms can become weak in the limit where the correlation time becomes sufficiently short, as already implied.

Another class of strong relaxation mechanisms is that of the Orbach processes, in which excited electronic states are important.⁸ This type of relaxation is not important for NMR problems, except perhaps for paramagnetic solids.

Finally we mention Anderson theory,⁸ which was first used to describe the exchange narrowing³ of electron spin resonances in solids. In NMR, it is adapted to estimate

linewidths of dilute heteronuclei in solids,³ and processes like solid state cross relaxation and magnetization (spin) diffusion for which perturbation theory is not applicable, but that are nevertheless slow.⁷

4 ENSEMBLES, SYSTEMS, OPERATORS, AND REPRESENTATIONS

We now describe the elements of models for relaxation theories. Here and throughout this article we only outline those topics that are relatively standard. The reader who is not familiar with topics mentioned is urged to refer to the literature surveyed above and to standard texts on quantum and statistical physics.

A typical relaxation theory treats the average behavior of an *ensemble* of systems. Most generally, each member of the ensemble is a replica of the NMR lab, according to Gibbs, but an almost equivalent view is that each member of the ensemble is represented by a single experiment on the same system, out of a large ensemble of experiments in which the sample is prepared as far as possible in the same way each time. A gentler version of an ensemble can be that it represents the average behavior of many pieces of a large sample of N particles ($N \approx 10^{23}$), each piece having fewer than N particles, but still a great many, say 10^{12} . Finally, it is useful sometimes, though not strictly correct, to view each member of the ensemble as one molecule out of the collection (ensemble) of molecules being studied. The latter view cannot be used for a rigorous treatment of intermolecular or collective effects such as intermolecular NOE or 'radiation damping'. In any case, it is most important to be entirely clear as to what system one is defining, before starting.

As already indicated, a starting point for any semiclassical weak relaxation theory is to write the Hamiltonian $\hat{\mathcal{H}}$ in the form

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_0 + \hat{K}(t) \quad (1)$$

where $\hat{\mathcal{H}}_0$ is the main Hamiltonian, and relaxation is produced by the randomly varying part $\hat{K}$. It is specifically assumed that $\hat{K}$ has zero value after being averaged over the ensemble: $\langle \hat{K}(t) \rangle = 0$, where the angular brackets always denote the ensemble average. It is important to remember that $\hat{K}$ is assumed to be different for each member of the ensemble.

It is useful to note explicitly that $\hat{K}$ can usually be written as the sum of more or less independent terms, each of which can be written (for one member of the ensemble) as a spin operator times a function of classical variables (usually internuclear distances, and angles defining directions of internuclear vectors):

$$\hat{K} = \sum_q H_q(t) \hat{K}^q \quad (2)$$

The H_q are ordinary real random functions of the time. They can be terms such as those of the dipolar interaction of BPP, for example $\hbar^2 \gamma^2 (1 - 3 \cos^2 \theta)/r^3$. The $\hat{K}^q$ s corresponding to this H_q would be the operators $\hat{I}_{1z} \hat{I}_{2z}$ and $-\frac{1}{4}(\hat{I}_1^- \hat{I}_2^+ + \hat{I}_2^- \hat{I}_1^+)$. In this case, the classical variable H_q is random because θ and

r vary randomly, in solution. The elements of $\hat{K}^a$ may also be functions of the time for a time-dependent *representation* of the system, discussed below. For weak relaxation, it turns out that all we need to know about $\hat{K}$ are the auto- and cross-correlation of the functions $\langle H_q(t)H_{q'}(t + \tau) \rangle$. These will be discussed later.

The quantum Hamiltonian is an operator, and the thing on which it operates is a wavefunction:

$$\psi = c_n(t)u_n \quad (3)$$

where the c_n are complex numbers that generally vary with time, and the u_n are a complete set of *basis functions*. There are rules concerning how to set up such a complete set, and how they must change under transformations of various kinds. For spin problems, we mention four, out of many, ways to define them.

1. The u_n can be wavefunctions that specify the orientation (or m_z , for $S > \frac{1}{2}$) of each spin in the system. These are eigenfunctions of the Zeeman Hamiltonian and we call this the ‘Zeeman’ representation.
2. The u_n can be eigenfunctions of the entire main Hamiltonian $\hat{H}_0$, with energy eigenvalues E_n . $\hat{H}_0$ includes, in addition to the Zeeman Hamiltonian, spin–spin coupling for molecules in solution. Deriving these u_n from the Zeeman ones can be easy—or it can be very complicated—but nevertheless it is useful to talk about them. This is the ‘Schrödinger’ representation. The terms c_n generally depend on time in this representation, as $\exp(iE_nt/\hbar)$, modified by relaxation.
3. The u_n can be appropriate for a rotating frame transformation. For such a transformation, most of the Zeeman Hamiltonian is removed, and the u_n are the same as for case 1 except that the new u_n are equal to those of case 1 multiplied by $\exp(-i\omega_j t)$, where ω_j are the sums of, or differences between, nuclear resonance frequencies of relevant spins. This could be called the ‘product operator’ representation, since it is used for product operator theory.
4. The representation may be one in which the entire average Hamiltonian $\hat{H}_0$ is transformed away. This is the ‘Heisenberg’ or ‘interaction’ representation. It is most convenient for setting up relaxation theory. In this representation, the c_n are time-independent except for the relaxing effect of $\hat{K}(t)$, and the new u_n are equal to those of the Schrödinger representation times $\exp(-iE_nt/\hbar)$. All operators such as $\hat{K}(t)$ are similar to their form in the Schrödinger representation, except that their off-diagonal elements are time-dependent.

The wavefunction ψ is completely specified by specifying the basis u_n and all the c_n . The latter set of numbers is viewed as a *vector in Hilbert space* in analogy to the set (x, y, z) of coordinates that represents the real-space position vector of a particle.

Before proceeding, we note that $\hat{H}_0$ can include time-varying things such as rf pulses or field gradients. For the most part, we ignore such fields. Equation (1) also omits any semiclassical interaction that restores thermal equilibrium. The equation should include another friction term that will do so.^{8,13,16} Otherwise, the energy of each system will increase continuously, toward infinite temperature. This is a consequence of the fact that $\hat{K}(T)$ does not have a temperature associated with it.

In fact, *nuclear spin relaxation theory is virtually identical to Brownian motion theory*. It deals with Brownian-like motion of vectors, in Hilbert space, that describe the spin system.^{8,10} In each time of the order of the correlation time τ_c , an individual system wavefunction changes very little, in analogy to the effect of single collisions on a large particle undergoing Brownian motion. The interested reader should read the last chapter of Reif’s text¹⁷ to see how Brownian motion of relatively large particles is related to fluctuating forces of the surrounding medium—in particular to the spectral densities (see below) of these forces. The analogy to Brownian motion may reassure the novice reader that nuclear spin relaxation involves nothing really new. In particular, Brownian motion theory always contains a presumed force of friction, and Einstein showed how the friction coefficient must be related to the diffusion coefficient, which is a manifestation of the fluctuating forces of collisions. Frictional forces were not described as such in early papers.^{15,16}

The statement in the above paragraph describes an *analogy*, which should not be confused with the important *applications* of NMR to the study of real diffusion. These include studies of translational diffusion, dating back to Hahn’s original papers on spin echoes, and of rotational diffusion, starting with BPP (reviewed, for example, in *Relaxation Effects of Chemical Exchange*).

5 THE DENSITY MATRIX AND THE RELAXATION MATRIX

The density matrix is defined by⁴

$$\sigma_{ij} = \langle c_i c_j^* \rangle \quad (4)$$

where $*$ here denotes the complex conjugate. Notice that it is a matrix whose elements depend on what representation we are using, which has to be kept in mind during any discussion or calculation. The density matrix can be shown to transform in the same way as any standard quantum operator, under change of representation, so it can be thought of as an object $\hat{\sigma}$ that is represented in some particular representation by a matrix σ_{ij} . Thus $\hat{\sigma}$ is often referred to as the density operator, even though it does not seem to operate on anything.

The symbol $\hat{\rho}$ was originally used for the density matrix of an entire system, including coordinates of nonspin variables. The notation $\hat{\sigma}$ was introduced to denote a “reduced” density matrix that describes the nuclear spin system alone. Often, as for example in the product operator formalism, $\hat{\sigma}$ is written as a sum of products of spin operators; this is what we mean by an operator formalism. Use of this language implies that correlations between spin orientations and molecule or lattice variables are, on the average, not large. This assumption has to be dropped for strong relaxation theories. In the absence of relaxation, $\hat{\sigma}$ obeys the quantum version of the Liouville equation:

$$\frac{d\hat{\sigma}}{dt} = \frac{i}{\hbar} [\hat{\sigma}, \hat{H}_0] \quad (5a)$$

where $[\hat{\sigma}, \hat{H}_0]$ denotes the commutator bracket $\hat{\sigma}\hat{H}_0 - \hat{H}_0\hat{\sigma}$.

The Schrödinger representation that we will use is not convenient for actual calculations, but is useful in developing and discussing the general theory. In this representation, the basis functions u_n are exact eigenvalues of $\hat{\mathcal{H}}_0$, as already mentioned. The diagonal element σ_{ii} of $\hat{\sigma}$ is simply the probability that the energy level E_i is occupied. As expected, the Liouville equation predicts that σ_{ii} will be time-independent, a consequence of the fact that $\hat{\mathcal{H}}_0$ is diagonal in this representation. The elements of $\hat{\sigma}$ represent the entire set of possible physical observables of the system. These are not the same things that we may observe in practice, and in NMR there is usually really only one quantity that we observe. It is the transverse magnetization in the fixed x direction, $\hat{M}_x$. Its expectation value is given by $\text{Tr}(\hat{M}_x \hat{\sigma})$, where Tr means a sum over diagonal elements. It is the sum of many off-diagonal elements of $\hat{\sigma}$ in the Schrödinger representation, because $\hat{M}_x$ has many off-diagonal elements in this representation, for a system of several spins. From the Liouville equation, the time dependence of an off-diagonal element σ_{ij} is given by a constant times $\exp[i(\omega_i - \omega_j)t]$. Each spectral line in a directly observed spectrum is a manifestation of a coherence represented by an off-diagonal density matrix element, damped, of course, by relaxation not included in equation (5a). However, typically $\hat{\sigma}$ has many more off-diagonal elements than are observed in this way; for a system of 10 protons, for example, it has only 1024 diagonal elements, but roughly a million off-diagonal elements. The vast majority of the latter are both uninteresting and difficult to study. Elements that are not directly observable in a simple free induction decay are called forbidden, and of these the most useful are the lower order (zero, double, triple, etc.) ‘multiple quantum’ coherences.⁶

As might be expected, the result of weak relaxation theory is an equation for $\hat{\sigma}$ that is a direct generalization of Bloch’s equations:

$$\frac{d\hat{\sigma}}{dt} = \frac{i}{\hbar}[\hat{\sigma}, \hat{\mathcal{H}}_0] + \hat{R}(\hat{\sigma} - \hat{\sigma}^0) \quad (5b)$$

where $\hat{\sigma}^0$ is the thermal equilibrium value of $\hat{\sigma}$, equal to a constant times $(\exp -\hat{\mathcal{H}}_0/RT)$. The extra term $\hat{R}(\hat{\sigma} - \hat{\sigma}^0)$ is shorthand for a matrix whose ij element is $\sum_{i'j'} R_{ij'j'}(\sigma_{i'j'} - \sigma_{i'j'}^0)$; thus the *relaxation matrix* $\hat{R}$ is a fourth-order matrix. We shall discuss it using the Schrödinger representation here. The elements of $\hat{\sigma}$ are analogous to the magnetizations in Bloch’s equations, and the term $i[\hat{\sigma}, \hat{\mathcal{H}}_0]/\hbar$ is analogous to $\gamma(\mathbf{B} \times \mathbf{H})$. The coefficients in $\hat{R}$ are extensions of Bloch’s rates T_1^{-1} and T_2^{-1} , and the term $\hat{\sigma}^0$ is similar to his M_0 .

As already mentioned, frictional forces must exist that return the system to equilibrium, and the term $-\hat{R}\hat{\sigma}^0$ was arbitrarily inserted to account for these. As included in equation (5b), it ensures that $d\hat{\sigma}/dt$ is zero at equilibrium, when $\hat{\sigma} = \hat{\sigma}^0$. Friction forces are connected with the memory of the surroundings: for example, as a spin precesses in matter, the interaction represented as relaxation by $\hat{\mathcal{H}}_1(t)$ will slightly deform the matter to produce a small local field at the spin. The deformation is analogous to the deformation in a bed when you lie on it. As the spin moves, this deformation follows it, but not instantly. There is a small lag, and this produces a memory field that is exactly right to make the system approach equilibrium.⁸ The $\hat{R}\hat{\sigma}^0$ term can also be fully justified by

a quantum derivation,¹⁶ or by taking spin interaction into account for the lattice’s motion.¹⁷

6 TRANSITION RATES

The semidiagonal element R_{ijj} is simply the rate constant for the transition from level i to level j . The theory of these transition rates was already fully implied in BPP, not requiring a density matrix for its description. Thus we can redefine σ_{ij} as a probability p_i that level i is occupied, and R_{ijj} as a transition rate w_{ij} from level j to i , writing equations of the form

$$\frac{dp_i}{dt} = \sum_j w_{ij}(p_j - p_j^0) \quad (6a)$$

where p_j^0 is the thermal equilibrium value of p_j , proportional to $\exp(-E_j/kT)$. The form of equation (6a) is based on the relaxation equation, equation (5b), and the w_{ij} are symmetric: $w_{ij} = w_{ji}$, as defined in the original theory.¹⁵ The w_{ij} are not identical to what are normally considered transition probabilities, which occur in the so-called master equation:

$$\frac{dp_i}{dt} = \sum_j (W_{ij}p_j - W_{ji}p_i) \quad (6b)$$

Here, detailed balance requires $W_{ij}/W_{ji} = \exp[-(E_i - E_j)/kT]$. Equation (6b) is also the equation for standard first-order chemical kinetics, if p_i is replaced by the molarity $[i]$ of systems in spin level i , and the W_{ij} are replaced with first-order rate constants usually denoted by k_{ij} or the equivalent.

Since the matrix w_{ij} is symmetric, whereas W_{ij} is not, equation (6a) is inconsistent with the more general equation, equation (6b), and with detailed balance. Apparently, the convenient form of relaxation theory described by equation (6a) is valid only in the high-temperature approximation, where $(E_i - E_j)/kT \ll 1$. Fortunately, this approximation is almost always obeyed for NMR experiments. In that case, it is reasonable to specify W_{ij} by

$$W_{ij} = w_{ij} \left(1 - \frac{E_i - E_j}{2kT}\right) \quad (7)$$

which preserves detailed balance within the high-temperature approximation. The problem with the semiclassical theory mentioned above can be avoided, when the high-temperature approximation is invalid, by either using the completely quantum version of the theory,¹⁵ or by augmenting the semiclassical model of equation (1) with a memory, or friction term, as already mentioned.^{13,16} A simple example of a memory effect is ‘radiation damping’ (see below).

For a large and important class of experiments such as NOESY, the situation is even simpler. With important exceptions such as methyl groups, there are no complicated correlations between spins, and the important evolution by relaxation is described by diffusion of magnetization among spins (‘spin diffusion’). Relaxation is described by

$$\frac{dm_i}{dt} = \sum_j s_{ij}(m_j - m_j^0) - r_1(m_i - m_i^0) \quad (6c)$$

where m_i is the z component of magnetization of the i th spin species, m_i^0 is its thermal equilibrium value, r_i is the relaxation rate of the i th spin due to all mechanisms, and the s_{ij} are cross relaxation rates between spins. Note that s and r are often denoted by σ and ρ in the literature. Furthermore, the term ‘relaxation matrix’ is often used in the literature of these problems, to denote the collection of relaxation rates; it is not to be confused with the more complicated $\hat{R}$ matrix of the full theory.

An equation similar to equation (6c) can also describe the ROESY experiment, with redefinition of m_i as magnetization along the effective field of spin i . We shall briefly return to ROESY below.

All these versions of NMR kinetic theory are described by first-order differential equations, whose evolution can be described by sums of simple normal modes, each having a single relaxation time. These modes include in principle all the m_i (or possibly σ_{ii}) and are time consuming to calculate. Magnetization diffusion and relaxation viewed in terms of normal modes has been applied by T. L. James to macromolecules. However, an equivalent approach is to ask how a localized departure from equilibrium, at a single spin i , spreads to other spins as time passes. This ‘Green’s function’ approach is perhaps more economical in computer time than the normal mode approach, and it may provide a rather direct and more intuitive model for the evolution of diagonal and cross peaks in NOESY and ROESY. Routines that can perform such a calculation are included in some NMR data analysis programs. The normal mode approach is more useful for problems having a high degree of symmetry.

7 LINEWIDTHS AND OFF-DIAGONAL ELEMENTS

In the Schrödinger representation, any element of σ_{ij} of $\hat{\sigma}$ varies as $\exp(i\omega_{ij}t)$, neglecting relaxation, where $\omega_{ij} = (E_i - E_j)/\hbar$. The elements of $\hat{R}$ are time-independent (only for this representation!). A *secular* term $R_{ii'jj'}$ is one for which $\omega_{ii'} = \omega_{jj'}$. All the rates in the previous section are thus secular, because all the ω_{ii} and ω_{jj} are zero. Likewise, terms of the relaxation matrix $\hat{R}$ terms R_{ijij} , which are rather direct analogs to Bloch’s rate T_2^{-1} , are secular. The minimum full linewidth of a spectral transition between levels i and j is R_{ijij}/π , just as the full linewidth for Bloch’s equations is $(\pi T_2)^{-1}$. Thus, if all relaxation terms of equation (5b) are ignored except R_{ijij} then σ_{ij} varies as a damped exponential, $\exp(i\omega_{ij}t + R_{ijij}t)$. The sign of R_{ijij} is negative (see below).

Those terms of the relaxation matrix $\hat{R}$ that are not of the form R_{ijij} or R_{ijij} can mostly be ignored. That is fortunate, because $\hat{R}$ has roughly 10^{12} elements for a 10-proton problem, for example.

Specifically, any element $R_{ii'jj'}$ connecting any density matrix element $\sigma_{ii'}$ to another one $\sigma_{jj'}$ can often be ignored provided

$$|\omega_{ii'} - \omega_{jj'}| |R_{ii'jj'}| \gg \text{replaced by } \gg \text{ then the element of } \hat{R} \text{ being considered is a time-independent relaxation term connecting two elements of } \hat{\sigma} \text{ that are varying rapidly compared with the element of } \hat{R}. \quad (8)$$

If equation (8) is strongly obeyed (if the equation is valid with $>$ replaced by $\gg$) then the element of $\hat{R}$ being considered is a time-independent relaxation term connecting two elements of $\hat{\sigma}$ that are varying rapidly compared with the element of $\hat{R}$.

These terms are called ‘nonsecular’, and they are expected to perturb the final solution by an amount equal to the ratio of the right-hand to the left-hand side of equation (8), compared with secular terms of the same size. The name and idea of secular and nonsecular perturbations date back to classical mechanics, and were invoked by Van Vleck in truncating the dipolar Hamiltonian in order to calculate moments of resonance lines.

Terms in $\hat{R}$ for which equation (8) is only weakly obeyed, or corresponding terms in operator-based theories of relaxation,¹⁴ should always be included in any solution of a relaxation problem. The effect of such terms can be dramatic, and can unexpectedly produce narrowing, and collapse of multiplets. A simple example is the non-observance of ^{14}N splitting of the proton resonances of NH groups, due to rapid electric quadrupole relaxation of the ^{14}N spin. The N–H J splitting is suppressed by rapid relaxation coupling of coherences of the product operator form $\hat{I}_z \hat{S}_x$, where I is ^{14}N and S is the NH proton. Of course, this example, like many, does not require density matrix relaxation theory in order to be understood. This kind of relaxation is called ‘narrowing of the second kind’.³

8 EFFECTS OF RF FIELDS: SPIN LOCKING

The consideration of nonsecular terms in $\hat{R}$ became richer when it was realized that the elements of $\hat{\sigma}$ can have their time dependence altered by the presence of rf fields, such as in a spin lock experiment. Off-diagonal elements can be driven to have periodic variation at the rf frequency, rather than their natural frequencies, and elements of $\hat{R}$ that connect two elements of σ which have slightly different frequencies become secular. Thus, rf fields can alter the relaxation behavior, as first shown by Vold and Vold. Here it is assumed that $\hat{R}$ itself is not affected by the rf field. A commonplace example of this effect is in the ROESY (CAMELSPIN) experiment of Bothner-By. Magnetizations of different spins cross relax in this experiment because they are spin locked at the same rf frequency, and these magnetizations correspond directly to off-diagonal density matrix elements that would evolve at different frequencies, and not cross relax, in the absence of the spin lock. It must be emphasized, however, that the ROESY experiment was undoubtedly invented and analyzed independently of the theory outlined in the present article.

The phenomena described in the last paragraph are quite general. Another useful measurement can be made on systems that are expected to have dynamic, chemical, or conformational changes taking place on a timescale in the range of 10 ms or slower. Then it is of interest to study the variation in the transverse relaxation time with respect to the spin-locking rf field intensity $\omega_1 = \gamma B_1$. This relaxation time is generally called $T_{1\rho}$, since the process it describes resembles a T_1 process, but in the rotating frame. The theory of $T_{1\rho}$ can be treated using spectral densities and density matrix theory, following Bloch, or it can with equal validity be treated using the type of theory reviewed in **Chemical Exchange Effects on Spectra**. In general, $T_{1\rho}$ starts to decrease below its value at zero B_1 , (which is the same quantity as T_2) at field intensities where $\omega_1 \tau_c$ approaches one. Here τ_c is the correlation time for the slow perturbation. Such a measurement yields an estimate of this correlation time, and also the general size of the shift ω_i associated with the perturbation.

9 CROSS-CORRELATION EFFECTS

An understanding of the effect of cross correlations between the random functions $H^q(t)$ in equation (2) can help to provide interesting information about a system from its linewidths or transition rates. This topic is reviewed in *Relaxation Processes: Cross Correlation and Interference Terms*. An important example is the often-seen unequal linewidth of ^{13}C (or ^{15}N) multiplets, due to correlation and interference between the dipolar interaction and the CSA of the ^{13}C nucleus. A rough estimate of the CSA can be obtained from this effect.⁵

To understand the general usefulness of cross-correlation effects, consider the dipolar interaction in a hypothetical spin system ABC, where nuclei A, B, and C are nonequivalent protons and the distances A to B, and B to C, are assumed fixed and equal. If the angle ABC could vary randomly with equal probability for all angles then the spectrum of B would show an uninteresting multiplet due to the uncorrelated dipolar interactions between A and B, and B and C. If, instead, the system is rigid and linear, with the angle ABC equal to 180° , the dipolar interactions mentioned above are highly correlated. If spins A and C are oriented oppositely for the rigid linear case, their dipole fields at B will cancel; if spins A and C are both oriented in the same direction, the dipolar fields always add. Thus, the centerlines of B's multiplet will be narrow, and the outer lines will be four times as broad as in the uncorrelated case.

An interesting example of a correlation effect is 'radiation damping'. This is due to the rf fields, fluctuating and induced, from the probe pickup coil. The effect is misnamed, because no radiation is involved. It is a correlated effect, because the field felt at each spin is virtually the same as at every other spin. This means that these fields cannot directly change the magnitude of total nuclear magnetism, only its direction, if rf inhomogeneity of the probe coil is ignored.

10 TRANSVERSE RELAXATION RATES AND DYNAMIC SHIFTS

Let us focus on two levels i and j giving an observable signal, or a forbidden coherence, at a frequency $\omega_{ij} = (E_i - E_j)/\hbar$, where E_i and E_j are the energies of the two levels. We shall not write down the form for the elements of $\hat{R}$ in general, which can be found in many texts, as well as in other articles in this Encyclopedia. However, it is of interest to write the expressions for elements of $\hat{R}$ that are most closely analogous to Bloch's relaxation rates as explained above. The term similar to T_1^{-1} is R_{iijj} , given by

$$\frac{1}{2} T_1^{-1} R_{iijj} = J_{ijij}(\omega_{ij}) + J_{jiji}(\omega_{ji}) \quad (9a)$$

Here T_1^{-1} is the apparent rate that would be measured for the spectral line at ω_{ij} by a selective saturation-recovery experiment, and '>' indicates that the actual apparent rate could be shortened by relaxation to levels other than i and j . The factor of $\frac{1}{2}$ multiplying T_1^{-1} is inserted because Bloch's T_1^{-1} is twice the rate constant connecting two levels in a two-level master equation, as one can verify by writing and solving such a master equation for the recovery of M_z . The

J s are Fourier transforms of correlation functions of $\hat{K}$. They are called spectral densities, and are given in general by

$$J_{ijj'j'}(\omega) = \int_{-\infty}^{\infty} e^{i\omega\tau} \langle K_{ij}(t) K_{i'j'}^*(t + \tau) \rangle d\tau \quad (10)$$

with * here denoting the complex conjugate. The expressions within the ensemble-average brackets $\langle \rangle$ are cross-correlation functions, or autocorrelation functions if $i', j' = i, j$. These are assumed to be real and independent of t , and are also assumed to be even functions of τ (that is, unchanged by the substitution of τ by $-\tau$). From these assumptions, it is easy to show that the right-hand side of equation (9a) is real, as it has to be.

The term of $\hat{R}$ most closely similar to Bloch's T_2^{-1} is

$$\begin{aligned} T_2^{-1} R_{ijij} &= 2J_{iijj}(0) - J_{iiii}(0) - J_{jjjj}(0) \\ &\quad - J_{ijij}(\omega_{ji}) - J_{jiji}(\omega_{ji}) \\ &\quad - \sum_{m \neq i, j} [J_{mimi}(\omega_{mi}) + J_{mjmj}(\omega_{mj})] \end{aligned} \quad (9b)$$

This equation is much simpler than it appears, and can be obtained from the original equations for the $\hat{R}$ matrix given elsewhere⁶ and in *Dynamic Frequency Shift; Relaxation Processes: Cross Correlation and Interference Terms and Relaxation Theory for Quadrupolar Nuclei* by rearranging sums, and substitution of equation (9a).

The first three terms on the right-hand side of equation (9b) can be rewritten [by substitution with equation (10)] as

$$\begin{aligned} &2J_{iijj}(0) - J_{iiii}(0) - J_{jjjj}(0) \\ &= - \int_{-\infty}^{\infty} \langle \Delta_{ij}(t) \Delta_{ij}(t + \tau) \rangle d\tau \end{aligned} \quad (11)$$

where $\Delta_{ij}(t) = K_{ii}(t) - K_{jj}(t)$. The quantity Δ_{ij} is just the fluctuating part of the first-order extra splitting between levels i and j produced by the perturbation $\hat{K}(t)$ for a member of the ensemble, and equation (11) is the zero-frequency spectral density associated with this fluctuation, or its 'motionally averaged' relaxation rate. This *adiabatic* term usually dominates relaxation in large molecules. Equation (11) also provides an important refinement over the rule of thumb above that transverse relaxation rates are proportional to $\omega_i^2 \tau_c$, where ω_i^2 is approximately the size of squares of elements of $\hat{K}$. For T_2 processes, it is the size of fluctuating *differences* between diagonal elements of $\hat{K}$ that matters. The adiabatic contribution to T_2^{-1} is often denoted by $(T_2^*)^{-1}$ (here of course, * does not indicate the complex conjugate).

For example, in larger proteins, the dipolar interaction between ^{15}N and H, for NH groups of fully ^{15}N -labeled proteins, might be expected to dominate linewidths. However, for double quantum evolution, as in heteronuclear double quantum correlation experiments, the dominant $\hat{I}_z \hat{S}_z$ part of the dipolar interaction does not contribute to widths, because it affects the two levels connected in the zero, and the double, quantum coherences equally. Thus the double quantum transition connects levels $m_I = m_S = +\frac{1}{2}$ with levels $m_I = m_S = -\frac{1}{2}$, and the expectation value of the operator $\hat{I}_z \hat{S}_z$ is the same for both of these levels. The spacing between these two

levels does not fluctuate as the molecule tumbles, even though the energy of each level fluctuates; they fluctuate together (as far as this particular dominant interaction is concerned). Simple reasoning of this kind is often useful in thinking about linewidths.

The next two terms of equation (9b) are equal, and the sum of their real parts is identical to R_{ijij} [see equation (9a)]. The real part often dominates, and its presence in equation (9b) indicates that T_1 processes will always contribute to T_2 processes. However, comparing with equation (9a), the contribution is only half of the minimum value T_1^{-1} . The origin of the factor $\frac{1}{2}$ can be seen for a model system consisting of a single spin interacting with a fluctuating field $\mathbf{h}(t)$. T_1 processes (longitudinal spin flips) are produced by both of the transverse components of $\mathbf{h}(t)$, namely h_x and h_y . However, transverse relaxation of magnetization M_x , for example, cannot be produced by h_x , only by h_y , because h_x is along M_x . Transverse relaxation can also be produced by h_z , but this latter contribution is the adiabatic kind of relaxation discussed above, represented by the first terms in equation (9b).

The terms of equation (9b) discussed so far are often described in the older literature by the equation $T_2^{-1} = (T_2^*)^{-1} + \frac{1}{2}T_1^{-1}$.

The real part of the last terms expresses the obvious fact that T_1 relaxation to other levels m , in a multispin or $S > \frac{1}{2}$ system, will also contribute to T_2 . However, in contrast to equation (9a), the last five terms of equation (9b) are not arranged in pairs ensuring that their sum is real. In fact, if the magnitudes of ω_{ij} , ω_{jm} or ω_{im} are greater than τ_c , the imaginary parts of these terms can be greater than the real parts, a fact that was not properly recognized in the earlier theories of weak relaxation, and was first emphasized by Paul Hubbard.¹⁵ These imaginary contributions to ' T_2 ' give rise to 'dynamic shifts' of resonances, and are reviewed in *Dynamic Frequency Shift*.

These dynamic shifts are useful for making an estimate of the size of fluctuating parts of $\hat{K}$. They can also be derived quantum mechanically as the second-order perturbation of the spin-lattice interaction, represented above semiclassically by $\hat{K}(t)$, on the spin levels.¹⁵ An important example of a dynamic shift is that of the resonance connecting the $\pm\frac{1}{2}$ levels of a quadrupolar spin, relaxed by a fluctuating electric field gradient. In this case, $\hat{K}$ does not connect these levels directly, and the first terms of equation (9b) are therefore small. The last terms are mainly imaginary provided $\omega_0\tau_c > 1$, where ω_0 is the Larmor frequency.

11 DERIVATION OF THE RELAXATION EQUATION

The general form of the terms of $\hat{R}$ is given in some of the other articles in this Encyclopedia. It is most easily derived in the time-dependent Heisenberg representation mentioned above, in which the time-average main Hamiltonian $\hat{\mathcal{H}}_0$ is transformed to zero, and each element of the perturbation $K_{ij}(t)$ is replaced by $e^{i\omega_{ij}t}K_{ij}(t)$. Lacking the perturbation $\hat{K}(t)$, each ensemble member would have a stationary wavefunction in this representation, and $\hat{\sigma}$ would be time-independent. Relaxation is treated by considering a time Δt that is somewhat larger than any correlation time τ_c , but shorter than any relaxation time. It is always possible to define

such a Δt , by the definition of weak limit relaxation, when that limit applies. One then gets an equation of motion by calculating $\hat{\sigma}(t + \Delta t) - \hat{\sigma}(t)$ using a perturbation expansion, and dividing by Δt to get $d\hat{\sigma}/dt$. The evolution of the c_i is calculated to second order in the elements of $\hat{K}$, for a member of the ensemble. Then the density matrix is formed from the c_i by using equation (4), and terms that are of first order in the $K_{ij}(t)$ vanish because the $K_{ij}(t)$ are zero in the ensemble average. The lowest nonzero terms are the second-order terms, while terms of higher than second order are assumed negligible, and are dropped. Finally, the solution outlined involves double integrals of correlation functions (multiplied by oscillating $e^{i\omega t}$ terms) with limits between t and $t + \Delta t$; these limits are extended to $\pm\infty$ because the integrands are assumed nonzero over only a short range, of the order of τ_c . The mathematics is very simple for secular elements of $\hat{R}$, and the assumptions involved are explained in detail elsewhere.^{4,15} For nonsecular terms, the situation is more complicated; the contribution to the change in $\hat{\sigma}$ for a given time is smaller than it is for secular terms, but this decrease in effectiveness appears to be entirely due to the fact that the elements of $\hat{\sigma}$ in the Schrödinger representation, connected by the elements of $\hat{R}$, have a different time variation. So it was proposed that these elements could be taken to be time-independent in the Schrödinger representation and have essentially the same form as the secular terms. This somewhat unsatisfactory reasoning seems to have withstood the test of time.

The spectral densities $J(\omega)$ of elements of $\hat{R}$ are usually smoothly varying functions that become small for $\omega\tau_c > 1$. If τ_c is small compared with the Larmor frequencies then all the J s can be replaced by their values at zero frequency, and the $\hat{R}\hat{\sigma}$ term can then be written as a pleasing double commutator of $\hat{K}$ with $\hat{\sigma}$. This operator expression is also applicable in a modified form for high-field NMR, where levels are grouped into collections having nearly the same energy.^{3,6,14} However, it is probably prudent to avoid using approximations in these operator methods for more complicated problems.

12 CONCLUSIONS

Weak relaxation theory was born with NMR, already well developed in BPP, and mature by the 25th anniversary of NMR. It achieved a new lease on life with the advent of FT NMR and, later, multidimensional methods, providing access to relaxation phenomena that were not dreamed of when the subject was developed. It is now virtually certain that computers will have a strong impact on the field, being able to predict the behavior of complex spin systems, to analyze data, and eventually to suggest better ways to obtain data, rather than relying on complicated analysis.

Experimentally, new developments will undoubtedly come from new pulse methods. An obvious general development will be the combination of pulse methods with high-speed high-resolution field cycling in some form, to map out completely the frequency dependence of spectral densities in a way that has so far been done only for the water resonance (described in *Dynamics of Water in Biological Systems: Inferences from Relaxometry*).

The theory we have described has had minor impact in other fields. Obviously, it is useful for electron paramagnetic

resonance. Theory equivalent to BPP has also been developed by Zusman and others to describe the nonadiabatic regime of electron transfer.¹⁸ Other forms of spectroscopy do not have the interesting variety of phenomena that NMR does, and such a theory is not needed.

1 INTRODUCTION

Inasmuch as three-fourths of all NMR-receptive nuclei have measurable quadrupole moments, the electric quadrupolar interaction, and its ability to effect nuclear spin relaxation, necessarily plays a central role in both the theory and practice of nuclear magnetic resonance. Furthermore, in addition to the importance on relaxing high-spin nuclei, quadrupolar interactions impact upon the relaxation features of scalar-coupled spin- $\frac{1}{2}$ nuclei.

Except for nuclei occupying molecular sites of cubic electronic symmetry, the interaction strength of the quadrupolar coupling typically is on the order of 10^6 – 10^8 s $^{-1}$, whereas comparable dipolar, spin rotation and anisotropic shielding interaction strengths are on the order of 10^4 – 10^5 s $^{-1}$. Hence, electric quadrupolar interactions usually result in extremely efficient *dissipation* of nuclear spin coherence and restoration of thermal polarization for all $I > 1$ (quadrupolar and multipolar) nuclei. However, weaker relaxation pathways, often neglected in the discussion of the relaxation of quadrupolar nuclei, are responsible for relaxation-induced polarization and coherence *transfer*.

In the context of high-resolution and multidimensional NMR, homogeneous line broadenings associated with the efficiency of quadrupolar relaxation present a number of challenging obstacles. In contrast, the general dominance of quadrupolar relaxation generally facilitates its application in the study of molecular dynamics. For applications involving spin- $\frac{1}{2}$ nuclei, it often proves difficult to isolate and identify competitive relaxation pathways. Furthermore, for spin- $\frac{1}{2}$ nuclei, inter- and intramolecular effects must be differentiated, whereas quadrupolar relaxation is purely intramolecular in nature.

Finally, from a theoretical vantage, a discussion of quadrupolar relaxation can be utilized to illustrate numerous symmetries and characteristics common to spin relaxation in any multistate system.

2 THE ELECTRIC QUADRUPOLE INTERACTION

The electric quadrupolar interaction between a nuclear spin $\hat{I}$ and a nonzero electric field gradient can be written compactly in tensor notation, $\hat{\mathcal{F}}^{QI} \propto \hat{I} \cdot \mathbf{Q} \cdot \hat{I}$. When written in this manner, the functional similarity between a quadrupolar interaction and an electron zero field splitting or a dipole–dipole coupling between equivalent nuclei is apparent. Since the coupling tensor $\mathbf{Q}$ is both symmetric and traceless, only two of the three principal components are independent. Although various conventions exist, this coupling is usually characterized by a principal value $q_{zz} \sum q_I$ and asymmetry $\eta = (q_{yy} - q_{xx})/q_{zz}$, with $|q_{zz}| > |q_{xx}| > |q_{yy}|$.

Application of the Wigner–Eckart theorem demonstrates that the quadrupolar interaction vanishes unless $I \geq 1$. Some of the more important members of the set of nuclei subject to the quadrupolar interaction are ^2H and ^{14}N ($I = 1$), ^7Li and ^{23}Na ($I = \frac{3}{2}$), ^{17}O and ^{27}Al ($I = \frac{5}{2}$), and ^{43}Ca and ^{59}Co ($I = \frac{7}{2}$).

If the electric field gradient tensor is axially symmetric ($\eta = 0$), the quadrupolar coupling can be written simply as

$$\hat{\mathcal{F}}^{QI} = \frac{e^2 q_I Q_I}{4I(2I-1)\hbar} (3\hat{I}_{z\text{mol}}^2 - \hat{I}^2) \quad (1)$$

Additional parameters appearing in equation (1) include the charge q_I and the nuclear electric quadrupole moment eQ_I . Occasionally, the quadrupolar coupling is written in terms of a gradient anisotropy $\Delta Q = \frac{3}{2}q_I = \frac{3}{2}q_{zz} = q_{zz} - \frac{1}{2}(q_{xx} + q_{yy})$. A subscript is attached to the operator $\hat{I}_z$ to emphasize that this interaction is defined in the molecular frame. In the presence of an applied external magnetic field $\mathbf{B}_0$, where $|\gamma_I B_0 \sum \omega_I| \gg |e^2 q_I Q_I / \hbar|$, the spins are effectively quantized in the laboratory frame. In all subsequent discussion, this form of the high-field approximation will be implicit. For arbitrary relative orientations of these two frames, $\hat{\mathcal{F}}^{QI}$ can be written as a scalar product of spin and spatial coordinates:

$$\hat{\mathcal{F}}^{QI} = \xi_{QI} \sum_n (-1)^n \hat{T}_Q^n(I) V_Q^{-n}(\theta, \phi) \quad (2a)$$

The spin operators are defined as

$$T_Q^{\pm 2} = \frac{\hat{I}_{\pm}^2}{I(2I-1)}, \quad \hat{T}_Q^{\pm 1} = \mp \frac{\hat{I}_{\pm}(2\hat{I}_z + 1)}{I(2I-1)} \quad (2b)$$

$$\hat{T}_Q^0 = \left(\frac{2}{3}\right)^{1/2} \frac{3\hat{I}_z^2 - \hat{I}^2}{I(2I-1)}$$

The lattice or orientation functions $V_Q^n(\theta, \phi)$ are normalized rank-2 spherical harmonics. The angular arguments position the unique axis of the diagonalized electric field gradient tensor in the laboratory frame. The interaction constant is defined as $\xi_{QI} = (\frac{3}{40}\pi)^{1/2} e^2 q_I Q_I / \hbar$.

Hence, in a rigid system such as a solid, the energy level spacings for quadrupolar nuclei depend on the molecular orientation relative to the direction of the external field. These

2 RELAXATION THEORY FOR QUADRUPOLEAR NUCLEI

levels do not vary in time, and a rigid lattice powder pattern results. However, in the presence of molecular motions, the energy levels appear time-dependent and act as a source of magnetic relaxation.

For a nonaxially symmetric field gradient, the electric quadrupolar interaction takes the form

$$\hat{\mathcal{H}}^{QI} = \frac{e^2 q_I Q_I}{4I(2I-1)\hbar} [(3\hat{I}_{z\text{mol}}^2 - \hat{I}^2) + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)] \quad (3)$$

Unfortunately, the analog of equation (2a) is cumbersome, and the separation of spin and spatial coordinates from the interaction constants proves impossible. However, it is possible to rewrite any traceless rank-2 tensor $\mathbf{Q}$ as the sum of two, axially symmetric composites:

$$\begin{bmatrix} q_{xx} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & q_{yy} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & q_{zz} \end{bmatrix} = \Delta Q^+ \begin{bmatrix} \frac{2}{3} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \end{bmatrix} + \Delta Q^- \begin{bmatrix} -\frac{1}{3} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & \frac{2}{3} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \end{bmatrix} \quad (4a)$$

where

$$\left. \begin{aligned} \Delta Q^+ &= q_{xx} - q_{zz} = -\Delta Q(1 + \frac{1}{3}\eta) \\ \Delta Q^- &= q_{yy} - q_{zz} = -\Delta Q(1 - \frac{1}{3}\eta) \\ \Delta Q &= q_{zz} - \frac{1}{2}(q_{xx} + q_{yy}) \\ \eta &= \frac{3(q_{yy} - q_{xx})}{2\Delta Q} \end{aligned} \right\} \quad (4b)$$

An important equivalence between the $(\Delta Q, \eta)$ and the $(\Delta Q^+, \Delta Q^-)$ representations is

$$\begin{aligned} & \frac{1}{2}[(q_{xx} - q_{yy})^2 + (q_{xx} - q_{zz})^2 + (q_{yy} - q_{zz})^2] \\ &= (\Delta Q)^2 (1 + \frac{1}{3}\eta^2) \\ &= (\Delta Q^+)^2 + (\Delta Q^-)^2 - (\Delta Q^+)(\Delta Q^-) \end{aligned} \quad (5)$$

The two resultant anisotropies $\Delta Q^\pm$ are axially symmetric and mutually orthogonal. This alternative description enables the separation of the interaction constants from the lattice variables as implied by equation (2a). However, with respect to relaxation considerations, these two composite interactions are temporally correlated, and this correlation must not be neglected.

3 ELECTRIC QUADRUPOLEAR RELAXATION OF ATHERMAL SPIN POLARIZATIONS

Spin-lattice or longitudinal relaxation in the $(2I + 1)$ -level system associated with a collection of isolated spin- I nuclei can be described in master equation form:¹

$$-\frac{d}{dt}P_n = \sum_{m \neq n} W_{nm}(\Delta P_m - \Delta P_n) \quad (6)$$

P_n is the population of the n th state, ΔP_n denotes the deviation of this population from the associated thermal equilibrium value, $\Delta P_n = P_n - P_n(\text{eq})$, and $W_{nm} (=W_{mn})$ is the appropriate transition probability per unit time. Because of the nature of the quadrupolar interaction, W_{nm} vanishes unless $m = n \pm 1$ or $m = n \pm 2$. Values for these two transition probabilities can be written in concise form as

$$\begin{aligned} W_{n,n-1} &= W_{-n+1,-n} \\ &= \frac{2(2n-1)^2(I-n+1)(I+n)}{I^2(2I-1)^2} J_1^Q(\omega_I) \end{aligned} \quad (7)$$

$$\begin{aligned} W_{n,n-2} &= W_{-n+2,-n} \\ &= \frac{2(I-n+2)(I-n+1)(I+n-1)(I+n)}{I^2(2I-1)^2} J_2^Q(2\omega_I) \end{aligned} \quad (8)$$

The spectral density function² for an *axially symmetric quadrupolar* coupling is defined as

$$\begin{aligned} J_k^Q(\omega) &= (4\pi)^{-1}(\xi_{QI})^2 \\ &\times \text{Re} \left[\int_0^\infty \langle Y_2^k(\theta(t), \phi(t)) Y_2^{-k}(\theta(0), \phi(0)) \rangle \right. \\ &\quad \left. \times \exp(-i\omega t) dt \right] \end{aligned} \quad (9)$$

For isotropic media ($\langle \hat{\mathcal{H}}^{QI}(t) \rangle = 0$), the k dependence of the spectral density is superfluous.³ In subsequent developments, *unless this index is explicitly shown*, the limit $J_k^Q(\omega) = J_{k'}^Q(\omega) \sum J^Q(\omega)$ is assumed.

For *isotropic, diffusional reorientation* of the molecular frame relative to the laboratory frame, equation (9) reduces to

$$J^Q(\omega) = \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} \quad (10)$$

The correlation time $\tau_2 = \frac{1}{6}D$, where D is the rotational diffusion constant.

For *symmetric-top reorientation* characterized by an axially symmetric diffusion tensor with principal components D_{zz} and $D_{xx} = D_{yy}$,

$$\begin{aligned} J^Q(\omega) &= \frac{3}{640} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \left[\frac{(3\cos^2\theta - 1)^2 \tau_{20}}{1 + (\omega\tau_{20})^2} \right. \\ &\quad \left. + \frac{12\cos^2\theta \sin^2\theta \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{3\sin^4\theta \tau_{22}}{1 + (\omega\tau_{22})^2} \right] \end{aligned} \quad (11)$$

Here θ is the angle between the principal axes of the diffusion and electric quadrupole tensors. The three correlation times are defined as $1/\tau_{2n} = 6D_{zz} + n^2(D_{zz} - D_{xx})$. In general, the molecular coordinate frames that diagonalize the diffusion and the electric field gradient tensors are not coincident.

The spectral density function, for an *asymmetric quadrupolar* coupling, assuming symmetric-top diffusional reorientation, can be described with either one of the two alternative

representations discussed earlier:

$$J^Q(\omega) = (16\pi)^{-1} \left\{ \frac{[\xi_{QIx}(3\cos^2\theta_x - 1)^2 + \xi_{QIy}(3\cos^2\theta_y - 1)]^2\tau_{20}}{1 + (\omega\tau_{20})^2} + 3(\xi_{QIx})^2 \left[\frac{4\cos^2\theta_x \sin^2\theta_x \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^4\theta_x \tau_{22}}{1 + (\omega\tau_{22})^2} \right] + 3(\xi_{QIy})^2 \left[\frac{4\cos^2\theta_y \sin^2\theta_y \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^4\theta_y \tau_{22}}{1 + (\omega\tau_{22})^2} \right] + 6\xi_{QIx}\xi_{QIy} \left[\frac{4\cos\theta_x \cos\theta_y \sin\theta_x \sin\theta_y \cos(\phi_x - \phi_y)\tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^2\theta_x \sin^2\theta_y \cos(2\phi_x - 2\phi_y)\tau_{22}}{1 + (\omega\tau_{22})^2} \right] \right\} \quad (12)$$

or

$$J^Q(\omega) = \frac{3}{640} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \left\{ \frac{(3\cos^2\theta - 1 - \eta \sin^2\theta \cos 2\phi)^2 \tau_{20}}{1 + (\omega\tau_{20})^2} + [12\sin^2\theta [\cos^2\theta (1 + 2\eta \cos 2\phi) + (\frac{1}{3}\eta)^2 (1 - \cos^2 2\phi \sin^2\theta)] \tau_{21}] [1 + (\omega\tau_{21})^2]^{-1} + [3\sin^4\theta - 2\eta \sin^2\theta (\cos^2\theta + 1) \cos 2\phi + \frac{1}{3}\eta^2 (\cos^2 2\phi \sin^4\theta + 4\cos^2\theta)] \frac{\tau_{22}}{1 + (\omega\tau_{22})^2} \right\} \quad (13)$$

The parameters ξ_{QIx} and ξ_{QIy} are defined as $(q_{xx} - q_{zz})(\frac{1}{30}\pi)^{1/2} e^2 Q_I / \hbar$ and $(q_{yy} - q_{zz})(\frac{1}{30}\pi)^{1/2} e^2 Q_I / \hbar$, respectively. Utilizing equation (5), it can be seen that for isotropic reorientation, equation (12) or equation (13) reduces to

$$J^Q(\omega) = (1 + \frac{1}{3}\eta^2) \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} = [(q_{xx} - q_{yy})^2 + (q_{xx} - q_{zz})^2 + (q_{yy} - q_{zz})^2] \times \frac{1}{240} \left(\frac{e^2 Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} \quad (14)$$

Although equation (6) implies that the spin-lattice relaxation is described by $2I + 1$ coupled equations, transformation to an appropriate operator basis, which results in both a conceptual and mathematical simplification, proves otherwise. Using the irreducible spherical tensor basis consisting of the operators

$$\left. \begin{aligned} \hat{T}_1^0 &\propto \langle \hat{I}_z \rangle \\ \hat{T}_2^0 &\propto \langle 3\hat{I}_z^2 - \hat{I}^2 \rangle \\ \hat{T}_3^0 &\propto \langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1) \rangle \\ \hat{T}_4^0 &\propto \langle 35\hat{I}_z^4 - 5\hat{I}_z^2(6\hat{I}^2 - 5) + 3\hat{I}^2(\hat{I}^2 - 2) \rangle \\ \hat{T}_5^0 &\propto \langle 63\hat{I}_z^5 - 35\hat{I}_z^3(2\hat{I}^2 - 3) + (15\hat{I}^4 - 50\hat{I}^2 + 12)\hat{I}_z \rangle \\ \hat{T}_6^0 &\propto \langle 231\hat{I}_z^6 - 105\hat{I}_z^4(3\hat{I}^2 - 7) + 21\hat{I}_z^2(5\hat{I}^4 - 25\hat{I}^2 + 14) \\ &\quad - 5(\hat{I}^6 - 8\hat{I}^4 + 12\hat{I}^2) \rangle \\ &\vdots \end{aligned} \right\} \quad (15)$$

the longitudinal relaxation is described by the concise expression

$$-\frac{d}{dt} \hat{T}_L^0 = \sum_{L'} R_{L,L'}^{0,I} (\Delta \hat{T}_{L'}^0) \quad (16)$$

If extreme narrowing [$J_k^Q(0) = J_k^Q(\omega_0) = J_k^Q(2\omega_0) \sum J_k^Q$] and spatial isotropy [$J_k^Q(\omega) = J_k^Q(\omega_0)$] obtain then⁴

$$R_{L,L'}^{0,I} = \delta_{L,L'} \{2L(L+1)[4I(I+1) - L(L+1) - 1](2I^2 - I)^{-2}\} J^Q \quad (17)$$

For various situations of practical importance, the spectral density J^Q is given by equations (10)–(13). Table 1 provides a listing of $R_{L,L'}^{0,I} J^Q$ for various ranks L and spins I .

If conditions of extreme narrowing and spatial isotropy are not realized, additional couplings of the form $R_{L,L'}^{0,I} = \delta_{LL\pm 2} C_{L,L\mp 2}^{0,I} [J_1^Q(\omega_I) - J_2^Q(2\omega_I)]$ arise. Specific values of the proportionality constant $C_{L,L\mp 2}^{0,I}$ for various spins I and ranks L can be found in the literature.^{5,6} Thus, monoexponential relaxation of the Zeeman magnetization ($\propto \hat{T}_1^0$) quantified by a well-defined spin-lattice relaxation rate $R_{11}^{0,I} = 1/T_1$ occurs for arbitrary I if and only if extreme narrowing and spatial isotropy obtain. In this limit, $1/T_1 = 4(2I+3)(2I^3 - I^2)^{-1} J^Q$.

The parity of each member of the operator basis introduced in equation (15) with respect to spin inversion is defined by

$$\exp(-i\pi \hat{I}_y) \hat{T}_L^0 \exp(+i\pi \hat{I}_y) = (-1)^L \hat{T}_L^0 \quad (18)$$

Relaxation effected via the quadrupolar interaction does not couple operators of different parity.⁷ If I is an integer then $\hat{T}_1^0$ couples into $I - 1$ additional polarizations of similar parity. An additional manifold comprising I polarizations, including ‘quadrupolar order’ ($\hat{T}_2^0$), also couple together. These latter polarizations are consequential only in anisotropic environments, where residual quadrupolar couplings lift the spectral degeneracy of various transitions. Similarly, if I is a half-integer then $\hat{T}_1^0$ couples into $\frac{1}{2}(2I+1)$ additional polarizations of similar parity. The remaining $\frac{1}{2}(2I-1)$ polarizations of opposite parity also couple together. Obviously, if $I = 1$ then there is monoexponential relaxation of the Zeeman polarization $\hat{T}_1^0$, characterized by the relaxation rate

$$R_{1,1}^{0,1} = 1/T_1 = 4[J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \quad (19)$$

and quadrupolar order, characterized by the relaxation rate

$$R_{2,2}^{0,1} = 12J_1^Q(\omega_I) \quad (20)$$

regardless of whether or not extreme narrowing obtains.

Although the relaxation characteristics of $I = 1$ are exceptionally simple, the behavior of $I = \frac{3}{2}$ is only slightly more complex.⁸ Quadrupolar polarization or alignment decays exponentially with rate

$$R_{2,2}^{0,3/2} = \frac{16}{3} [J_1^Q(\omega_I) + J_2^Q(2\omega_I)] \quad (21)$$

Zeeman and octupolar ($\hat{T}_3^0$) order each evolve biexponentially. For an initial spin preparation (perturbation) that only disturbs Zeeman order, it can be shown that

$$\left. \begin{aligned} \frac{\Delta \langle \hat{I}_z(t) \rangle}{\Delta \langle \hat{I}_z(0) \rangle} &= \frac{1}{5} \exp[-\frac{16}{3} t J_1^Q(\omega_I)] \\ &\quad + \frac{4}{5} \exp[-\frac{16}{3} t J_2^Q(2\omega_I)] \\ \frac{\langle \hat{I}_z(0) \rangle - \langle \hat{I}_z(t \rightarrow 0) \rangle}{\Delta \langle \hat{I}_z(0) \rangle} &\approx R_{1,1}^{0,3/2} t \\ &= \frac{16}{15} t [J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (22)$$

4 RELAXATION THEORY FOR QUADRUPOLEAR NUCLEI

$L = 8$							$\frac{9}{7}J^Q$	$\frac{26}{9}J^Q$
$L = 9$								$\frac{10}{9}J^Q$

$$\left. \begin{aligned} \frac{\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1)(t) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} &= \frac{6}{5} \{ \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \\ &\quad - \exp[-\frac{16}{3}tJ_2^Q(2\omega_I)] \} \\ \frac{\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1)(t \rightarrow 0) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} &\approx -R_{3,1}^{0,3/2}t \\ &= -\frac{32}{5}t[J_1^Q(\omega_I) - J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (23)$$

For spin $I = \frac{3}{2}$, it is illustrative to define two fictitious spin operators,⁹ $\langle \hat{I}_z^b \rangle = \frac{3}{2}[(P_{3/2} - P_{1/2}) + (P_{-1/2} - P_{-3/2})]$ and $\langle \hat{I}_z^n \rangle = 2(P_{1/2} - P_{-1/2})$. Thus, $\langle \hat{I}_z \rangle = \langle \hat{I}_z^b \rangle + \langle \hat{I}_z^n \rangle$ and $\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1) \rangle = \langle \hat{I}_z^b \rangle - \frac{3}{2}\langle \hat{I}_z^n \rangle$. These identifications permit the following transformation of the kinetic equations for $I = \frac{3}{2}$:

$$\frac{5}{2} \frac{\langle \hat{I}_z^b(t) \rangle - \frac{3}{5}\langle \hat{I}_z^b(\text{eq}) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} = 2 \exp[-\frac{16}{3}tJ_2^Q(2\omega_I)] - \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \quad (24)$$

$$\frac{5}{3} \frac{\langle \hat{I}_z^n(t) \rangle - \frac{3}{5}\langle \hat{I}_z^n(\text{eq}) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} = \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \quad (25)$$

For $I = \frac{3}{2}$, one has the highly unusual situation where a specific population difference ($P_{3/2} - P_{1/2}$ or $P_{-1/2} - P_{-3/2}$) is characterized by simple exponential relaxation. Furthermore, if $J_2^Q(2\omega_I) < \frac{1}{2}J_1^Q(\omega_I)$, the deviation population difference $\Delta(P_{1/2} - P_{-1/2})$ initially grows rather than decays!

Although integrated forms of equation (16) cannot be written in tractable form, for higher spin nuclei, the *initial* response to any perturbation of $\hat{I}_z$ is always described by

$$\frac{\langle \hat{I}_z(0) \rangle - \langle \hat{I}_z(t \rightarrow 0) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} \approx R_{1,1}^{0,I}t \quad (26)$$

where

$$R_{1,1}^{0,I} = 1/T_1 = \frac{4}{5}(2I+3)I^{-2}(2I-1)^{-1}[J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \quad (27)$$

4 ELECTRIC QUADRUPOLEAR RELAXATION OF NUCLEAR SPIN COHERENCE

Because of the efficiency of the quadrupolar interaction in effecting nuclear spin relaxation, usually inhomogeneous

line broadening can be assumed negligible, and spin-spin or transverse relaxation rates can be abstracted directly from measurement of linewidths.

In addition to the aforementioned $2I + 1$ populations, a collection of isolated spin- I nuclei is characterized by $2I$ single quantum coherences (1QCs), $2I - 1$ double quantum coherences (2QCs), ..., two $(2I - 1)$ QCs and one $(2I)$ QC. At thermal equilibrium, all coherence vanishes. Generalized 'spin-spin' relaxation in a multilevel system can be described in a manner analogous to equation (6):

$$\begin{aligned} -\frac{d}{dt}\chi_{nn'} &= i(\omega_{nn'} + \Omega_{nn'})\chi_{nn'} \\ &\quad + \left[Z_{nn'} + \frac{1}{2} \sum_j (W_{nj} + W_{n'j}) \right] \chi_{nn'} \\ &\quad + \sum_{m,m'} \delta(\omega_{nn'} - \omega_{mm'}) (W_{nm} W_{n'm'})^{1/2} \chi_{mm'} \end{aligned} \quad (28)$$

In the absence of applied rf fields, the evolution of coherence between states $|n\rangle$ and $|n'\rangle$, $\chi_{nn'}$, is characterized by an intrinsic frequency $\omega_{nn'}$, a dynamic frequency shift, $\Omega_{nn'}$, an adiabatic term or zero frequency contribution $Z_{nn'}$, lifetime terms $W_{nn'}$, which were defined earlier, and a secular coupling term $(W_{nm} W_{n'm'})^{1/2}$, which vanishes unless the coherences $\chi_{nn'}$ and $\chi_{mm'}$ are degenerate or overlapping (the secular approximation). The validity of equation (28) is restricted to the motionally narrowed, perturbative regime, $1/\tau_2 \gg Z_{nn'}, |\hat{\mathcal{F}}^{QI}|$.

In the absence of multiplet structure attributed to a residual quadrupolar interaction, each set of $2I + 1 - n$, n QCs are degenerate. With the additional stipulation of extreme narrowing, the perturbation-response characteristics of these coherences are remarkably simple. Once again, this is revealed by transformation to an irreducible spherical tensor operator basis:

$$\left. \begin{aligned} \hat{T}_1^{\pm 1} &\propto \langle \hat{I}_{\pm} \rangle \\ \hat{T}_2^{\pm 1} &\propto \langle \hat{I}_{\pm}(2\hat{I}_z \pm 1) \rangle \\ \hat{T}_2^{\pm 2} &\propto \langle \hat{I}_{\pm}^2 \rangle \\ \hat{T}_3^{\pm 1} &\propto \langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z + (2 - \hat{I}^2)] \rangle \\ \hat{T}_3^{\pm 2} &\propto \langle \hat{I}_{\pm}^2(\hat{I}_z \pm 1) \rangle \\ \hat{T}_3^{\pm 3} &\propto \langle \hat{I}_{\pm}^3 \rangle \\ &\vdots \\ \hat{T}_{2I}^{\pm(2I-1)} &\propto \langle \hat{I}_{\pm}^{(2I-1)}[2\hat{I}_z \pm (2I-1)] \rangle \\ \hat{T}_{2I}^{\pm 2I} &\propto \langle \hat{I}_{\pm}^{2I} \rangle \end{aligned} \right\} \quad (29)$$

The relaxation behavior of these coherences can be cast in a form identical to equation (16):

$$-\frac{d}{dt}\hat{T}_L^{\pm k} = \pm ik\omega_I + \sum_{L'} R_{L,L'}^{k,I} \hat{T}_L^{\pm k} \quad (30)$$

For the moment, the dynamic frequency shift is ignored.

The validity of the secular approximation ensures that only coherences of similar precessional frequency couple together. In the limit of extreme narrowing,

$$R_{L,L'}^{k,I} = R_{L,L'}^{0,I} = \delta_{LL'} [2L(L+1) \times [4I(I+1) - L(L+1) - 1](2I^2 - I)^{-2}] J^Q \quad (31)$$

When extreme narrowing fails, additional couplings of the form $R_{L,L'}^{k,I} = \delta_{LL\pm 2} \sum_{n=0}^2 C_{L,L\mp 2}^{k,n,I} J_n^Q(n\omega_I)$ arise. Selected values of $C_{L,L\mp 2}^{1,n,I}$ for various spins I and ranks L can be found in the literature.⁶ Again, monoexponential relaxation of single quantum coherence or ‘transverse’ magnetization ($\propto \hat{T}_1^{\pm 1}$), quantified by a well-defined spin–spin relaxation rate $R_{1,1}^{1,I} = 1/T_2$, results for arbitrary I if and only if extreme narrowing obtains: $1/T_2 = 1/T_1 = 4(2I+3)(2I^3 - I^2)^{-1} J^Q$.

However, there are other interesting decay rates that can be expressed in closed analytic form. For example, the dissipation of $(2I)QC$ ($\hat{T}_{2I}^{2I}$) and in-phase ($\hat{T}_{2I-1}^{2I-1}$) and antiphase ($\hat{T}_{2I}^{2I-1}$) $2I - 1$ multiple quantum coherences are determined by the respective rates

$$R_{2I,2I}^{2I,I} = (4I^{-1})J_1^Q(\omega_I) + 8I^{-1}(2I-1)^{-1}J_2^Q(2\omega_I) \quad (32)$$

$$R_{2I-1,2I-1}^{2I-1,I} = 2I^{-2}(2I-1)^{-1}\{3(2I-1)J_0^Q(0) + [4I(2I-1) + (2I-3)^2]J_1^Q(\omega_I) + 2(4I-3)J_2^Q(2\omega_I)\} \quad (33)$$

$$R_{2I,2I}^{2I-1,I} = 2I^{-2}(2I-1)^{-1}\{3(2I-1)J_0^Q(0) + (2I-3)^2J_1^Q(\omega_I) + 2(4I-3)J_2^Q(2\omega_I)\} \quad (34)$$

These expressions demonstrate that for $I = 1$, not only do Zeeman and quadrupolar polarizations relax exponentially, so do both forms of single quantum coherence and the unique double quantum coherence:

$$R_{2,2}^{1,1} = 2[3J_0^Q(0) + J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (35)$$

$$R_{1,1}^{1,1} = 1/T_2 = 2[3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (36)$$

$$R_{2,2}^{2,1} = 4J_1^Q(\omega_I) + 8J_2^Q(2\omega_I) \quad (37)$$

Equations (19), (20), and (35)–(37) summarize completely the relaxation characteristics for $I = 1$. Similarly, the description for $I = \frac{3}{2}$, initiated with equations (21)–(25), can now be completed. For $I = \frac{3}{2}$, forms of spin order associated with $\hat{T}_3^{\pm 3}$, $\hat{T}_3^{\pm 2}$, $\hat{T}_2^{\pm 2}$, and $\hat{T}_2^{\pm 1}$ dissipate in time exponentially with the following relaxation rates:

$$R_{3,3}^{3,3/2} = \frac{8}{3}J_1^Q(\omega_I) + \frac{8}{3}J_2^Q(2\omega_I) \quad (38)$$

$$R_{3,3}^{2,3/2} = \frac{8}{3}J_0^Q(0) + \frac{8}{3}J_2^Q(2\omega_I) \quad (39)$$

$$R_{2,2}^{2,3/2} = \frac{8}{3}J_0^Q(0) + \frac{16}{3}J_1^Q(\omega_I) + \frac{8}{3}J_2^Q(2\omega_I) \quad (40)$$

$$R_{2,2}^{1,3/2} = \frac{8}{3}J_0^Q(0) + \frac{8}{3}J_1^Q(\omega_I) + \frac{16}{3}J_2^Q(2\omega_I) \quad (41)$$

In-phase and doubly antiphase $1QC$, $\hat{T}_1^{\pm 1}$ and $\hat{T}_3^{\pm 1}$, couple together, and each evolves biexponentially. For an initial spin preparation (perturbation) that selectively disturbs one-spin order, $\langle \hat{I}_{\pm}(0) \rangle \neq 0$, it can be shown that

$$\left. \begin{aligned} \frac{\langle \hat{I}_{\pm}(t) \rangle}{\langle \hat{I}_{\pm}(0) \rangle} &= \frac{1}{3} \exp[-\frac{8}{3}tJ_1^Q(\omega_I)] \\ &\times \{3 \exp[-\frac{8}{3}tJ_0^Q(0)] + 2 \exp[-\frac{8}{3}tJ_2^Q(2\omega_I)]\} \\ - \frac{\langle I_{\pm}(t \rightarrow 0) \rangle - \langle \hat{I}_{\pm}(0) \rangle}{\langle \hat{I}_{\pm}(0) \rangle t} &\approx R_{1,1}^{1,3/2} = 1/T_2 \\ &= \frac{8}{15}[3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (42)$$

$$\left. \begin{aligned} \frac{\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)](t) \rangle}{\langle \hat{I}_{\pm}(0) \rangle} &= \frac{6}{5} \exp[-\frac{8}{3}tJ_1^Q(\omega_I)] \{ \exp[-\frac{8}{3}tJ_0^Q(0)] \\ &- \exp[-\frac{8}{3}tJ_2^Q(2\omega_I)] \} \\ - \frac{\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)](t \rightarrow 0) \rangle}{\langle \hat{I}_{\pm}(0) \rangle t} &\approx R_{3,1}^{1,3/2} \\ &= \frac{16}{5}[J_0^Q(0) - J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (43)$$

Introducing two fictitious spin operators $\langle \hat{I}_{\pm}^b \rangle = \sqrt{3}$ ($\chi_{3/2, 1/2} + \chi_{-1/2, -3/2}$) and $\langle \hat{I}_{\pm}^n \rangle = 2\chi_{1/2, -1/2}$ {with $\langle \hat{I}_{\pm} \rangle = \langle \hat{I}_{\pm}^b \rangle + \langle \hat{I}_{\pm}^n \rangle$ and $\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)] \rangle$ } results in the following transformation of the kinetic equations for $I = \frac{3}{2}$:

$$\frac{5}{2} \frac{\langle \hat{I}_{\pm}^b(t) \rangle}{\langle \hat{I}_{\pm}^b(0) \rangle} = \exp[-\frac{8}{3}tJ_2^Q(2\omega_I) - \frac{8}{3}tJ_1^Q(\omega_I)] \quad (44)$$

$$\frac{5}{3} \frac{\langle \hat{I}_{\pm}^n(t) \rangle}{\langle \hat{I}_{\pm}^n(0) \rangle} = \exp[-\frac{8}{3}tJ_0^Q(0) - \frac{8}{3}tJ_1^Q(\omega_I)] \quad (45)$$

For $I = \frac{3}{2}$ both of the coherences $\langle \hat{I}_{\pm}^b \rangle$ and $\langle \hat{I}_{\pm}^n \rangle$ are characterized by simple exponential relaxation. This representation clearly illustrates one of the most interesting and useful feature of electric quadrupolar relaxation. The decay of coherence between the states $|\frac{1}{2}\rangle$ and $|- \frac{1}{2}\rangle$ is determined by a rate free from adiabatic contributions.

In numerous practical situations, a partially averaged quadrupole coupling of residual amplitude $\langle \hat{\mathcal{F}}^{QI}(t) \rangle = \omega_Q (3\hat{I}_z^2 - \hat{I}^2)$ removes spectral degeneracies and eliminates all secular couplings from equation (28). In this limit, the free decay of nQC between states $|m\rangle$ and $|m-n\rangle$ is characterized by a unique, well-defined relaxation rate, which can be written in closed form as

$$\begin{aligned} (1/T_2)_{m,m-n} &= [I(2I-1)]^{-2} \{ [6n^2(2m-n)^2]J_0^Q(0) \\ &+ [4(4m^2+1)[I(I+1)-m^2]-16m^2 \\ &- 2n(2m-n)[4I(I+1)-8m^2-5 \\ &+ 4n(2m-n)]J_1^Q(\omega_I) \\ &+ [4(I^2-m^2-1)[I(I+2)-m^2]+16m^2 \\ &+ 2n(2m-n)[2I(I+1)-2m^2-5 \\ &+ n(2m-n)]J_2^Q(2\omega_I) \} \end{aligned} \quad (46)$$

Once again, it is emphasized that the coherence between states $|m\rangle$ and $|-m\rangle$ has no adiabatic $[J_0^Q(0)]$ contribution. In the slow motion limit $[\omega_0\tau_2 \gg 1]$, or, equivalently, $J_0^Q(0) \gg J_1^Q(\omega_I), J_2^Q(2\omega_I)$, all transitions except the $|m\rangle \leftrightarrow |-m\rangle$ n -quantum transition are dramatically broadened leaving behind a solitary, narrowed component, which contributes a fractional intensity

$$\left[\prod_{i=1}^{n+1} (2i-1) \right] \left[\prod_{i=1}^n (2I+2i-n) \right] \left[\prod_{i=1}^n (2i) \right]^{-1} \left[\prod_{i=1}^{n+1} (2I+2i-n-1) \right]^{-1} \quad (47)$$

to the overall intensity of the n QC. For half-integral spin, the 1QC is the transition that attracts most interest. The relaxation rate for this unique 1QC is defined as

$$(1/T_2)_{1/2,-1/2} = (2I+3)I^{-2}(2I-1)^{-1} \{ 2J_1^Q(\omega_I) + [(I+\frac{3}{2})(I-\frac{1}{2})-1]J_2^Q(2\omega_I) \} \quad (48)$$

Equation (48) is more general than suggested, and obtains in isotropic media for those situations where $J^Q(0)$ dominates, thereby quenching the secular coupling. Equations (46) and (48) assume that $J_k^Q(k\omega_I \pm 3k(2I-k)\omega_Q) = J_k^Q(k\omega_I)$. In the unlikely situation where this assumption fails, equation (46) becomes much more complex. For example, the specific relaxation rate $(1/T_2)_{1/2,-1/2}$ is given by

$$\begin{aligned} (1/T_2)_{1/2,-1/2} = [I(2I-1)]^{-2} \{ & [4I(I+1)-3][J_1^Q(\omega_I+6\omega_Q) \\ & + J_1^Q(\omega_I-6\omega_Q)] \\ & + (I+\frac{3}{2})(I-\frac{1}{2})[(I-\frac{3}{2})(I+\frac{5}{2}) \\ & \times [J_2^Q(2\omega_I+18\omega_Q) + J_2^Q(2\omega_I-18\omega_Q)] \\ & + (I+\frac{1}{2})^2[J_2^Q(2\omega_I+6\omega_Q) + J_2^Q(2\omega_I-6\omega_Q)]] \} \quad (49) \end{aligned}$$

5 ELECTRIC QUADRUPOLEAR RELAXATION IN THE ROTATING FRAME

The preceding sections have summarized nuclear spin relaxation induced by the electric quadrupolar interaction in the absence of applied rf fields. However, sometimes it is advantageous and more informative to perform relaxation studies in the presence of a resonant or ‘spin locking’ field. The resultant measurement of relaxation in ‘the rotating frame’, provides the researcher with the opportunity to examine certain spectral densities while selectively suppressing other contributions.

It has been shown that expressions for rotating frame relaxation can be obtained very simply by replacing spectral density functions in the laboratory frame by new linear combinations of spectral density functions J_{kp}^Q .¹⁰ If it is assumed that a spin lock field of amplitude B_{sl} ($\gamma I B_{sl} = \omega_{sl} \ll \omega_I/\gamma_I$) is applied on resonance then

$$J_{0\rho}^Q(0) = \frac{1}{4}J_0^Q(0) + \frac{3}{4}J_2^Q(2\omega_I) \quad (50)$$

$$J_{1\rho}^Q(\omega_I) = \frac{1}{2}J_1^Q(\omega_I) + \frac{1}{2}J_2^Q(2\omega_I) \quad (51)$$

$$J_{2\rho}^Q(2\omega_I) = \frac{3}{8}J_0^Q(2\omega_{sl}) + \frac{1}{2}J_1^Q(\omega_I) + \frac{1}{8}J_2^Q(2\omega_I) \quad (52)$$

Thus, equation (27) becomes

$$R_{1,1}^{0,I\rho} = 1/T_{1\rho} = \frac{2}{5}(2I+3)I^{-2}(2I-1)^{-1} \times [3J_0^Q(2\omega_{sl}) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (53)$$

and the analogous expression for $R_{1,1}^{1,I}$,

$$R_{1,1}^{1,I} = 1/T_2 = \frac{2}{5}(2I+3)I^{-2}(2I-1)^{-1} \times [3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (54)$$

reduces to

$$\begin{aligned} R_{1,1}^{1,I\rho} = 1/T_{2\rho} = \frac{1}{10}(2I+3)I^{-2}(2I-1)^{-1} \\ \times [3J_0^Q(2\omega_{sl}) + 3J_0^Q(0) \\ + 14J_1^Q(\omega_I) + 20J_2^Q(2\omega_I)] \quad (55) \end{aligned}$$

All expressions previously introduced can be transcribed in a similar fashion.

6 THE ELECTRIC QUADRUPOLEAR INTERACTION AND DYNAMIC FREQUENCY SHIFTS

The dynamic frequency shift is associated with the imaginary part of the spectral density function introduced in equation (9):

$$\begin{aligned} L_k^Q(\omega) = (\xi_{QI})^2 \text{Im} \left[\int_0^\infty \langle Y_2^k(\theta(t), \phi(t)) Y_2^{-k}(\theta(0), \phi(0)) \rangle \right. \\ \left. \times \exp(-i\omega t) dt \right] \quad (56) \end{aligned}$$

For isotropic, diffusional reorientation of the molecular frame relative to the laboratory frame, equation (56) reduces to

$$L^Q(\omega) = \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\omega \tau_2^2}{1 + \omega^2 \tau_2^2} = \omega \tau_2 J^Q(\omega) \quad (57)$$

Because the dynamic frequency shift is negligible in extreme narrowing and has no adiabatic component, often this term is dismissed. However, it has been shown previously that the relaxations of numerous coherences also have no adiabatic contribution, and, in the slow motion regime, the dynamic shift can be a dominating effect.¹¹ The maximum dynamic frequency shift is on the order of $|\hat{\mathcal{F}}^{QI}|^2/\omega_I$ and can easily exceed several kilohertz.

To illustrate the effect of the dynamic shift, consider the coherence between states $|m\rangle$ and $|m-n\rangle$ in the limit where each transition is well resolved. The dynamic frequency shift of this coherence is described by the expression

$$\begin{aligned} \Omega_{m,m-n} = 2n[I(2I-1)]^{-2} \{ [-4I(I+1) + 24m(m-n) \\ + 8n^2 + 1]L_1^Q(\omega_I) + [4I(I+1) - 12m(m-n) \\ - 4n^2 - 2]L_2^Q(2\omega_I) \} \quad (58) \end{aligned}$$

Of special importance are expressions for those coherences where the adiabatic contribution to the linewidth vanishes:

$$\begin{aligned} \Omega_{m,-m} = 4m[I(2I-1)]^{-2} \{ [-4I(I+1) + 8m^2 + 1]L_1^Q(\omega_I) \\ + [4I(I+1) - 4m^2 - 2]L_2^Q(2\omega_I) \} \quad (59) \end{aligned}$$

The relative shift of any two components of the n QC is given by the expression

$$\Omega_{m,m-n} - \Omega_{m',m'-n} = 24n[I(2I-1)]^{-2}(m-m')(m+m'-n) \times [2L_1^Q(\omega_I) - L_2^Q(2\omega_I)] \quad (60)$$

Except for the case where $m = I$ and $n = 2I$, equation (58) differs dramatically from equation (46). Consequently, there is no simple relationship between the dynamic shift and linewidth (relaxation rate) for any given spectral component.

The effects of the dynamic frequency shift on the various forms of spin order, $\hat{T}_L^{\pm k}$, can be written in a manner analogous to equation (30):

$$-\frac{d}{dt}\hat{T}_L^{\pm k} = \sum_{L'} S_{L,L'}^{k,I} \hat{T}_{L'}^{\pm k} \quad (61)$$

Like other relaxation parameters introduced previously, $S_{L,L'}^{k,I}$ vanishes unless $L = L'$, $L' \pm 2$. In extreme narrowing, the term $S_{1,3}^{1,I}$ is proportional to $2L_1^Q(\omega_I) - L_2^Q(2\omega_I)$ and scales as $(\omega_I\tau_2)^3 J^Q(\omega_I)$, thus ensuring the insignificance of the dynamic frequency shift in this limit. The intrinsic shift of the transverse 'magnetization', $S_{1,1}^{1,I}$, can be written as

$$S_{1,1}^{1,I} = -\frac{2}{3}(2I+3)I^{-2}(2I-1)^{-1}[L_1^Q(\omega_I) + 2L_2^Q(2\omega_I)] \quad (62)$$

Figure 1 summarizes the frequency dependence of the various relaxation rates introduced thus far. Rates applicable for $I = 1$ are shown explicitly. Note that the second-order dynamic frequency shift associated with the 2QC exceeds the relaxation rate in the slow motion limit ($\omega_I\tau_2 \gg 1$).

Figure 1 A plot of the various quadrupolar relaxation rates for an $I = 1$ nuclear spin versus isotropic rotational correlation time, measured in units of the reciprocal Larmor frequency. Conventional rates, $1/T_1$, $1/T_2$ ($= 1/T_{1\rho}$ in the limit shown), and $1/T_{2\rho}$ are represented by the heavy full curves. Rates associated with relaxation of the three forms of two-spin order are shown as lighter full curves. The dynamic frequency shift of the double quantum coherence is shown as a dotted curve

7 EFFECTS OF ALTERNATIVE SOURCES OF RELAXATION FOR QUADROPOLAR NUCLEI

Although $I \geq 1$ nuclei generally are driven towards equilibrium by electric quadrupolar relaxation, other sources of relaxation play important roles in relaxation-induced polarization and coherence transfer.¹² For example, as resonance experiments are performed at higher and higher magnetic field strengths, anisotropic shielding will continue to play an increasingly important role in magnetic relaxation of quadrupolar nuclei.

Utilizing the spin operators and notation introduced earlier, the relaxation of a nuclear spin I by an axially symmetric anisotropic shielding ($\Delta\sigma = \sigma_{zz} - \sigma_{xx} = \sigma_{zz} - \sigma_{yy}$) is described by the concise, general expression:

$$R_{L,L'}^{k,I} = R_{L,L'}^{k,I'} = \delta_{LL'} \{2L(L+1)J_1^{\text{SA}}(\omega_I) + k^2 [\frac{8}{3}J_0^{\text{SA}}(0) - 2J_1^{\text{SA}}(\omega_I)]\} \quad (63)$$

For isotropic reorientation,

$$J^{\text{SA}}(\omega) = \frac{1}{30} \frac{(\gamma_I B_0 \Delta\sigma_I)^2 \tau_2}{1 + \omega^2 \tau_2^2} \quad (64)$$

This expression, when compared with equation (31), indicates that higher forms of spin order are relaxed with increasing efficiency by shielding anisotropy.

Of special interest are the adiabatic contributions, which dominate the decay of coherence when extreme narrowing fails. In the limit where residual couplings result in well-resolved structure, the adiabatic contribution associated with the coherence between states $|m\rangle$ and $|m-n\rangle$ is simply $\frac{8}{3}n^2 J_0^{\text{SA}}(0)$. This result is independent of I or m , and only depends on the coherence order n . Meanwhile, the quadrupolar adiabatic contribution, given by equation (46), is $[I(2I-1)]^{-2}6n^2(2m-n)^2 J_0^Q(0)$. Once again, it is noted that this contribution vanishes when $n = 2m$. It should be clear that there are numerous situations where the electric quadrupolar contribution will be selectively suppressed and the relaxation characteristics of high-spin nuclei can be determined by alternative, intrinsically less efficient, relaxation pathways.

The preceding arguments implicitly presume that relaxation rates for quadrupolar and anisotropic shieldings are additive. Since both interactions are molecule-fixed and transform identically under molecular reorientation, these interactions are temporally correlated, and interference effects between these interactions must be considered. The contribution of this interference to the adiabatic portion of $(1/T_2)_{m,m-n}$ is given by the expression

$$(1/T_2)_{m,m-n}^{\text{adiabatic}} = \frac{1}{5}\zeta n^2(2m-n)(2I^2 - I)^{-1} \times (e^2 q_I Q_I / \hbar) \gamma_I B_0 \Delta\sigma_I \tau_2 \quad (65)$$

where ζ is the relevant correlation factor. Unlike other relaxation parameters mentioned thus far, this interference distinguishes between the decay rates of the spin-inverted coherences, $\chi_{m'}$ and $\chi_{-n'-n}$.

To illustrate the significance of equation (65), consider the situation where the unique axis of the quadrupole and anisotropic shielding interactions are coincident ($\zeta = 1$) and the slow motion limit obtains. Assuming the quadrupole interaction is significantly stronger than the anisotropic

shielding interaction, the differential linebroadening can be written as

$$\frac{(1/T_2)_{m,m-n} - (1/T_2)_{-m,n-m}}{(1/T_2)_{m,m-n} + (1/T_2)_{-m,n-m}} = \frac{\frac{16}{9}I(2I-1)(2m-n)\xi}{[\frac{8}{9}I(2I-1)\xi]^2 + (2m-n)^2} \approx \frac{16I(2I-1)}{9(2m-n)}\xi \quad (66)$$

where $\xi = \gamma_I B_0 \Delta\sigma_I / (e^2 q_I Q_I / \hbar)$. For example, if $I = \frac{5}{2}$, the asymmetry in the relaxation rates (linewidths) of the two 1QCs, $\chi_{3/2,1/2}$ and $\chi_{-1/2,-3/2}$, is $\frac{80}{9}\xi$. Assuming that ξ^{-1} is on the order of 100, the anisotropic shielding interaction is 1000 times less effective than the quadrupolar interaction at relaxing 1QC directly [$\frac{8}{3}J_0^{SA}(0) : \frac{6}{25}J_0^Q(0)$]. However, this same set of parameters will result in a 10% relaxation asymmetry between these two components!

Another source of relaxation that may play an increasingly important role in the relaxation of quadrupolar nuclei is the electron–nuclear anisotropic hyperfine interaction. Although the hyperfine interaction can effect nuclear spin relaxation in numerous ways, in this discussion, only relaxation effects attributed to the coupling of a nuclear spin to the thermal average of electron spin, $\langle \hat{S}_z(\text{eq}) \rangle = g_e \beta S(S+1)B_0/3kT$, modulated by molecular reorientation, are considered. In appropriate limits, this interaction, which is formally equivalent to an anisotropic shielding, results in ‘Curie’ relaxation of nuclear spin.¹³ The effect of ‘Curie’ relaxation on the various spin operators introduced earlier can be summarized by the expression

$$R_{L,L'}^{k,I} = R_{L,L'}^{k,I'} = \delta_{L,L'} \{ 2L(L+1)J_1^{\text{CR}}(\omega_I) + k^2 [\frac{8}{3}J_0^{\text{CR}}(0) - 2J_1^{\text{CR}}(\omega_I)] \} \quad (67)$$

For isotropic reorientation,

$$J^{\text{CR}}(\omega) = \frac{3}{10} \left(\frac{g_e \beta S(S+1)B_0}{3kT} \right)^2 (\gamma_I g_e \beta (r^{-3})^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2}) \quad (68)$$

Like anisotropic chemical shielding, this interaction can interfere with the quadrupolar interaction. The contribution of this interference to the adiabatic portion of $(1/T_2)_{m,m-n}$ is given by

$$(1/T_2)_{m,m-n}^{\text{adiabatic}} = \frac{3}{5}\zeta n^2(2m-n)(2I^2 - I)^{-1} \frac{e^2 q_I Q_I}{\hbar} \times \left[\frac{g_e \beta S(S+1)B_0}{3kT} \right]^2 (\gamma_I g_e \beta (r^{-3})^2 \tau_2) \quad (69)$$

where ζ is the relevant correlation factor.

In general, interference (dipole–quadrupole, anisotropic shielding–quadrupole, ‘Curie spin’–quadrupole, or quadrupole–quadrupole) retards the relaxation process and results

in polarization/coherence transfer. In a spherical tensor description of relaxation, interference (cross correlation) between anisotropic shieldings or ‘Curie spin’ and the electric quadrupolar interaction results in terms such as $R_{L,L\mp 1}^{k,I}$ being nonzero. Hence, various forms of spin order of differing parity are coupled together by these interference terms. This coupling persists in all motional limits. As noted earlier, the magnitudes of these couplings scale as the geometric mean of the two competitive interactions, and can be significant even in the limit where one interaction dominates conventional relaxation parameters.¹⁴

8 IMPACT OF QUADRPOLAR RELAXATION ON SPIN- $\frac{1}{2}$ NUCLEI

In multispin systems containing both quadrupolar ($I \geq 1$) and dipolar ($I = \frac{1}{2}$) nuclei, the high-spin nuclei generally are relaxed efficiently by quadrupolar interactions whereas spin- $\frac{1}{2}$ nuclei relax on a slower timescale. Thus, from the perspective of a spin- $\frac{1}{2}$ nucleus (S), the scalar coupling to a quadrupolar nucleus (I), $J\hat{S} \cdot \hat{I}(t)$, appears time-dependent, and, on the average, vanishes. Although the quadrupolar nucleus provides a source of relaxation (scalar relaxation of the second kind) for spin- $\frac{1}{2}$ nuclei, multiplet structure disappears as these spins are decoupled by the relaxation process.¹⁵

Nevertheless, there are an increasing number of studies demonstrating that various quadrupolar nuclei often exhibit narrowed lines and multiplet structure in solution state NMR studies. Such situations commonly characterize studies involving important isotopes of hydrogen, nitrogen and oxygen. In the limit where the spectrum of spin S consists of $2I + 1$ evenly spaced multiplet components, quadrupolar relaxation of spin I generally provides the dominant relaxation sink for dissipation of S -spin 1QC. However, neither I -spin adiabatic terms nor I -spin dynamic frequency shifts will influence the behavior of spin S . If it is assumed that all $2I + 1$, 1QC components are well resolved then a well-defined relaxation rate $1/T_2$ can be assigned to each coherence associated with the S -spin transition $|\frac{1}{2}, m\rangle \leftrightarrow |-\frac{1}{2}, m\rangle$:

$$(1/T_2)_{I,m} = 4(2I^2 - I)^{-2} \{ [I(I+1)(4m^2 + 1) - m^2(4m^2 + 5)]J_1^Q(\omega_I) + [I^2(I+1)^2 - 2I(I+1)(m^2 + 1) + m^2(m^2 + 5)]J_2^Q(2\omega_I) \} \quad (70)$$

A listing of these relaxation rates for half-integer spin is given in Table 2.

Also, quadrupolar–anisotropic shielding interference—for spin I !—can dramatically effect linewidths in the S spectrum,

Table 2 The Electric Quadrupolar Contribution to the Relaxation Rate $(1/T_2)_{I,m}$ for each Single Quantum Coherence Identified with the Specific Transition $|S = \frac{1}{2}, S_z = \frac{1}{2}; I, m\rangle \leftrightarrow |S = \frac{1}{2}, S_z = -\frac{1}{2}; I, m\rangle$

	$I = \frac{3}{2}$	$I = \frac{5}{2}$	$I = \frac{7}{2}$	$I = \frac{9}{2}$
$m = \pm \frac{1}{2}$	$\frac{8}{3}(J_1^Q + J_2^Q)$	$\frac{16}{25}(J_1^Q + \frac{7}{2}J_2^Q)$	$\frac{40}{147}(J_1^Q + 7J_2^Q)$	$\frac{4}{27}(J_1^Q + \frac{23}{2}J_2^Q)$
$m = \pm \frac{3}{2}$	$\frac{8}{3}(J_1^Q + J_2^Q)$	$\frac{36}{25}(\frac{14}{9}J_1^Q + J_2^Q)$	$\frac{8}{7}(J_1^Q + \frac{9}{7}J_2^Q)$	$\frac{2}{3}(J_1^Q + \frac{13}{6}J_2^Q)$
$m = \pm \frac{5}{2}$		$\frac{4}{5}(2J_1^Q + J_2^Q)$	$\frac{120}{147}(\frac{37}{15}J_1^Q + J_2^Q)$	$\frac{38}{27}(J_1^Q + J_2^Q)$
$m = \pm \frac{7}{2}$			$\frac{8}{21}(3J_1^Q + J_2^Q)$	$\frac{14}{27}(\frac{24}{7}J_1^Q + J_2^Q)$
$m = \pm \frac{9}{2}$				$\frac{2}{9}(4J_1^Q + J_2^Q)$

as shown by the following expression:

$$(1/T_2)_{I,m} = 4m(2I^2 - I)^{-1}[2I(I+1) - 2m^2 - 1] \\ \times \frac{\zeta}{5} \frac{e^2 q_I Q_I}{\hbar} \frac{\gamma_I B_0 \Delta \sigma_I \tau_2}{1 + \omega_I^2 \tau_2^2} \quad (71)$$

Finally, quadrupolar–dipolar interferences can induce significant dynamic frequency shifts of individual spin- $\frac{1}{2}$ multiplet components and serve as a novel source of scalar relaxation.¹⁶

9 SUMMARY

In this article, the essential perturbation–response characteristics of quadrupolar (multipolar) nuclei have been introduced. For electric quadrupolar relaxation in the limit where the spectral density is neither projection- (k) nor frequency-dependent, exceptionally simple behavior is predicted [cf. equation (31)]. Likewise, when residual splittings suppress transverse cross relaxation, elementary expressions adequately describe the decay of all forms of spin coherence [cf. equation (46)]. In the slow motion limit, where adiabatic terms generally dominate the decay of coherence, it is recognized that various coherences, which lack an adiabatic contribution, decay on the timescale of the longitudinal magnetization. For these coherences, the dynamic frequency shift can prove important. Although quadrupolar interactions efficiently dissipate coherence and thermalize polarization, transfer of polarization is driven by interference effects and, necessarily, by weaker interactions that generally play only a very minor role in conventional relaxation studies.

1 INTRODUCTION

The off-resonance rotating frame spin–lattice relaxation experiment is a preeminent technique for the measurement of molecular rotational diffusion. The method relies on a ratio of relaxation expressions that are sensitive to the correlation time-dependent spectral densities, thereby obviating the need for a direct determination of relaxation times. Off-resonance rotating frame spin–lattice relaxation has been used to study rotational diffusion in aqueous solution and under in vivo conditions, and for the investigation of magnetization transfer phenomena. Off-resonance rotating frame spin–lattice relaxation considerations have also been used to create a high-resolution NMR three-dimensional off-resonance ROESY experiment, designated O-ROESY. Applications of the O-ROESY experiment include the assessment of macromolecular internal motion, internuclear distance, and the rotational correlation time for reorientational motion.

The off-resonance rotating frame spin–lattice relaxation experiment is established by the application of a low-power rf field off-resonance from a selected resonance. Thus, the essence of this experiment is simply described as a form of off-resonance saturation, in which a selected resonance is partially saturated, resulting in signal intensity diminution, in a manner explicitly dependent on molecular motion and/or magnetization transfer. Several reviews describing this experiment have appeared.^{1,2}

The different guises of the off-resonance rotating frame spin–lattice relaxation experiment showing the reduction in signal intensity as a consequence of the application of a low-power off-resonance rf irradiation field are shown in Figure 1.

2 THEORY

2.1 Off-Resonance Rotating Frame Experiment

The theoretical basis of the off-resonance rotating frame spin–lattice relaxation experiment was established by Jones³

and Blicharski⁴ who derived the relevant expressions appropriate for both spin- $\frac{1}{2}$ and quadrupolar spin-1 nuclei.

In a coordinate frame rotating with angular velocity $\omega = \omega \mathbf{k}$, the effective field $\mathbf{B}_e$ is given by

$$\mathbf{B}_e = \frac{\omega_e}{\gamma_I} = (B_0 - \omega/\gamma_I)\mathbf{k} + B_2\mathbf{i} \quad (1)$$

where $\omega_e = |\omega_e|$ is the angular precessional frequency about the effective field for an ensemble of noninteracting spins with gyromagnetic ratio γ_I , $\mathbf{B}_0 = B_0\mathbf{k}$ is the static magnetic field strength, $\mathbf{i}$ and $\mathbf{k}$ are unit vectors, and B_2 is an rf field off-resonance by an amount Δ :

$$\Delta = 2\pi \nu_{\text{off}} = -\gamma_I \left(B_0 - \frac{\omega}{\gamma_I} \right) \quad (2)$$

ν_{off} is the difference in frequency between the applied off-resonance rf field and the selected resonance. The effective field vector, $\mathbf{B}_e$, is inclined to the static magnetic field, $\mathbf{B}_0$, at an angle Θ defined by

$$\Theta = \arctan \left(\frac{\gamma_I B_2}{\Delta} \right) \quad (3)$$

The angular precessional frequency about the effective field vector is

$$\omega_e = \frac{\Delta}{\cos \Theta} \quad (4)$$

Assuming exponential relaxation of the magnetization aligned along $\mathbf{B}_e$ ($\mathbf{M}_e$), which is defined by the time constant $T_{1\rho}^{\text{off}}$, the magnetization ratio, M_e/M_0 , can be shown to be equal to $\cos \Theta$ ($T_{1\rho}^{\text{off}}/T_1$) in the high temperature limit [$kT \gg \gamma_I(h/2\pi)B_0$], with $B_0 > B_e$.⁵ In the conventional implementation of the experiment utilizing continuous wave rf irradiation to establish the off-resonance spin lock, the projection of $\mathbf{M}_e$ on the z axis of the rotating frame is measured. Thus, the signal intensity ratio, $R = M_z/M_0$ [$= \cos \Theta$ (M_e/M_0)] also equals $\cos^2 \Theta$ ($T_{1\rho}^{\text{off}}/T_1$). This equation is valid under the saturating condition [$(\gamma B_2)^2 T_1 T_2 \gg 1$]. M_e is obtained in the presence of, whereas M_0 is obtained in the absence of, the off-resonance rf irradiation field. For a small effective-field inclination angle, the $\cos^2 \Theta$ term may be neglected.

The time constant $T_{1\rho}^{\text{off}}$ may be directly measured by use of the conventional inversion–recovery pulse sequence modified to include off-resonance irradiation during the relaxation interval between the inversion and read pulses.⁶

2.2 Random Isotropic Reorientation

For random isotropic molecular reorientation involving two intramolecular dipolar coupled spin- $\frac{1}{2}$ heteronuclei, designated I and S , the following intramolecular dipole–dipole relaxation expressions for a particular spin S , in the absence of cross relaxation and under the far off-resonance condition, $|\Delta| \geq 5\gamma_S B_2$ and $\omega_e \ll \omega_0$ (off-resonance irradiation experiment only), may be written^{7,8}

$$\left(\frac{1}{T_1} \right)_{\text{DD,rot}}^{SI} = \sum_{i=1}^N (K_{IS})_i [J_0(\omega_{I_i} - \omega_S) + 3J_1(\omega_S) + 6J_2(\omega_{I_i} + \omega_S)] \quad (5)$$

Figure 1 Schematic representation of the different forms of the off-resonance rotating frame spin-lattice relaxation experiment. Resonances A and B are assumed to be in chemical exchange equilibrium. In each case the dotted lineshape represents the response of the A resonance to the off-resonance rf irradiation. (a) Conventional representation of the off-resonance rotating frame spin-lattice relaxation technique employed for the determination of the rotational correlation time. The far off-resonance limiting value of the intensity ratio equals unity. Magnetization transfer effects are assumed to be absent. (b) Conventional representation of the saturation transfer experiment employed for the determination of kinetic rate constants. The absence of off-resonance effects on resonance A is assumed. (c) The effect of exchange on the behavior of the off-resonance rotating frame spin-lattice relaxation experiment from a very broad spectral component (NMR ‘invisible’) into an NMR ‘visible’ pool of spins. The far off-resonance limiting value of the intensity ratio is less than unity. Off-resonance and magnetization transfer effects on resonance A are assumed. (d) The effect of exchange on the behavior of the off-resonance rotating frame spin-lattice relaxation experiment when both pools of spins are NMR ‘visible’. Off-resonance and magnetization transfer effects are assumed. (Reproduced by permission of Plenum Press from T. Schleich et al.²)

$$\left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{DD,rot}}^{SI} = \left(\frac{1}{T_1}\right)_{\text{DD,rot}}^{SI} + (\sin^2 \Theta) \sum_{i=1}^N (K_{IS})_i [2J_0(\omega_e) + \frac{3}{2}J_1(\omega_{I_i} + \omega_e) + \frac{3}{2}J_1(\omega_{I_i} - \omega_e)] \quad (6)$$

where $K_{IS} = (h/2\pi)^2 \gamma_I^2 \gamma_S^2 / 20r_{IS}$. $J_n(\omega)$ is the spectral density function in which motional dynamics information is embedded, h is Planck’s constant, γ_I and γ_S are the gyromagnetic ratios for the I and S spins, respectively, ω_I and ω_S are the respective angular Larmor precessional frequencies, r_{IS} is the distance between the I and S spins, and N is the number of I spins responsible for dipole–dipole IS relaxation. The summation over N is necessary when more than one I spin is responsible for relaxation, and allows for the occurrence of different spectral densities for each of the interactions. For biological applications, I and S typically represent ^1H , and ^{13}C or ^{31}P , respectively. Analogous relaxation expressions for $(1/T_1)_{\text{DD,rot}}^{SS}$ and $(1/T_{1\rho}^{\text{off}})_{\text{DD,rot}}^{SS}$ may

be written for homonuclear two-spin systems with $S = \frac{1}{2}$ (e.g., ^1H , ^{31}P).⁹

In many instances the off-resonance rotating frame experiment spin-lattice relaxation experiment is performed in water, a proton-containing solvent. Under such circumstances it may be necessary to consider intermolecular contributions $[(1/T_1)_{\text{DD,trans}}^{SH}$ and $(1/T_{1\rho}^{\text{off}})_{\text{DD,trans}}^{SH}]$ to the total dipole–dipole relaxation rate from solvent (water) translational motion. The relevant expressions to enable inclusion of intermolecular relaxation effects arising from solvent diffusion have been derived.² CSA relaxation contributions assume significance at high magnetic field strengths for the protein peptide carbonyl carbon atom and the phosphoryl group of phosphorus metabolites. Relaxation expressions for CSA relaxation are presented elsewhere.^{1,2} The total relaxation rate is obtained by summing the individual relaxation rates contributed by each of the assumed mechanisms:

$$\left(\frac{1}{T_1}\right)_{\text{total}} = \left(\frac{1}{T_1}\right)_{\text{DD,rot}}^{SI} + \left(\frac{1}{T_1}\right)_{\text{DD,rot}}^{SS} + \left(\frac{1}{T_1}\right)_{\text{DD,trans}}^{SH} + \left(\frac{1}{T_1}\right)_{\text{CSA}}^S \quad (7)$$

$$\left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{total}} = \left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{DD,rot}}^{SI} + \left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{DD,rot}}^{SS} + \left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{DD,trans}}^{SH} + \left(\frac{1}{T_{1\rho}^{\text{off}}}\right)_{\text{CSA}}^S \quad (8)$$

For random isotropic reorientational motion of an $I = 1$ spin, the quadrupolar relaxation mechanism contribution is usually dominant. The relevant expressions and their validation for the assessment of rotational diffusion by off-resonance rotating frame spin-lattice relaxation have been presented.¹⁰

2.3 Random Anisotropic Reorientation

Anisotropic molecular reorientation is encountered with non-spherical macromolecules, i.e., one represented hydrodynamically by an ellipsoid of revolution. The expressions appropriate for isotropic tumbling require modification to take into account differential motion about the major and minor axes of revolution. Expressions appropriate for anisotropic reorientational motion involving dipole-dipole and CSA relaxation have been derived.^{1,2}

2.4 Spectral Density Functions

The rotational correlation time reflects the rapidity of reorientational motion responsible for magnetic relaxation. For an uncharged spherical rigid rotor at infinite dilution, engaged in isotropic reorientational motion, the rotational correlation time is defined by the hydrodynamic volume. Correction procedures to account for the effect of finite macromolecular concentration on the correlation time have been described.² In biological systems, nuclear spins are likely to be distributed among different microenvironments, thus leading to a distribution of correlation times. Many studies assume, for simplicity, a single (average) rotational correlation time for the characterization of reorientational motion.

The spectral density function for dipolar relaxation is

$$J_n(\omega) = \frac{2\tau_0}{1 + \omega^2\tau_0^2} \quad (9)$$

where τ_0 is the rotational correlation time for isotropic reorientational motion of a rigid uncharged spherical particle.² The spectral density functions pertinent to CSA relaxation for isotropic reorientational motion as well as the corresponding dipolar and CSA expressions appropriate for anisotropic motion are summarized elsewhere.^{1,2}

2.5 Equivalence of Off-Resonance Rotating Frame Spin-Lattice Relaxation Formalism to the Bloch Equations for Off-Resonance Irradiation

Under appropriate conditions, the off-resonance rotating frame spin-lattice relaxation formalism leads to results equivalent to the steady state solution of the Bloch equation for the z magnetization. The necessary requirements were first noted

by Bendel and James.¹¹ Manipulation of off-resonance rotating frame spin-lattice relaxation theory, assuming appropriate conditions,² leads to the following expression:

$$\left(\frac{M_z}{M_0}\right)_{\text{off-reson}} = \frac{1 + (\omega - \omega_0)^2 T_2^2}{1 + (\omega - \omega_0)^2 T_2^2 + T_1 T_2 (\gamma B_2)^2 \left[1 + \frac{1}{(\omega - \omega_0)^2 T_2^2}\right]} \quad (10)$$

whereas the Bloch expression for the z magnetization is

$$\left(\frac{M_z}{M_0}\right)_{\text{Bloch}} = \frac{1 + (\omega - \omega_0)^2 T_2^2}{1 + (\omega - \omega_0)^2 T_2^2 + T_1 T_2 (\gamma B_2)^2} \quad (11)$$

Equations (10) and (11) converge when

$$\frac{1}{(\omega - \omega_0)^2 T_2^2} \ll 1 \quad (12)$$

thus, both z magnetization formalisms converge under saturating conditions $[T_1 T_2 (\gamma B_2)^2 \gg 1]$, and when $(\omega - \omega_0) \gg 1/T_2$. It should be noted that when the offset frequency comes close to the resonance of interest, the Bloch equation formalism deviates from off-resonance rotating frame spin-lattice relaxation formalism. As zero frequency is approached, $(M_z/M_0)_{\text{Bloch}}$ [equation (11)] approaches a finite spectral intensity ratio defined by $1/[1 + T_1 T_2 (\gamma B_2)^2]$, whereas $(M_z/M_0)_{\text{off-reson}}$ approaches zero.

2.6 Simulated Behavior of the Off-Resonance Rotating Frame Spin-Lattice Experiment

For illustrative purposes the off-resonance rotating frame spin-lattice relaxation behavior of the peptide chain backbone ^{13}C carbonyl carbon present in a hypothetical rigid protein engaged in isotropic reorientation is considered. For the isotropic tumbling of a rigid spherical protein each peptide bond carbonyl carbon is equivalent to all other residues in terms of its contribution to the resonance intensity, assuming that local peptide geometries and principal values of the peptide bond carbonyl carbon chemical shift tensor are identical. By contrast, for anisotropic reorientational motion, this assumption is not valid. Simulations describing anisotropic reorientational motion are considered elsewhere.^{1,2} The calculation of the spectral intensity ratio for proteins takes into account intramolecular ^{13}C - ^1H dipole-dipole interactions between the carbonyl carbon of the peptide bond and H- α , and CSA relaxation of the peptide carbonyl carbon. Intramolecular ^{13}C - ^{14}N dipole-dipole contributions and intermolecular ^{13}C - ^1H dipole-dipole interactions arising from solvent translational motion are negligible, and thus ignored.

The spectral intensity ratio, R , is typically measured in an off-resonance rotating frame spin-lattice relaxation experiment, and is defined by the ratio of $T_{1\rho}^{\text{off}}$ to T_1 . The theoretical dependence of $1/T_1$ on τ_0 displays a maximum when $\omega_c^2 \tau_0^2 = 1$, and is therefore dependent on the static magnetic field strength, moving to shorter τ_0 values with increasing field strength. Figure 2 shows the dependence of $1/T_{1\rho}^{\text{off}}$ on τ_0 at three values of ν_{off} at constant B_2 field

Figure 2 Theoretical dependence of the ^{13}C carbonyl carbon off-resonance rotating frame spin-lattice relaxation rate constant ($1/T_{\rho}^{\text{off}}$) on the correlation time for random isotropic reorientation (τ_0). The computed curves assume dipolar relaxation by a proton $2.16 \text{ \AA}$ from the ^{13}C carbonyl carbon and CSA relaxation contributions at 7.05 T . Values of 81.8 ppm and -0.82 were used for the anisotropy factor and asymmetry parameter, respectively. An off-resonance field of $0.5 \times 10^{-4} \text{ T}$ applied 5 (—), 15 (---), and 45 (····) kHz off-resonance was assumed. (Reproduced by permission of Plenum Press from T. Schleich et al.²)

strength. At values of $\omega_c^2 \tau_0^2 \leq 1$, $1/T_{\rho}^{\text{off}}$ is independent of ν_{off} , whereas for τ_0 values such that $(\omega_c \tau_0)^2 > 1$ the dependence of $1/T_{\rho}^{\text{off}}$ becomes significant. A minimum occurs at a value of τ_0 corresponding to an R value of 0.5 , i.e., an inflection point in a plot of R versus τ_0 (see Figure 3). As shown in Figure 3 the window of motional sensitivity of the off-resonance rotating frame spin-lattice relaxation experiment is approximately 1 – 1000 ns .

The effect of increasing ν_{off} (at constant B_2 field strength) is to shift the inflection of the R vs. τ_0 curve to longer correlation times, whereas, for the converse situation of variable B_2 field strength at constant ν_{off} , as shown in Figure 4, the inflection point of the curve moves to shorter correlation times with increasing B_2 field strength. The consequence of altering either

Figure 3 Simulation of the ^{13}C carbonyl carbon intensity ratio ($R = T_{\rho}^{\text{off}}/T_1$) vs. τ_0 at 7.05 T . The computed curves assume dipolar and CSA relaxation mechanism contributions using the parameters listed in Figure 2. An off-resonance field of $0.5 \times 10^{-4} \text{ T}$ applied 5 (—), 15 (---), and 45 (····) kHz off-resonance was assumed. (Reproduced by permission of Plenum Press from T. Schleich et al.²)

Figure 4 Simulation of the ^{13}C carbonyl carbon intensity ratio ($R = T_{\rho}^{\text{off}}/T_1$) vs. τ_0 at 7.05 T . The computed curves assume dipolar and CSA relaxation mechanism contributions using the parameters listed in Figure 2. An off-resonance field of 0.4×10^{-4} (—), and 0.2×10^{-4} (---) T was applied 5 kHz off-resonance. (Reproduced by permission of Plenum Press from T. Schleich et al.²)

ν_{off} or B_2 is to change both the angle that the effective field makes with the z axis as well as the precessional frequency (ω_e) of the nuclear spins about B_e .

The intensity ratio can also be plotted versus ω_e (at constant B_2), i.e., in the form of a frequency-dependent or dispersion curve, as shown in Figure 5, for several different values of τ_0 . The intensity ratio dispersion curve has the advantage that the effects of polydispersity and chemical exchange can be readily assessed. The frequency-dependent form of the experiment therefore incorporates the results of a number of different off-resonance rotating experiments performed at different values of ν_{off} , but at constant B_2 .

Figure 5 Simulation of the ^{13}C carbonyl carbon intensity ratio ($R = T_{\rho}^{\text{off}}/T_1$) vs. the angular precessional frequency of the effective field (ω_e) produced by a radiofrequency field applied off-resonance at three different values of τ_0 : 20 (—), 100 (---), and 500 (····) ns. In aqueous solution at 20°C , assuming a protein partial specific volume of $0.73 \text{ cm}^3 \text{ g}^{-1}$, and an average hydration value of $0.51 \text{ g of H}_2\text{O g}^{-1}$ of protein, these correlation times represent hydrated macromolecular masses of 39.2 , 196.1 , and 980 kDa , respectively. The computed curves assume an off-resonance field strength of $0.4 \times 10^{-4} \text{ T}$ and a B_0 strength of 7.05 T . Dipolar and CSA relaxation mechanism contributions were assumed using the parameters listed in Figure 2. (Reproduced by permission of Plenum Press from T. Schleich et al.²)

A potential source of intramolecular dipole–dipole relaxation of the peptide bond carbonyl carbon is the amide proton. However, simulations indicate this source of relaxation to be negligible.²

The simulated behavior of the ^{13}C off-resonance rotating frame spin–lattice relaxation experiment is also representative of the behavior of other spin- $\frac{1}{2}$ nuclei, as well as spin = 1 quadrupolar nuclei, engaged in isotropic reorientational motion.

The rotational correlation time obtained using an assumed isotropic model for the analysis of an anisotropically reorienting particle will be larger than the corresponding value for a sphere of equivalent volume. The resulting value of the correlation time is denoted $\tau_{0,\text{eff}}$. The error associated with the application of an isotropic reorientational model to an anisotropically tumbling particle may be estimated by use of an empirically derived polynomial in which the rigid rotor axial ratio is the independent variable.¹²

3 EXPERIMENTAL IMPLEMENTATION

The implementation of the off-resonance rotating frame spin–lattice experiment using continuous wave irradiation is straightforward on modern spectrometers, and is described in detail elsewhere.^{1,2} Calibration of the B_2 off-resonance irradiation field is of critical importance. Detailed procedures to accomplish B_2 field calibration have been described.^{1,2} The experimental intensity ratio, R , as a function of offset frequency, is the ratio of the measured intensity in the presence of an off-resonance irradiation field to a reference intensity obtained with very far off-resonance irradiation. For well-separated resonances the intensity is obtained by integration, whereas for overlapping resonances lineshape deconvolution is generally required in order to provide the relevant signal intensities.

Quantitative analysis of the R vs. ω_e dispersion curve is achieved by nonlinear least-squares regression with R and ω_e the respective dependent and independent variables. Nonlinear regression is performed by incorporating the appropriate (for the specific case under consideration) off-resonance rotating frame spin–lattice relaxation formalism into a program such as NONLINWOOD.¹³ The effective (average) rotational correlation time, $\tau_{0,\text{eff}}$, and the intensity ratio very far off-resonance, $R(\omega_e \rightarrow \infty)$, are fit to the experimental data using a model which assumes a single correlation time for random isotropic tumbling. Saturation transfer effects are manifested by dispersion curves which plateau at R (large ω_e) values less than unity. In this case, the effective rotational correlation time and the rate constant, k_a , for exchange from site A to B (2-site exchange is assumed) can be fit to the experimental data using a modified formalism.² Other models may be employed which recognize anisotropic motion, or polydispersity arising from discrete mixtures or from assumed models of association.

4 APPLICATIONS

4.1 Protein Rotational Diffusion

The ^{13}C off-resonance rotating frame spin–lattice relaxation experiment has been applied to a variety of proteins in dilute

Figure 6 Log of rotational correlation time (τ_0) vs. log of protein molecular mass (MM). (—) Theoretically predicted dependence of τ_0 (Stokes–Einstein equation) on protein molecular mass. (●) Rotational correlation times determined from experimental R vs. ω_e dispersion curves by nonlinear least squares analysis (with the inclusion of carbonyl carbon backbone segmental and side-chain internal motion, and corrections for anisotropic reorientation and viscosity effects) for lysozyme (14.6 kDa, $a/b = 1.7$), chymotrypsinogen A (25 kDa, $a/b = 2.0$), concanavalin A (53 kDa, $a/b = 2.1$), bovine serum albumin (69 kDa, $a/b = 2.9$), yeast alcohol dehydrogenase (141 kDa, $a/b = 2.8$), β _H-crystallin (250 kDa, $a/b = 1.6$), apoferritin 440 kDa, $a/b = 1.0$), thyroglobulin (669 kDa), and α -crystallin (800 kDa). Temperature = 23 °C.¹⁴ (Reproduced by permission of Wiley from S. X. Wang et al.¹⁴)

aqueous solution for the purpose of determining rotational correlation times. As noted by James et al.⁷ values of the protein rotational correlation time ($\tau_{0,\text{eff}}$) for six monodisperse protein preparations, varying in axial ratio (a/b) from 1.2 to at least 3.5, and spanning the molecular mass range from 14.6 to 150 kDa, obtained by assuming isotropic reorientational motion, were in reasonable agreement with those evaluated by the use of well-established rotational diffusion techniques. A more recent study improved the agreement between experimentally derived and theoretically estimated rotational correlation times, and established the upper molecular mass limit to be at least 800 kDa, by including carbonyl carbon backbone segmental and side-chain internal motion in the analysis, as well as corrections for anisotropic shape and viscosity effects.¹⁴ A comparison of the experimental τ_0 values with those expected theoretically as a function of molecular mass is shown in Figure 6. Departures from expected behavior occur at a molecular mass as low as 50 kDa, unless internal motion effects are included in the formalism.¹⁴

Aqueous proton solvent translational diffusion does not appear to be a significant complication in the determination of native globular protein rotational correlation times. An exception may be for very high molecular mass particles, in which case it is possible to make a correction by inclusion of a solvent-derived intermolecular dipole–dipole relaxation contribution in the analysis.²

Polydisperse protein systems may also be analyzed if a model describing the molecular weight distribution is known or a reasonable one can be assumed.¹⁵ Other studies involving concentration-dependent association include γ -crystallin^{2,16} and the pH-dependent aggregation of lysozyme.^{1,2} For γ -crystallin the observed dependence of the derived isodesmic association constant on concentration was attributed to the

Figure 7 Pulse sequence for the O-ROESY experiment.¹⁹ Elements of both the NOESY and ROESY experiments are incorporated in this sequence. The off-resonance spin lock is applied during the mixing time in the form of a Shifted Laminar Pulse (SLP).²⁰ Presaturation is used to minimize the water signal contribution

effect of ‘macromolecular crowding’. Application has also been made to the aggregation of hemoglobin S aggregation in oxygenated sickle cells.¹⁷ Other studies have examined the rotational diffusion characteristics of crystallins in ocular lens tissues homogenates.¹⁸

4.2 Off-Resonance ROESY Experiment

Off-resonance irradiation considerations have been included in the ROESY experiment, thereby establishing a three-dimensional off-resonance version of the two-dimensional ROESY experiment, designated O-ROESY.¹⁹ The salient difference between the O-ROESY and ROESY experiments is that the on-resonance spin lock is replaced by an off-resonance spin lock applied at frequency ν_{off} and at field strength B_2 . The O-ROESY pulse sequence is shown in Figure 7.

Experimentally the O-ROESY experiment is implemented by the use of Shifted Laminar Pulses²⁰ to ensure phase coherency between the off-resonance irradiation spin lock irradiation and the $(\pi/2)_y$ hard pulse. Variation of ν_{off} at constant B_2 creates a suite of two-dimensional experiments with frequency-dependent (ν_{off}) dispersion behavior in the cross-peak intensity established by the relevant interacting spin- $\frac{1}{2}$ nuclei. This stack of two-dimensional spectra contains a third frequency domain, thereby, in essence, defining a three-dimensional experiment. The cross-peak intensity dispersion curve contains a continuously increasing NOESY contribution at the expense of ROESY as the off-resonance spin lock frequency is increased. This experiment has been described in terms of product operator formalism for interacting homonuclear spin- $\frac{1}{2}$ nuclei leading to an expression for the dependence of cross-peak intensity dispersion behavior of ν_{off} (at constant B_2).²¹ Analysis of experimental cross-peak intensity dispersion data permits the evaluation of the internal motion correlation time of the internuclear vector defined by the relevant nuclei, its order parameter, the internuclear separation distance, as well as the rotational correlation time for macromolecular reorientational motion. An example for lysozyme is shown in Figure 8.

The O-ROESY experiment is analogous to the heteronuclear two-dimensional off-resonance experiments proposed by Peng and Wagner.²²

4.3 Phosphorus Metabolite Rotational Diffusion

Phosphorus-31 off-resonance rotating frame spin-lattice relaxation experiments have been used to study phosphorus

Figure 8 Normalized O-ROESY cross-peak intensity vs. off-resonance spin lock frequency (B_2 field strength = 1.2×10^{-4} T) obtained for the lysozyme C- α protons ($\circ$, $d_{\alpha\alpha}$ [45–51]; $\bullet$, $d_{\alpha\alpha}$ [2–39]).¹⁹ Normalization of off-resonance cross-peak intensity is relative to the on-resonance cross-peak intensity. The solid lines are the theoretical curves obtained by a theoretical fit to the experimental data, and are described by the following parameters for $d_{\alpha\alpha}$ [45–51] and $d_{\alpha\alpha}$ [2–39], respectively: internal correlation time, τ_i , 1.0, 1.2 ns; order parameter, S , 0.86, 0.82; correlation time for overall reorientational motion, $\tau_{o,\text{eff}}$, 6.4 and 6.3 ns (temperature = 35 °C)

metabolite rotational diffusion in tissue, as a means of exploring the issue of ‘free’ versus ‘bound’ metabolites.²² Effective rotational correlation times for the major phosphorus metabolites present in cortical and nuclear bovine calf lens homogenates were obtained assuming isotropic reorientational motion. Intramolecular dipole–dipole (^{31}P – ^1H , ^{31}P – ^{31}P), CSA, and solvent (water) translational dipole–dipole (^{31}P – ^1H) relaxation contributions were included in the analysis. In several cases the limiting value of the spectral intensity ratio failed to reach unity at large offset frequency, necessitating use of a modified formalism incorporating chemical exchange-mediated saturation transfer between two sites.²⁴

4.4 Saturation Transfer

The extension of off-resonance rotating frame spin-lattice relaxation theory to include the effects of chemical exchange-mediated saturation transfer affords knowledge about the occurrence of magnetization exchange kinetic processes in addition to the usually obtained rotational diffusion behavior. Analytical expressions have been derived²⁴ describing the time-dependent and steady-state behavior of the exchanging nuclear magnetization experiencing off-resonance field-induced partial or complete saturation.

Specific applications of the modified formalism include the exchange of free and G-actin-bound adenosine triphosphate (ATP), creatine kinase-catalyzed phosphocreatine (PCr), and ATP γ -phosphate exchange, and phosphorus metabolite exchange between two different relaxation environments, representing mobile and relatively immobile (solid-like) pools of metabolites present in bovine calf nuclear ocular lens tissue homogenates.^{2,24} The extended formalism also permits evaluation of saturation transfer experiments involving slowly tumbling or motionally restricted metabolites when nonselective, off-resonance, partial saturation effects become appreciable.

4.5 Proton Magnetization Transfer

The off-resonance rotating frame spin-lattice relaxation formalism has been extended to include the effects of magnetization occurring between 2 proton spin baths. The intensity ratios for the A and B spins are given by:^{2,25}

$$R^A = \frac{\left[R_A \left(\frac{R_T}{f} + R_B + \frac{1}{T_{e,B}} \right) \cos^2 \Theta_A + R_B R_T \cos^2 \Theta_B \right]}{D^{\text{off}}} \quad (13a)$$

$$R^B = \frac{\left[R_B \left(R_T + R_A + \frac{1}{T_{e,A}} \right) \cos^2 \Theta_B + R_A \frac{R_T}{f} \cos^2 \Theta_A \right]}{D^{\text{off}}} \quad (13b)$$

where $R_{A,B}$ and R_T are the rate constants for longitudinal relaxation of the A or B spins in the absence of cross relaxation, and the cross-relaxation rate constant for magnetization transfer from the A to B spin systems, respectively. By contrast, for magnetization transfer from the B to the A spin system the rate constant is equal to R_T/f , where f represents the ratio of the number of B spins to the number of A spins. The terms D^{off} and $1/T_{e,A,B}$ are given by

$$D^{\text{off}} = R_A^{\text{off}} R_B^{\text{off}} + R_A^{\text{off}} \frac{R_T}{f} + R_B^{\text{off}} R_T \quad (14c)$$

$$\frac{1}{T_{e,A,B}} = \frac{T_2 \omega_1^2}{1 + 4\pi^2 \Delta_{A,B}^2 T_2^2} \quad (14d)$$

respectively, where $R_A^{\text{off}} = 1/T_{1\rho,A}^{\text{off}} = R_A + 1/T_{e,A}$, $R_B^{\text{off}} = 1/T_{1\rho,B}^{\text{off}} = R_B + 1/T_{e,B}$, $\omega_1^2 = (\gamma B_2)^2$, and Δ is the offset of the rf irradiation field from the A or B spins. The other symbols have their usual meaning. Using the expression for $1/T_{e,A,B}$ given by equation (14d), equations (13a) and (13b) can be shown to be equivalent to the equations obtained by solution of the relevant six coupled Bloch equations,²⁵ when the value of $\cos^2 \Theta$ is approx. 1. Thus, the off-resonance rotating frame spin-lattice formalism and the Bloch formalism modified to include cross relaxation are identical under the usual experimental conditions employed.

This formalism has been applied to the study of proton magnetization transfer between water and rotationally immobilized protein in a wide variety of tissues,² and represents a form of the saturation transfer experiment.

1 INTRODUCTION

When a molecule rotates, a magnetic field is generated by the rotational motion, and the magnetic moments of the nuclei in the molecule experience this magnetic field. The energies of the nuclear spins, therefore, vary with the magnitude of the rotational magnetic field, and we say that there exists a ‘spin–rotation’ interaction between each nuclear spin and the rotational motion of the molecule. Since the size of the rotational magnetic field at the nucleus is proportional to the magnitude of the rotational angular momentum of the molecule, the Hamiltonian operator for the spin–rotation interaction, $\hat{\mathcal{H}}_{\text{SR}}$, is generally written in the form¹

$$\hat{\mathcal{H}}_{\text{SR}} = \hat{\mathbf{I}} \cdot \mathbf{C} \cdot \mathbf{J} \quad (1)$$

where $\hat{\mathbf{I}}$ is the dimensionless spin angular momentum operator of the nucleus, $\mathbf{J}$ is the rotational angular momentum of the molecule (in units of J s), and $\mathbf{C}$ is the spin–rotation interaction tensor (in units of s^{−1}). The elements of $\mathbf{C}$ are empirical constants that, in favorable cases, can be measured by molecular beam resonance or estimated from nuclear shielding constants.²

All molecules in gases, liquids and many solids are constantly in motion and undergo frequent collisions with other molecules. Since the rotational angular momentum of a molecule may change during a collision with another molecule, the magnitude of the spin–rotation interaction in the molecule varies with time. This time-dependent interaction connects the nuclear spin system to the motional degrees of freedom of the molecule and provides a pathway for the transfer of energy between the nuclear spins and the rotational motion of the molecule (see also *Brownian Motion and Correlation Times*). This energy transfer from the nuclear spins to other degrees of freedom is just spin–lattice (or longitudinal) relaxation, so the motional modulation of spin–rotation interactions gives a contribution to nuclear relaxation that is generally referred to as spin–rotation relaxation. Spin–rotation relaxation was first proposed by Schwinger, and was established as the predominant mechanism for spin–lattice relaxation in hydrogen gas by Bloom³ in 1957,

and in several polyatomic gases by 1961 (see also *Gas Phase Studies of Intermolecular Interactions and Relaxation*).

Spin–rotation relaxation is important for nuclei in small molecules (e.g., ¹H₂, C¹H₄, C¹⁹F₄, ¹³C₆D₆) in gas (see *Gas Phase Studies of Intermolecular Interactions and Relaxation* and *Gases at High Pressure*) and liquid phases,^{4,5} for nuclei in highly mobile environments on large molecules in liquid solution (e.g., protons in CH₃ groups of peptides and proteins), and occasionally for nuclei in highly symmetric molecules or ions in solids [e.g., N¹H₄⁺ in NH₄Cl(s)].

2 BASIC THEORY OF SPIN–ROTATION RELAXATION

In order to develop theoretical expressions for the spin–rotation contributions to nuclear spin relaxation rates, it is important to recognize that the nuclear spin angular momentum operator $\hat{\mathbf{I}}$ is quantized along the static magnetic field (i.e., in a coordinate system fixed in the laboratory), while $\mathbf{C}$ is best described in its principal axis coordinate system, which is fixed in the molecule. In this principal axis frame, the Cartesian form of $\mathbf{C}$ is diagonal and has elements C_x , C_y , and C_z . The description of the transformation from laboratory to molecular coordinates is most compact if we recognize that $\hat{\mathbf{I}}$ is a spherical tensor of rank 1, so that the molecular k component, $\hat{I}_k^{\text{molec}}$, is related to the laboratory m component, $\hat{I}_m$, by the relation

$$\hat{I}_k^{\text{molec}} = \sum_{m=-1}^1 \hat{I}_m \mathcal{D}_{mk}^{(1)}[\Omega(t)] \quad (2)$$

where $\mathcal{D}^{(1)}[\Omega(t)]$ is the Wigner rotation matrix, which describes the transformation of the components of a spherical tensor of rank 1, and $\Omega(t)$ is the set of Euler angles connecting the laboratory and molecular frames at time t . Having made these connections, we can show the time dependence of the spin–rotation interaction explicitly:

$$\hat{\mathcal{H}}_{\text{SR}}(t) = \sum_{m,k,l=-1}^1 \hat{I}_m \mathcal{D}_{mk}^{(1)}[\Omega(t)] C_{kl} J_l(t) \quad (3)$$

where $J_l(t)$ is the l spherical tensor component of the rotational angular momentum of the molecule in the molecule-fixed coordinate system at time t , and the elements of the spin–rotation interaction tensor are

$$C_{kl} = C_0 \delta_{k,-l} (\delta_{k,0} - \delta_{|k|,1}) + \Delta C \delta_{k,-l} (2\delta_{k,0} + \delta_{|k|,1}) + \delta C \delta_{k,l} \delta_{|k|,1} \quad (4)$$

in the spherical tensor representation. In equation (4),

$$\left. \begin{aligned} C_0 &= \frac{1}{3} (C_x + C_y + C_z) \\ \Delta C &= \frac{1}{3} [C_z - \frac{1}{2} (C_x + C_y)] \\ \delta C &= \frac{1}{2} (C_x - C_y) \end{aligned} \right\} \quad (5)$$

In the Redfield description of relaxation (see *Relaxation Theory: Density Matrix Formulation*), it is easily shown that the rates of transverse and longitudinal relaxation, R_1 and R_2 ,

2 SPIN-ROTATION RELAXATION THEORY

respectively, due to motional modulation of an interaction of the form

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hbar \sum_{m=-1}^1 \hat{I}_m V_m(t) \quad (6)$$

where $V(t)$ has a random time dependence, are given by

$$\left. \begin{aligned} R_1 &= \frac{1}{T_1} = 2 \int_0^\infty \overline{V_1^*(0) V_1(t)} \exp(-i\omega_0 t) dt \\ R_2 &= \frac{1}{T_2} \\ &= \int_0^\infty \overline{V_1^*(0) V_1(t)} \exp(-i\omega_0 t) dt + \int_0^\infty \overline{V_0^*(0) V_0(t)} dt \end{aligned} \right\} \quad (7)$$

In these equations, T_1 is the spin-lattice relaxation time, T_2 is the spin-spin relaxation time, $\overline{V_\mu^*(0) V_\mu(t)}$ is the time correlation function for the stationary random variable $V_\mu(t)$, and ω_0 is the nuclear resonance frequency (in s^{-1}) for nucleus I . The bar in $\overline{V_\mu^*(0) V_\mu(t)}$ represents an average over all the molecules in the sample (the 'ensemble').

The correlation functions arise in the expressions for the relaxation rates because the interactions between the spin and lattice systems exhibit random time dependence (see also **Brownian Motion and Correlation Times**). A time correlation function is a quantitative measure of the time period over which a precise knowledge of the value of the random variable at time zero allows an accurate prediction of its value at some time t later. Generally, the correlation function is approximately equal to 1 at short times, and decays to zero at longer times after many changes in the random variable have occurred. The time dependence of the correlation function can be characterized by a correlation time τ_c . For a correlation function $\overline{V^*(0) V(t)}$, the correlation time is defined by

$$\tau_c = \int_0^\infty \frac{\overline{V^*(0) V(t)}}{|\overline{V(0)}|^2} dt \quad (8)$$

Qualitatively, a correlation function is approximately unity for times $t \ll \tau_c$ and is zero for $t \gg \tau_c$. In the expressions for the relaxation rates, it is the Fourier transforms or spectral densities $\mathcal{J}(\omega)$ of the correlation functions

$$\mathcal{J}(\omega) = \int_0^\infty \overline{V^*(0) V(t)} \exp(-i\omega t) dt \quad (9)$$

that appear. Qualitatively, $\mathcal{J}(\omega)$ is large and approximately constant for $\omega \ll \tau_c^{-1}$, and is zero for $\omega \gg \tau_c^{-1}$. Note that τ_c is proportional to $\mathcal{J}(0)$.

For spin-rotation interactions, we make the connection

$$V_m(t) = \hbar^{-1} \sum_{k,l=-1}^1 \mathcal{D}_{mk}^{(1)}[\Omega(t)] C_{kl} J_l(t) \quad (10)$$

and note that the correlation time for the correlation function $\overline{V_1^*(0) V_1(t)}$ is short compared with ω_0^{-1} , so that $\mathcal{J}(\omega_0) = \mathcal{J}(0)$ and we can write

$$R_{1\text{SR}} = R_{2\text{SR}} = 2\hbar^{-2} \sum_{k,l,k',l'=-1}^1 C_{k'l'} C_{kl} \mathcal{J}_{k'l'kl} \quad (11)$$

where $R_{1\text{SR}}$ and $R_{2\text{SR}}$ are, respectively, the spin-rotation contributions to the rates of longitudinal and transverse nuclear

relaxation, and the zero-frequency spectral density $\mathcal{J}_{k'l'kl}$ is given by

$$\mathcal{J}_{k'l'kl} = \int_0^\infty \overline{\mathcal{D}_{1k'}^{(1)*}[\Omega(t)] J_{l'}^*(t) \mathcal{D}_{1k}^{(1)}[\Omega(0)] J_l(0)} dt \quad (12)$$

The spin-rotation correlation functions

$$G_{k'l'kl}(t) = \overline{\mathcal{D}_{1k'}^{(1)*}[\Omega(t)] J_{l'}^*(t) \mathcal{D}_{1k}^{(1)}[\Omega(0)] J_l(0)} \quad (13)$$

involve the time dependence of *both* the angular momentum and the orientation of the molecule. They are very different from the reorientational correlation functions $\overline{\mathcal{D}_{mk'}^{(2)*}[\Omega(t)] \mathcal{D}_{mk}^{(2)}[\Omega(0)]}$ involved in the relaxation contributions from rotational modulation of intramolecular dipole-dipole, anisotropic chemical shift, and electric quadrupolar interactions, since the reorientational correlation functions involve only the orientation of the molecule, not its angular momentum. The values of the spectral densities $\mathcal{J}_{k'l'kl}$, and hence the spin-rotation relaxation rates, are determined by the rotational dynamics of the molecules in the medium being studied. The general expression for the spin-rotation relaxation rate given in Equation (11) does not convey any clear and simple relationships between the relaxation rate and physical parameters that characterize the rotational dynamics of the molecules in the medium. These relationships are most clearly developed by investigating the simple physical models used to describe the rotational motion of the molecules in the medium. It is best to focus our attention on the spin-rotation relaxation and rotational dynamics of molecules in fluids, mobile species in disordered solids, and rotating methyl groups in large molecules in turn, since the models used to describe the motions in each are different.

3 SPIN-ROTATION RELAXATION IN FLUIDS

3.1 The Hubbard Model and the Hubbard Relation

In Hubbard's classic work⁶ on spin-rotation relaxation of spherical top molecules in liquids, he assumed that the rotational motion of a molecule was like that of a rigid macroscopic sphere immersed in a viscous fluid and experiencing strong random torques due to the Brownian motion of other molecules, just as Bloembergen, Purcell, and Pound⁷ had done in their classic description of dipolar relaxation in liquids (see **Brownian Motion and Correlation Times**). Hubbard found that the spin-rotation relaxation rate could be written as⁶

$$R_{1\text{SR}} = R_{2\text{SR}} = \frac{2Ik_B T}{\hbar^2} (C_o^2 + 2\Delta C^2) \tau_J \quad (14)$$

where I is the moment of inertia of the spherical molecule, k_B is the Boltzmann constant, and τ_J is the correlation time for the rotational angular momentum of the molecule. In deriving this result, Hubbard assumed that the reorientation of the molecule was very slow compared with the modulation of its angular momentum by collisions with other molecules in the liquid, so that the spin-rotation correlation function in Equation (13) is approximately

$$\begin{aligned} G_{k'l'kl}(t) &\approx \overline{\mathcal{D}_{1k'}^{(1)*}[\Omega(0)] \mathcal{D}_{1k}^{(1)}[\Omega(0)]} \int_0^\infty \overline{J_{l'}^*(t) J_l(0)} dt \\ &\approx \frac{1}{3} \delta_{k,k'} \int_0^\infty \overline{J_{l'}^*(t) J_l(0)} dt \end{aligned} \quad (15)$$

In Hubbard's model, the angular momentum of a molecule is assumed to follow the rotational Langevin equation

$$\frac{d\mathbf{J}}{dt} = -\frac{\xi_R}{I}\mathbf{J} + \mathcal{T}(t) \quad (16)$$

where ξ_R is the rotational friction coefficient describing the viscous retarding torque on the molecule and $\mathcal{T}(t)$ is the Brownian torque due to the rapid random motions of other molecules. The correlation function for the i th Cartesian component of the angular momentum is

$$\overline{J_i(t)J_i(0)} = I k_B T \exp(-t/\tau_J) \quad (17)$$

and the angular momentum correlation time is given by

$$\tau_J = I/\xi_R \quad (18)$$

so there is a clear relationship between the angular momentum correlation time, which determines the rate of spin-rotation relaxation, and the rotational friction coefficient. The latter may be estimated from the Stokes relationship

$$\xi_R = 8\pi a^3 \eta \quad (19)$$

where a is the hydrodynamic radius of the spherical molecule and η is the viscosity of the fluid medium. Hubbard showed that the reorientational correlation time $\tau_\theta^{(2)}$, which characterizes the random time dependence of the orientation of the molecule (see *Brownian Motion and Correlation Times*) within the reorientational part of the correlation function $G_{k'l'kl}(t)$ and determines the rate of intramolecular dipolar relaxation, is also related to the rotational friction coefficient by

$$\tau_\theta^{(2)} = \xi_R/6k_B T \quad (20)$$

The celebrated 'Hubbard relation'

$$\tau_\theta^{(2)} \tau_J = I/6k_B T \quad (21)$$

was obtained⁶ by combining equations (18) and (20). Equations (14) and (21) are valid for spherical molecules in the region where molecular rotation is slow compared with the rate of fluctuations in the angular momentum ($\tau_J \ll \tau_\theta^{(2)}$).

For nonspherical molecules, the friction coefficients describing the viscous retarding torques in the rotational Langevin equations [see equation (16)] are different for the x , y , and z components of the angular velocity, and equation (14) becomes

$$R_{1SR} = R_{2SR} = \frac{2k_B T}{3\hbar^2} (I_x C_x^2 \tau_{J_x} + I_y C_y^2 \tau_{J_y} + I_z C_z^2 \tau_{J_z}) \quad (22)$$

where τ_{J_x} , τ_{J_y} , and τ_{J_z} are the correlation times for the respective angular velocity components. In deriving this result, the precession terms in the rotational Langevin equations for the angular velocity components are ignored, so Equation (22) is valid only in the limit $\tau_{J_x}, \tau_{J_y}, \tau_{J_z} \ll \tau_\theta^{(2)}$.

Some of the important extensions of the Hubbard model will be discussed presently, but it is useful to investigate spin-rotation relaxation in dilute gases first in order to put the later extensions into a more complete perspective.

3.2 Relaxation in Dilute Fluids

In a dilute gas,² the molecules rotate freely and their rotational angular momenta remain constant during the long

periods between collisions with other molecules (see also *Gas Phase Studies of Intermolecular Interactions and Relaxation* and *Gases at High Pressure*). The orientation of the molecule $\Omega(t)$ and its angular momentum $\mathbf{J}$ are intimately connected since the rotational velocity for a spherical top molecule is just $\mathbf{J}/I$. The 'inertial' motion of the molecules in the intervals between collisions has important effects on the rate of spin-rotation relaxation. The ensemble average of each of the spin-rotation correlation functions for an ensemble of freely rotating spherical top molecules, $G_{k'l'k}^{\text{free}}(t)$, can be expressed as the sum of a constant term and terms with Gaussian time dependence. If the time between collisions in the gas is long compared with the time required for a complete rotation of the molecule, the time-dependent terms in the free rotor correlation function do not contribute to the spin-rotation spectral densities, and one obtains the spin-rotation relaxation rate⁸

$$R_{1SR} = R_{2SR} = \frac{2I k_B T}{\hbar^2} (C_0^2 + \frac{4}{5} \Delta C^2) \tau_J \quad (23)$$

where τ_J is the time between collisions that randomize the magnitude and/or direction of the angular momentum vector of the molecule.

It is useful to compare equations (14) and (23) in order to discern the important differences in the rates of spin-rotation relaxation in dense and dilute fluids. Clearly, the time between 'collisions' in the liquid will be much shorter than in the gas, so τ_J is much longer, and hence spin-rotation relaxation is much faster, in the gas phase. The isotropic spin-rotation interactions, which are characterized by the constant C_0 , give contributions to spin relaxation rates that have the same form for all fluids. This is not surprising, because the isotropic spin-rotation interactions are completely independent of molecular reorientation, so their time correlation should be characterized completely by the angular momentum correlation time τ_J . On the other hand, the spin relaxation rates due to motional modulation of the anisotropic parts of the spin-rotation interaction (characterized by ΔC) are smaller by a factor of $\frac{2}{5}$ in the dilute gas owing to the 'inertial' motion of the molecules. This inertial motion causes a loss of correlation in the anisotropic spin-rotation interactions during the long periods of free rotation, and this leads to less effective spin-rotation relaxation in the dilute gas. Inertial effects also produce dramatic changes in the reorientational correlation time $\tau_\theta^{(2)}$ and hence in the relaxation contributions from dipole-dipole and electric quadrupolar interactions.

3.3 The Extended Diffusion Model

The importance of inertial effects on the relaxation rates in gases leads one to ask about their potential importance in dense fluids. A simple model that spans the range from the dense fluid to the dilute gas is the extended diffusion model for rotational motion in fluids.^{9,10} The extended diffusion model uses a rather crude idealized picture for the rotational motion of molecules in a fluid—the molecules rotate just as though they were in a very dilute gas, except that instantaneous random torques continually change the direction and possibly the speed of the rotational motion (see also *Brownian Motion and Correlation Times*). In this model, the orientation and angular momentum of a general molecule is followed in microscopic detail. The molecules are assumed to rotate freely during a series of 'diffusive' steps, which are interrupted by random impulsive torques. These 'collisional events' (the

random torques due to the Brownian nature of the fluid) are assumed to follow a Poisson distribution with average time τ_J between collisions. The collisions are taken to be instantaneous and are assumed to randomize the orientation (M diffusion) or both the orientation and magnitude (J diffusion) of the angular momentum vector. Although the reorientational correlation times $\tau_\theta^{(2)}$ in the M- and J-diffusion limits differ significantly, the spin-rotation relaxation rates are the same in both limits. For a spherical top molecule, the spin-rotation relaxation rate is given by

$$R_{\text{ISR}} = R_{\text{2SR}} = \frac{2Ik_B T}{\hbar^2} \left\{ C_0^2 + \frac{4}{5} \Delta C^2 F \left[\frac{1}{2^{1/2} \bar{\omega} \tau_J} \right] \right\} \tau_J \quad (24)$$

where

$$F[x] = 1 + x^2 - 2x^4 [1 - \pi^{1/2} x \exp(x^2) \text{erfc}(x)] \\ \approx \begin{cases} \frac{5}{2} \left(1 - \frac{3}{2x^2} + \frac{21}{4x^4} + \dots \right) & \text{for large } x \\ 1 + x^2 - 2x^4 + \dots & \text{for small } x \end{cases} \quad (25)$$

$\text{erfc}(x)$ is the complementary error function and

$$\bar{\omega} = k_B T / I \quad (26)$$

is the average rotational velocity. When τ_J is much shorter than the time $\bar{\omega}^{-1}$ for the molecule to make a complete rotation, as it is in a dense liquid, equation (24) reduces to equation (14); and in the limit $\tau_J \gg \bar{\omega}^{-1}$, which is appropriate for a dilute gas, Equation (24) reduces to equation (23). The extended diffusion model can also be used to describe spin-rotation relaxation in linear, symmetric top⁹ and asymmetric top¹⁰ molecules. In molecules of all symmetries, the temporal behavior of all components of the angular momentum vector is characterized by a single correlation time τ_J .

3.4 The Fokker-Planck-Langevin Model

The Fokker-Planck-Langevin model¹¹⁻¹⁸ for the rotational motion of molecules in fluids is a true extension of the rotational diffusion model (see *Brownian Motion and Correlation Times*) used by Bloembergen, Purcell, and Pound to treat dipole-dipole magnetic relaxation, and by Hubbard to describe spin-rotation relaxation. In the Hubbard model, the stochastic behavior of the angular momentum is assumed to follow a rotational Langevin equation [see Equation (16)], and the conditional probability density $P(\Omega, t | \Omega_0)$ that a molecule will have orientation between Ω and $\Omega + d\Omega$ at time t , given that it had orientation between Ω_0 and $\Omega_0 + d\Omega_0$ at time zero, follows a rotational diffusion equation. This treatment of orientational and angular velocity variables as essentially independent processes is valid only if $\tau_J \ll \tau_\theta^{(2)}$. In the Fokker-Planck-Langevin model, the angular velocity is again assumed to follow a rotational Langevin equation (including the terms describing the precession of the angular velocity components), but the orientational behavior is not treated independently. Instead, the molecular rotation is treated as a Markovian process, and the focus is on the joint conditional probability density $P(\omega, \Omega, t | \omega_0, \Omega_0)$ that a molecule will have angular velocity between ω and $\omega + d\omega$ and orientation between Ω and $\Omega + d\Omega$ at time t , given that it had angular velocity between ω_0 and $\omega_0 + d\omega_0$ and orientation between Ω_0 and $\Omega_0 + d\Omega_0$ at time zero. $P(\omega, \Omega, t | \omega_0, \Omega_0)$ follows the rotational Fokker-Planck equation. For a spherical molecule¹⁸, the Fokker-Planck-Langevin model gives the spin-rotation relaxation rate

$$R_{\text{ISR}} = R_{\text{2SR}} = \frac{2Ik_B T}{\hbar^2} [C_0^2 + 2\Delta C^2 f(\tau_J)] \tau_J \quad (27)$$

where

$$f(\tau_J) = 1 - \frac{3}{2} \bar{\omega}^2 \tau_J^2 + \frac{13}{4} \bar{\omega}^4 \tau_J^4 - \frac{22}{3} \bar{\omega}^6 \tau_J^6 + \dots \quad (28)$$

For nonspherical molecules, the precessional motion of the angular velocity leads to a more complicated relationship between the angular velocity correlation time and the friction coefficient than that given in equation (18). This leads to an expression for the spin-rotation relaxation rate that is similar to equation (22), but contains corrections to the correlation times and additional small cross-correlation terms (e.g., terms containing $C_x C_y$).

4 SPIN-ROTATION RELAXATION IN MOLECULES WITH INTERNAL ROTATION

In a large molecule that tumbles very slowly in solution, the motion of the nuclei on a fragment that can undergo facile internal rotation will be dominated by the internal rotational motion, and the rate of spin-rotation relaxation should be determined by the correlation time for the velocity of this internal motion, rather than the correlation time for the angular velocity of the molecule itself. A number of models have been proposed to describe the spin-rotation relaxation rate in the presence of internal rotation.¹⁹⁻²²

A phenomenological libration model¹⁹ has been developed to describe the spin-rotation relaxation contributions to the ¹³C-relaxation rates of carbon atoms in methyl groups (see also *Carbon-13 Relaxation Measurements: Organic Chemistry Applications*). The basic physical assertions here are

1. if the methyl group rotates freely, the correlation time for the angular velocity of the internal rotator is just the time required for it to rotate by 1 rad;
2. when the rotator experiences a barrier to free rotation, its angular velocity correlation function will decay more rapidly and lead to a shorter angular velocity correlation time.

In this model, the potential governing the rotational motion of the methyl group has threefold symmetry with a barrier V_0 between the three potential wells, and a methyl group will spend an average time $\tau_{\text{libration}}$ in one potential well before rotating through 120° into the next well. It is usually assumed that the $I_z C_z^2 \tau_z$ term dominates the other terms in equation (22), and τ_z is given by

$$\tau_z^{-1} = \tau_{\text{free}}^{-1} + \tau_{\text{libration}}^{-1} \quad (29)$$

where τ_{free} is the time required for a freely rotating (unhindered) internal rotator to rotate through 1 rad. The magnitude of $\tau_{\text{libration}}$ is governed by the height of the barrier, and is calculated from an ensemble average of the semiclassical libration frequencies over all bound states (states with energy less than V_0) of the hindered internal rotator.

More fundamental and elaborate descriptions²⁰⁻²² of the spin-rotation relaxation rates of nuclei on internal rotators have used the extended diffusion or Fokker-Planck-Langevin models for both internal rotation and overall molecular rotation. The classical equation of motion for the internal rotator, including the potential barrier to rotation, is solved

exactly, and V_0 enters the spin-rotation correlation times via the 'free rotor' internal angular velocity-orientation correlation functions. The expressions for the relaxation rates are very complicated and contain terms arising from the internal rotation and from the overall rotation of the molecule.

5 SPIN-ROTATION RELAXATION IN SOLIDS

In solids, the molecules or ions are fixed at lattice positions, but highly symmetric ions or molecules in a rotationally disordered solid may exhibit some rotational motion. The rudimentary phenomenological model²³ that has been developed to describe the spin-rotation relaxation rate for nuclei in a molecule or ion in a solid is based on the idea that molecules in a solid are rotationally restrained in a cage of other molecules, but that reorientation can occur if the cage expands or if the molecule acquires enough energy to overcome the potential barrier to rotation. (In fact, this model was first presented as a phenomenological explanation of observed spin-rotation relaxation in liquids, but was quickly supplanted by Hubbard's model). When rotation does occur, it is viewed as a random jump of short duration from one orientation to another uncorrelated orientation. In this picture, the angular velocity of the molecule is zero except during one of the random jumps. Assuming that the times between random jumps follow a Poisson distribution with mean time τ between jumps, one finds that

$$R_{1SR} = R_{2SR} = \frac{1}{3} \gamma^2 \langle B_{SR}^2 \rangle \Delta^2 \tau^{-1}, \quad (30)$$

where γ is the magnetogyric ratio for the nucleus, $\langle B_{SR}^2 \rangle$ is the mean square magnetic field produced by the spin-rotational interaction during a random jump, and Δ is the duration of the random jump. It is expected that $\gamma^2 \langle B_{SR}^2 \rangle$ will be proportional to the temperature T , and to the squares of the spin-rotation constants for the molecule, and that τ will decrease with increasing temperature.

1 INTRODUCTION

The use of conventional NMR relaxation measurement techniques for studying moderately rapid atomic motions may result in observation of the following phenomena:

1. a decrease (or a minimum)¹ of the spin–lattice relaxation time T_1 in a plot of T_1 versus temperature;
2. motional narrowing of the resonance linewidth² (or motional lengthening of the free induction decay or the spin–spin relaxation time T_2);
3. a decrease² in the Hahn echo decay time compared to the Carr–Purcell–Meiboom–Gill (CPMG)³ time constant (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

The term ultralow motions⁴ refers to motions that are observable by NMR but are sufficiently infrequent that they produce no motional narrowing of the resonance line and make no measurable contribution to the spin–lattice relaxation rate. Typical T_1 minima correspond to motions for which the mean atomic jump rate $1/\tau_c$ is of the order of the nuclear precession frequency Ω_0 ($\approx 10^8$ s⁻¹, typically).¹ Motions having jump frequencies one or two orders of magnitude higher or lower than that for the minimum usually still give measurable contributions to the relaxation rate. Since the condition for motional narrowing is that the atomic jump time τ_c be less than T_2 , ultralow motions are typically those for which $T_2 < \tau_c < T_1$.⁴ A very wide range of atomic motions falls under this classification, since $T_2 \approx 10^{-4}$ – 10^{-5} s in solids, while T_1 can be as long as several seconds to hours in length.

It is clearly desirable to extend to lower frequencies the frequency range (and thus the temperature range) of motions that can be studied. One advantage of studying a wider range of atomic motions is that motions having slightly different activation energies may be distinguished if they are observed over a sufficiently wide temperature range. Also, motions associated with a particular phenomenon, like a phase transition, may occur only in a particular temperature region.

The basic idea of the ultralow motion techniques can be understood by considering what happens to a T_1 minimum if the field B_0 , and thus the resonant frequency, is greatly reduced. According to the Bloembergen, Purcell, and Pound (BPP) theory,¹ atomic diffusion or molecular reorientations

will cause fluctuations in the dipolar interactions that can be treated as perturbations on the Zeeman levels, and, furthermore, these fluctuations can be described by an exponential correlation function. BPP derived for T_1 an expression of the form

$$\frac{1}{T_1} \approx \frac{\Omega_d^2 \tau_c}{1 + \Omega_0^2 \tau_c^2} \quad (1)$$

where Ω_0 is the Larmor angular frequency and Ω_d is the angular frequency corresponding to a typical dipolar splitting. (Actually, there are additional terms of similar form. For interactions involving identical spins, there is an extra term proportional to $1/(1 + 4\Omega_0^2 \tau_c^2)$; for heteronuclear systems, there are also terms having $[1 + (\Omega_I - \Omega_S)^2 \tau_c^2]$ and $[1 + (\Omega_I + \Omega_S)^2 \tau_c^2]$ in the denominator.) Equation (1) predicts that, in a temperature plot of T_1 , there will be a minimum value for T_1 at the temperature for which $\tau_c \approx \Omega_0^{-1}$, in agreement with the idea that the transition probability $1/T_1$ arises largely from frequency components in the perturbation that equal the energy level spacing divided by $\hbar$. If Ω_0 is reduced, the minimum will correspond to a longer value of τ_c , and thus to lower frequency motions. For a typical diffusion mechanism, atomic jumps become less frequent as the temperature is lowered. Thus the T_1 minimum in a low field will occur at a lower temperature than would the T_1 minimum at a higher field.

There are experimental problems associated with attempting to study relaxation in very weak fields where the NMR signal might be very small (see *Zero Field NMR*). There are also theoretical difficulties, since the theory underlying equation (1) is a perturbation theory that treats the fluctuating dipolar Hamiltonian due to diffusion as a perturbation on the Zeeman Hamiltonian; such an assumption may not be valid in very weak applied fields. Solutions to both these problems will now be discussed. Ultralow motion techniques have been reviewed by Ailion.^{5–7}

2 SPIN–LATTICE RELAXATION IN THE ROTATING FRAME ($T_{1\rho}$)

One approach to studying relaxation in weak applied fields and yet having the strong signal strength for a large field is to use the field cycling method^{8,9} (see *Field Cycling Experiments*), in which the external magnetic field is reduced adiabatically to a small value and subsequently increased adiabatically back to the original value, where the signal is measured. If there are no irreversible processes, the entropy will be constant, and the full signal will be measured after the remagnetization. However, atomic diffusion constitutes an irreversible process, which will cause a loss of dipolar order. Thus, by plotting the signal strength versus time in the demagnetized state, the weak field relaxation can in principle be measured. One difficulty with this approach is that it may be difficult to satisfy the requirement that the demagnetization and remagnetization processes be sufficiently slow that the adiabatic condition is satisfied and yet be rapid compared with T_1 .

An alternate approach is to measure $T_{1\rho}$, the spin–lattice relaxation time in the rotating frame of the rf field B_1 (see *Magnetization Transfer between Water and Macromolecules in Proton MRI*). According to Redfield,¹⁰ a spin system

in an rf field strong enough to saturate the resonance line (i.e., $\gamma^2 B_1^2 T_1 T_2 \gg 1$) will form a canonical distribution among energy levels separated by γB_{eff} rather than γB_0 , where the effective field B_{eff} in a frame rotating at angular frequency ω is given by

$$B_{\text{eff}} = B_1 i + (B_0 - \omega/\gamma) k \quad (2)$$

In this case, the spins will, after equilibrium has been achieved, be characterized by a ‘spin temperature in the rotating frame’, which means that Curie’s law will hold, but with $M_{\text{eq}} = CH_{\text{eff}}/T$. The significance is that, at exact resonance ($B_0 = \omega/\gamma$), the equilibrium magnetization M_{eq} will be parallel to B_1 rather than to B_0 . The $T_{1\rho}$ minimum will then occur when $\gamma B_1 \tau_c \approx 1$, for B_0 at exact resonance. Since B_1 is typically of order 1–50 G, this minimum arises from much lower frequency motions than does the normal T_1 minimum. If B_1 is much larger than the magnetic dipolar or electric quadrupolar local fields, the dipolar and quadrupolar fluctuations can still be treated by perturbation theory (this approach is called the ‘weak collision’ theory).¹¹ If, on the other hand, B_1 is comparable to or less than the dipolar or quadrupolar local fields, perturbation theory fails, and a different theory, called the ‘strong collision’ theory,¹² must be used. In this article, we shall consider the case for a spin- $\frac{1}{2}$ nucleus or one in which quadrupolar interactions can be neglected; the inclusion of quadrupolar interactions in the strong collision theory has been described by Ailion.⁵

2.1 Weak Collision Theory

All of the weak collision calculations are applications of the BPP theory in which the fluctuating dipolar Hamiltonian is treated as a perturbation on the Zeeman system. The only important difference is that the basic laboratory frame Hamiltonian is replaced by a rotating frame Hamiltonian in which B_0 is replaced by B_{eff} , as given by equation (2). At exact resonance, this theory predicts that $T_{1\rho}$ should exhibit a low-frequency minimum of the form

$$\frac{1}{T_{1\rho}} = K \frac{\tau_c}{1 + 4\Omega_1^2 \tau_c^2} \quad (3)$$

where $\Omega_1 (= \gamma B_1)$ is proportional to the energy level splitting in the rotating frame. Thus the $T_{1\rho}$ minimum occurs when $\tau_c \approx (2\Omega_1)^{-1}$, which may be several orders of magnitude longer than the value of τ_c at a typical T_1 minimum. Accordingly, a $T_{1\rho}$ minimum is deeper than a T_1 minimum, and corresponds to slower atomic motions occurring at lower temperatures, as shown in Figure 1.

2.2 Strong Collision Theory

In order to get even more effective relaxation so as to observe even lower frequency motions, B_1 , and thus Ω_1 in equation (3), can be reduced to a value comparable to the local dipolar field, or even to zero (e.g., by adiabatic demagnetization in the rotating frame (ADRF),¹³ which is discussed in Section 3.3). In this case, equation (3) would predict that the minimum would not occur unless τ_c were infinite. However, perturbation theories like BPP and the weak collision theory will not be valid, since the perturbation

Figure 1 Temperature plot of relaxation times (T_2 , T_1 , $T_{1\rho}$, and T_{1D}) and atomic jump time τ_c . (Reproduced by permission of Academic Press from D. C. Ailion, in ‘Methods of Experimental Physics’, ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

(the dipolar Hamiltonian) in this case is comparable to or larger than the unperturbed Hamiltonian (the Zeeman Hamiltonian). Nevertheless, the condition for the relaxation time minimum in zero magnetic field can still be easily understood. The underlying physical basis for all relaxation time minima is that the most effective relaxation (and thus the minimum) occurs when the principal frequency components of the fluctuating Hamiltonian are comparable to the energy level splitting (in units of $\hbar$). We have seen, for Zeeman relaxation in the laboratory or rotating frames, that this requirement is equivalent to requiring that $1/\tau_c \approx \Omega_0$ or $1/\tau_c \approx \Omega_1$, respectively. For relaxation due to a fluctuating dipolar Hamiltonian in zero field, the energy level splittings $\hbar\Omega_d$ are determined by dipolar interactions. Thus the minimum in zero field occurs when $1/\tau_c \approx \Omega_d$ or $\tau_c \approx T_2$, which is at the onset of motional narrowing. The zero field relaxation time for the case in which quadrupolar interactions can be neglected is commonly called the dipolar relaxation time T_{1D} ,¹⁴ and is also shown in Figure 1.

In order to study the dynamics of the atomic motions, it is desirable to obtain theoretical expressions that relate the measured relaxation time $T_{1\rho}$ or T_{1D} to the atomic jump time τ_c throughout the temperature range of observations. Experimental procedures for measuring these relaxation times are described in Sections 2.3 and 3.3, respectively. The strong collision theory, originally developed by Slichter and Ailion¹² for low-field relaxation, is not a perturbation theory, but is based on the assumption that sufficient time elapses between diffusion jumps to allow the dipolar and rotating frame Zeeman interactions to cross relax to a common spin temperature between each jump. This temperature is then disturbed by the sudden change in dipolar energy resulting from a jump, but reequilibrates in a time of order T_2 to a new value prior to the next jump. This spin temperature assumption is thus equivalent to requiring that $\tau_c \gg T_2$; hence the strong collision theory will be valid in the ‘rigid lattice’ below both the $T_{1\rho}$ minimum and the temperature for motional narrowing. If the

ADRF process is complete so that B_1 is reduced to zero in the demagnetized state, the ADRF process will have transferred long-range Zeeman order due to spins aligned preferentially along B_{eff} to short-range dipolar order from spins aligned along their individual local fields. A single diffusion jump per spin will then have a major effect on the relaxation so that, in zero B_1 , we should expect $T_{1\rho}$ ($= T_{1D}$ for zero field) to be of order τ_c . In the weak collision regime, much less of the order is dipolar and much more is Zeeman; accordingly, it will take many jumps to relax the magnetization, and $T_{1\rho}$ will be much larger than τ_c . Both these effects are shown in Figure 1.

The actual strong collision result¹² for $T_{1\rho}$ at exact resonance due to dipolar fluctuations of a homonuclear (i.e., having only one nuclear species) system in a field B_1 is

$$\frac{1}{T_{1\rho}} = \frac{1}{T_{1D}} \frac{B_D^2}{B_1^2 + B_D^2} \quad (4)$$

where B_D is the dipolar local field. We see that $T_{1\rho}$ reduces to T_{1D} in the limit as B_1 approaches zero. Note that the local field B_D can be determined experimentally by measuring $T_{1\rho}$ versus B_1^2 for fixed T_{1D} (i.e., at a fixed temperature).

2.3 Experimental Techniques for Measuring $T_{1\rho}$

Essentially all methods for measuring $T_{1\rho}$ start by tipping the magnetization from its original direction (the z direction) to a direction parallel to B_{eff} in the rotating frame, a procedure called spin locking. For exact resonance, the magnetization would then be aligned parallel to B_1 (in contrast to the situation immediately after a $\frac{1}{2}\pi$ pulse, when the magnetization would be perpendicular to B_1). $T_{1\rho}$ can then be determined by measuring the magnetization as a function of time τ in the aligned state, since $T_{1\rho}$ is given by

$$M_x = M_0 \exp(-\tau/T_{1\rho}) \quad (5)$$

where M_x is the height of the FID following the turn-off of the variable length B_1 pulse. Figure 2 shows several different pulse sequences for measuring $T_{1\rho}$.

3 DIPOLAR RELAXATION IN THE LABORATORY FRAME (T_{1D})

3.1 Homonuclear Systems

For homonuclear systems, T_{1D} can be calculated by considering the fractional change in dipolar energy per jump for N jumping atoms with a time τ_c between jumps

$$\frac{1}{T_{1D}} = \frac{N}{\tau_c} \frac{E_{Df} - E_{Di}}{E_{Di}} = \frac{N}{\tau_c} \frac{\langle \hat{\mathcal{H}}_{Df}^{(0)} \rangle - \langle \hat{\mathcal{H}}_{Di}^{(0)} \rangle}{\langle \hat{\mathcal{H}}_{Di}^{(0)} \rangle} \quad (6)$$

where E_{Di} and E_{Df} are, respectively, the dipolar energies before and after a jump. $\hat{\mathcal{H}}_{Di}^{(0)}$ and $\hat{\mathcal{H}}_{Df}^{(0)}$ are, similarly, the secular parts of the dipolar Hamiltonian (i.e., those parts that commute with the Zeeman Hamiltonian), and the angle brackets indicate expectation values. If the system can be characterized by a spin temperature before each jump, the expectation values can be expressed as traces of the quantum

Figure 2 Pulse sequences for measuring $T_{1\rho}$. (a), (b), and (c) all have a spin locking sequence followed by a long rf pulse. The spin locking in (a) consists of a $\frac{1}{2}\pi$ pulse followed by a $\frac{1}{2}\pi$ phase shift. In (b), spin locking is achieved by a π pulse about B_{eff} (at an angle of 45° with respect to the z direction). In (c), B_1 is turned on when the z field (or frequency) is far off resonance, and spin locking is achieved as a result of an adiabatic return to resonance. In (d), spin locking is achieved, as in (a), by a $\frac{1}{2}\pi$ pulse followed by a $\frac{1}{2}\pi$ phase shift; $T_{1\rho}$ is measured by monitoring the FID following short pulses of duration θ . (Reproduced with modifications by permission of Academic Press from D. C. Ailion, in 'Methods of Experimental Physics', ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

mechanical operators, and the following expression is obtained in the high-temperature approximation:²

$$\frac{1}{T_{1D}} = \frac{N}{\tau_c} \frac{\text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)})^2 - \text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)}\hat{\mathcal{H}}_{Df}^{(0)})}{\text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)})^2} \quad (7)$$

This equation can be rewritten as

$$\frac{1}{T_{1D}} = \frac{2(1-p)}{\tau_c} \quad (8)$$

where $1-p$ is a calculable geometrical factor of order unity that characterizes the fractional change in energy resulting from a diffusion jump. Because of this factor, T_{1D} shows a 10–20% dependence on the orientation of the field B_0 relative to the crystal axes, and, furthermore, this anisotropy depends on diffusion mechanism.¹⁵ We also note that T_{1D} is of order τ_c , as we have seen intuitively. Diffusion can be studied by measuring either T_{1D} or $T_{1\rho}$, provided the relaxation rate due to diffusion is greater than the relaxation rate due to other T_1

processes. The condition for observability of diffusion effects is then that $\tau_c < T_1$. Since T_1 values are typically 10^{-3} – 10^3 s, this condition is much less stringent than the condition for motional narrowing ($\tau_c < T_2$).

We should note that the strong collision formula, equation (8), can be used to obtain τ_c from the measured relaxation time, assuming $\tau_c \gg T_2$. BPP-type theories can be used to determine τ_c in the motionally narrowed region where $\tau_c \ll T_2$. In the vicinity of the T_{1D} minimum, neither theory is valid.

3.2 Heteronuclear Systems

A problem arises in the interpretation of T_{1D} measurements for heteronuclear systems in which one nuclear species is diffusing and the others are stationary. For simplicity, consider a system containing two species of comparable abundance and gyromagnetic ratio, whose spin quantum numbers are labeled I and S . Assume further that the I and S spins are in strong contact. (A good example would be the alkali halide LiF, in which every lithium atom is surrounded by fluorines, and vice versa.) The problem is that if the I spins are irradiated and T_{1D} is measured, the result will be the same as when the S spins are irradiated and their T_{1D} measured, independent of which spin is actually diffusing.¹⁶ Hence, from a T_{1D} measurement alone, it would not be possible in this case to determine which species is diffusing. This feature arises because there is normally strong coupling between parts of the dipolar interaction involving different species (i.e., the I – I and S – S dipolar terms are strongly coupled through the I – S interaction). So, if an S spin undergoes a jump, there will be rapid cross relaxation between I – I and S – S terms, which will result in the local heating being transferred rapidly to the entire spin system. Thus, in the strong collision limit, the entire dipolar reservoir is describable by a single temperature prior to a diffusion jump, but either spin species alone is not.

Fortunately, there is a way to determine in a T_{1D} experiment which spin species is diffusing for the case where the S spins are weakly magnetic (small γ_S) compared with the more strongly magnetic I spins (large γ_I). If the relaxation is due to the motion of S spins, T_{1D} will have an enormous anisotropy, whereas for diffusion of I spins the anisotropy will be very small [arising only from the $1 - p$ factor in equation (8)]. A more general strong collision theory,¹⁷ appropriate for heteronuclear systems, shows that, for the case in which the strongly magnetic I spins are diffusing, only the I – I interaction terms need be kept. The resulting expression for $1/T_{1D}$ is similar to equation (8), only with p replaced by p_{II} and τ_c by τ_I :

$$\frac{1}{T_{1D}} = \frac{2(1 - p_{II})}{\tau_I} \quad (9)$$

However, if T_{1D} is due to the diffusion of weakly magnetic S spins then the diffusion produces significant changes in the I – S interaction, with the result that

$$\frac{1}{T_{1D}} = \frac{1 - p_{SI}}{\tau_S} \frac{B_{DIS}^2}{B_{DII}^2} \quad (10)$$

where B_{DIS} and B_{DII} are the I – S and I – I contributions to the dipolar local fields and τ_S is the time between jumps of the S spins. The precise definitions of these local fields and the parameters p_{II} and p_{SI} are given by Stokes and Ailion.¹⁷ equation (10) predicts a strong anisotropy, arising from the

factor B_{DIS}^2/B_{DII}^2 , which is absent for motion by I atoms. The observation of this anisotropy would confirm that the diffusion arises from the motion of weakly magnetic spins. The experimental verification of this idea is shown in Figure 7 in Section 5 below.

3.3 Experimental Techniques for Measuring T_{1D}

There are basically two commonly used methods for measuring T_{1D} , and each involves transferring order to the dipolar system and then monitoring the decrease in dipolar order arising from dipolar relaxation. The first technique consists in following a spin locking sequence by an adiabatic demagnetization–remagnetization cycle of the rf field.⁵ The second consists in creating a state of dipolar order by a pair of phase-shifted pulses and then using a third pulse to monitor the decrease in dipolar order due to the relaxation.¹⁴ Both are shown in Figure 3.

3.3.1 Adiabatic Demagnetization in the Rotating Frame (ADRF)

This method, illustrated in Figure 3(a), is similar to the methods for measuring $T_{1\rho}$, shown in Figure 2(a)–(c), except that spin locking is now followed by an adiabatic demagnetization of B_1 to zero followed a variable time later by an adiabatic remagnetization, so that the NMR signal can be measured. The adiabatic demagnetization transfers order from Zeeman order in the rotating frame to dipolar order (in alignment of the spins along the local fields). The subsequent remagnetization converts the remaining dipolar order (not destroyed by the dipolar relaxation) back to Zeeman order, where it is observed in the form of an FID following the turn-off of the rf pulse. Dipolar relaxation results in a reduction in this FID.

One limitation of this technique arises from the conflicting requirements that the B_1 sweep be adiabatic yet that it also be

Figure 3 Pulse sequences for measuring T_{1D} . (a) The ADRF sequence showing demagnetization of B_1 following spin locking. (b) The phase-shifted pulse pair sequence. The first two pulses are separated by a time that is approximately T_2 for maximum signal. (Reproduced with modifications by permission of Academic Press from D. C. Ailion, in 'Methods of Experimental Physics', ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

completed in a time short compared with T_{1D} . This limitation makes it difficult to measure a T_{1D} less than about 0.1–1 ms.

3.3.2 Phase-Shifted Pulse Pair

This method, shown in Figure 3(b), avoids the difficulty in measuring a short T_{1D} inherent in ADRF. In this technique, a state of dipolar order is created by applying two closely spaced pulses that are 90° out of phase. The dipolar order is observed by applying a third pulse of arbitrary phase in the (x, y) plane. The dipolar signal that appears after the third pulse is proportional to the time derivative of the FID.

A major disadvantage of this technique is that the maximum efficiency for transfer of order is only about 56%, in contrast to the 100% efficiency theoretically obtainable with ADRF.

In summary, the ADRF technique is superior when measuring longer relaxation times or when $T_{1\rho}$ measurements are also desired, while the phase-shifted pulse pair method is better for very short T_{1D} measurement.

4 DIPOLAR RELAXATION IN THE ROTATING FRAME ($T_{1D\rho}$)

The last paragraph of Section 3.2 described the possibility of using a measurement of the anisotropy of T_{1D} in a single crystal to verify that a weakly magnetic spin species is diffusing. There are two disadvantages of this approach:

1. single crystals are not always available;
2. even though S spins are diffusing, they may not be dominating T_{1D} if they are sufficiently weakly magnetic or low in abundance.

This second feature can be seen in equation (10), since, for $B_{DIS} \ll B_{DII}$, we have $T_{1D} \gg \tau_S$ for weak (S) spin motion. In contrast, for strong (I) spin motion, $T_{1D} \approx \tau_I$. These results arise from the fact that the heat capacities of the terms involving S spins are much smaller than the I – I heat capacities. Accordingly, it may be very difficult, or even impossible, in many cases to study the diffusion of sufficiently weak S spins in a T_{1D} experiment.

In order to determine the diffusing species in a slow motion experiment, it is necessary to identify a parameter that is sensitive to which species is diffusing. If this parameter can be varied by the experimenter then the diffusing species can be identified and studied. Furthermore, for the case of diffusion by spins that are so weakly magnetic as to preclude their study through direct T_{1D} measurement, it is desirable to vary the parameter so as to enhance the temperature change of the entire system resulting from the weak spins' motions. A way to perform such experiments is to observe the dipolar relaxation in the rotating frame of one of the species, say, the I spins. In this frame, only part of the original dipolar Hamiltonian will be secular. The symbol $T_{1D\rho}$ is used for the relaxation time of this secular part of the rotating-frame Hamiltonian, in analogy to T_{1D} , which is the relaxation time for the secular part of the laboratory-frame dipolar Hamiltonian. $T_{1D\rho}$ may be considered to be the dipolar relaxation time in the rotating frame, whereas T_{1D} is the dipolar relaxation time in the laboratory frame. In contrast to T_{1D} , $T_{1D\rho}$ may depend on the angle θ_I between $\mathbf{B}_{\text{eff}}$ and $\mathbf{B}_0$ in the rotating reference frame. For diffusion by the strong I spins, $T_{1D\rho} = T_{1D}$ and is described by equation (9) for all θ_I except near the magic angle θ_m (defined by $\cos^2 \theta_m = \frac{1}{3}$), where there is a

Figure 4 Pulse sequence for measuring $T_{1D\rho}$. The lower part of the figure shows the variation of $\Delta\omega_I = \gamma_I B_0 - \omega_I$, the off-resonance frequency of B_{1I} . (Reproduced with modifications by permission of the American Physical Society from H. T. Stokes and D. C. Ailion, *Phys. Rev. B*, 1978, **18**, 141)

small change.¹⁷ However, for diffusion by weak S spins, the following expression is obtained for $T_{1D\rho}$:¹⁷

$$\frac{1}{T_{1D\rho}(\theta_I)} = \frac{1}{\tau_S} \frac{\cos^2 \theta_I B_{DIS}^2 (1 - p_{SI}) + 2B_{DSS}^2 (1 - p_{SS})}{[\frac{1}{2}(3 \cos^2 \theta_I - 1)^2 B_{DII}^2 + \cos^2 \theta_I B_{DIS}^2 + B_{DSS}^2]} \quad (11)$$

where $1 - p_{SI}$ and $1 - p_{SS}$ are geometrical factors of order unity (analogous to p of the conventional strong collision theory). In contrast to the result obtained in the case of diffusion by the strong I spins, this expression predicts a very strong dependence of $T_{1D\rho}$ on θ_I , which can be observed experimentally, using the pulse sequence described in the next section.

4.1 Experimental Technique for Measuring $T_{1D\rho}$

Figure 4 shows a pulse sequence that can be used to measure $T_{1D\rho}$.¹⁷ A spin locking sequence followed by an ADRF is applied on resonance to the I spins. This step transfers Zeeman order, which was originally along $\mathbf{B}_0$, to dipolar order. A large off-resonance pulse is then applied, which does not change the dipolar order but rather changes its reference frame from the laboratory frame to the rotating frame. After establishing a spin temperature in the rotating frame, the frequency of the rf pulse is then reduced adiabatically toward resonance, thereby reducing B_{eff} and changing θ_I . By reversing this sequence, the remaining order is transferred back to laboratory-frame Zeeman order, where it appears as an FID following the turn-off of the rf pulse. If one increases the time τ in the state at θ_I , the magnitude of the resulting FID will be reduced, owing to $T_{1D\rho}$ relaxation. A plot of magnetization versus τ on a semilogarithmic plot will yield a straight line of slope $-1/T_{1D\rho}(\theta_I)$. To vary θ_I , one merely needs to vary the frequency of the pulse (and thus b_2) in the variable time interval τ .

5 EXPERIMENTAL RESULTS USING ULTRASLOW MOTION TECHNIQUES

Ultraslow motions have been widely studied in the last 30 years, generally via $T_{1\rho}$ and T_{1D} measurements. It would be impossible in this article to summarize all the applications. Instead, just a few examples will be given to confirm various

Figure 5 $T_{1\rho}$ versus reciprocal temperature in metallic lithium, with $B_1 = 1.3 \times 10^{-4}$ T. (Reproduced with modifications by permission of the American Physical Society from D. C. Ailion and, C. P. Slichter, *Phys. Rev.*, 1965, **137**, A235)

features of the previous discussion and illustrate the kinds of additional information that may be obtained from such measurements.

Figure 5 shows the original $T_{1\rho}$ data of Ailion and Slichter¹⁸ in metallic lithium. The principal feature is that the $T_{1\rho}$ minimum is symmetric and occurs at the onset of motional narrowing. Furthermore, the minimum value of $T_{1\rho}$ is within an order of magnitude of T_2 , as expected from the strong collision theory. Figure 6 shows a plot of the atomic jump time obtained from the experimental $T_{1\rho}$ values, using the strong collision theory. As can be seen, the data exhibit Arrhenius behavior over eight orders of magnitude, and correspond to extremely slow diffusion (of the order of one atomic jump per second) at the lowest temperatures.

Figure 7 shows the verification of the prediction of a very strong anisotropy in T_{1D} described in Section 3.2 for a system having diffusion dominated by weakly magnetic spins. These measurements were performed on a single crystal of KF doped with 0.1% CaF_2 . In this case, mobile potassium vacancies are created to compensate for the extra charge of the Ca^{2+} . We thus have a case in which the diffusion of weak spins (potassium) dominates T_{1D} (of fluorine). The solid curve is the calculated anisotropy of the local field factor of equation (10).

Figure 8 shows experimental verification of the strong collision theory for $T_{1D\rho}$. The sample used in this experiment is the same KF:0.1% CaF_2 single crystal used for the data of

Figure 7. The curve is calculated from equation (11). All the strong dependence of $T_{1D\rho}$ on θ_I (described earlier) appears, thereby indicating that the weak S spins (in this case, ^{39}K) are diffusing rather than the strong I spins (^{19}F here).

A possibly important potential application of this $T_{1D\rho}$ technique is the study of impurity diffusion. In this case, the S spins are weak because their concentration N_S is small (but γ_S may be large). As in the case of small γ_S , diffusion by the weak S spins should again be characterized by a sharp dip in $T_{1D\rho}$ at the magic angle. For this application to be fruitful, an abundant, easily observable I spin species must exist and be in good thermal contact with the S spins. However, it has been shown¹⁹ that nonadiabatic effects will also give rise to a dip in $T_{1D\rho}$ at the magic angle, which could mask the effect of the S spins' diffusion. Nevertheless, by appropriately modifying the 'adiabatic' sweeps of Figure 4, these effects can be minimized.¹⁹

An interesting new application of ultraslow motion NMR has been developed²⁰ to study the ultraslow hopping of selenium atoms between two sites in crystalline Se having well-resolved separate NMR lines. By selective excitation, one of the lines is saturated. Then, as the ^{77}Se atoms jump between the two sites, the magnetization of the previously saturated site builds up and the magnetization of the previously unsaturated site decreases. By measuring the time constant for these decays, the jump time τ_c and the diffusion constant D can

Figure 6 τ_c versus reciprocal temperature in metallic lithium. The experimental points were obtained from the data of Figure 5 using the strong collision theory in the low-temperature region and the weak collision theory in the high-temperature region. The 'gap' in the middle corresponds to the region around the $T_{1\rho}$ minimum where neither theory is valid. In the high temperature region, values of τ_c obtained from Holcomb and Norberg²¹ were also plotted. (Reproduced with modifications by permission of the American Physical Society from D. C. Ailion and C. P. Slichter, *Phys. Rev.*, 1965, **137**, A235)

both be directly determined. Excellent agreement was found between D measured by this NMR approach and D measured by radioactive tracers. As with the T_{1D} measurements, this technique will be able to observe jump times limited by T_1 for these specialized systems.

6 CONCLUSIONS

The most obvious advantage of the slow motion methods is to extend downward in temperature the range over which atomic diffusion can be studied. As a result, diffusion mechanisms occurring only at lower temperatures can be observed. Moreover, since the effect of diffusion on the dipolar relaxation time will be much greater than its effect on the spin-lattice relaxation time, going to zero field magnifies the relaxation effects, thereby making possible the observation of diffusion whose relaxation effects might otherwise be too weak to be observable. A measurement of the frequency dependence of the relaxation time can determine the relaxation mechanism and can check the validity of the theory used, such as the

Figure 7 T_{1D} anisotropy in KF:0.1% CaF_2 at 227°C. The crystal was rotated about its [110] axis. The curve is the calculated anisotropy of $B^2/D_{II}/B^2/D_{IS}$. (Reproduced by permission of the American Physical Society from H. T. Stokes and D. C. Ailion, *Phys. Rev. B*, 1978, **18**, 141)

assumption of an exponential correlation function, underlying equation (1). $T_{1\rho}$ and T_{1D} measurements greatly increase the frequency range available, since they are effectively very low frequency measurements (of order 10^3 Hz), in contrast to typical T_1 measurements (of order 10^7 Hz). Finally, by having a wider temperature range available, it is possible to observe the onset of other diffusion mechanisms having different activation energies. $T_{1D\rho}$ measurements can be used to enhance the NMR effects arising from the ultraslow motions of weakly magnetic nuclei and, possibly, impurities.

1 INTRODUCTION

Quantum chemical studies are usually carried out on gases and solids where reasonable approximations can be invoked to yield accurate results. This is despite the fact that most important reactions occur in the liquid phase where both dynamics and intermolecular interactions are important. Molecular dynamics simulations are a well established technique for the study of liquids and provide a means of determining structural and dynamic properties as well as understanding the structure of the fluid and dynamics in fluids on a molecular level. Furthermore, the conditions of the system can be precisely controlled, and are not affected by experimental measurement. By combining molecular dynamics simulation with *ab initio* quantum chemical calculation, the range of liquid properties that can be determined is expanded. There are still limitations to the size of the system that can be studied and the timescale over which it can be investigated; however with advances in computational power these limitations will continue to be reduced.

The complexity of the structure and dynamics of liquids also presents difficulties to the experimentalist. The experimentalist must invoke various approximations to interpret the

measurements made on these systems. Often it is difficult to test the accuracy of these approximations using experimental methods. Theoretical investigations using simulation and quantum chemical calculations can thus be used to obtain reliable interpretations of the experimental data.

The difference between the gas phase value and the liquid value is the ‘solvent effect’. Most explanations of chemical reactions and processes are on the molecular level, without a solvent, and any unexpected behavior is often referred to as a solvent effect. A sound knowledge of the solvent effect on various properties is therefore necessary in understanding and predicting chemical behavior. Often the effects of solvents are identified by looking at trends observed in given properties and through development of models. However, because simulations are carried out at molecular level, a real understanding of the influences of the solvent can be obtained using simulations.

In this review we discuss the combined use of simulation and quantum chemical methods to determine the nuclear quadrupole coupling constants, nuclear magnetic resonance (NMR) relaxation times, chemical shifts and J-couplings in liquids. A chapter discussing nuclear quadrupole coupling constants and NMR relaxation in liquids was recently published in Volume 7 of *Theoretical and Computational Chemistry*.¹

The quadrupole coupling energy is the interaction energy between the nuclear electric quadrupole moment and the electric field gradient (EFG) at the site of the nucleus that exists due to the rest of the molecule and its surroundings. The EFG is a traceless tensor, V , and in its principal axes system (α , β , γ) can be represented by two quantities, e.g., equation (1)

$$eq = V_{\alpha\alpha}$$

$$\eta = \left(\frac{V_{\beta\beta} - V_{\gamma\gamma}}{V_{\alpha\alpha}} \right) \quad (1)$$

The axes are chosen such that the components of the EFG tensor have the order $|V_{\alpha\alpha}| > |V_{\beta\beta}| > |V_{\gamma\gamma}|$. η is called the ‘asymmetry parameter’ and $\chi = e^2qQ/h$ is known as the nuclear quadrupole coupling constant (NQCC) where Q is the nuclear quadrupole moment. The nuclear quadrupole moment is a property of the nucleus itself. Since the EFG depends on the electric field around the nucleus, the EFG, NQCC and asymmetry parameter are sensitive to the environment of the nucleus.

Quantum mechanical calculations allow calculation of the EFG at a nucleus and therefore calculation of the NQCC and asymmetry parameter at the nucleus of a molecule is straightforward. However, since quantum mechanical calculations become more expensive in computer-time as the system size increases, the size of the molecule for which these properties can be calculated is limited. For liquid systems, this means that only the effects of a limited number of neighboring molecules (a cluster or supermolecule) can be considered or that the solvent must be treated in an approximate way. Furthermore, in the liquid state the environment of a nucleus is continually changing, and therefore an ensemble of clusters of molecules must be considered. The calculation of the NQCC for liquids using *ab initio* methods is discussed below.

Under extreme narrowing conditions, the spin-lattice relaxation time is given by equation (2)

$$\frac{1}{T_1} = \frac{3}{8} \frac{2I+3}{I^2(2I-1)} \left(\frac{2\pi eQ}{h} \right)^2 \int_0^\infty dt \langle V_{zz}(0)V_{zz}(t) \rangle \quad (2)$$

where I is the nuclear spin, h is Planck's constant and $\langle V_{zz}(0)V_{zz}(t) \rangle$ is the correlation function of the field gradient in the laboratory coordinate system. Defining an effective correlation time, transforming to a principal axis system and using the definitions for the NQCC and asymmetry parameters above, the spin-lattice relaxation time can be expressed as equation (3)

$$\frac{1}{T_1} = \frac{3}{40} \frac{2I+3}{I^2(2I-1)} (2\pi\chi)^2 \tau_{\text{eff}} \left(1 + \frac{\eta^2}{3}\right) \quad (3)$$

Using this relationship, experimental values for the NQCC are often obtained from the measured T_1 and an indirect measurement or estimate of τ_{eff} . Since the value of τ_{eff} is not directly available from experiment, it is often assumed that the rotation is isotropic so that a correlation time can be estimated from the rotational correlation time along a bond or the dipole-dipole relaxation time. The asymmetry parameter cannot generally be determined directly from experiment if the NQCC is unknown, and therefore it is often assumed to be zero or is estimated from experimental or calculated gas phase or solid state values. In many cases these approximations are not justified and need to be tested. It should be noted that, in order to aid comparison between the experimental and computed NQCCs, the ensemble average NQCCs are often computed as roots of the mean square values. Calculation of various relaxation times and their equivalence is discussed in the Results section below, and compared with experimental results where available.

Recently, a new experimental method of determining the liquid state NQCC has been used by Farrar and co-workers who observed a high degree of correlation between the NQCC of a nucleus and its chemical shift.²⁻⁴ These experimental results have been found to be in good agreement with the simulated values.

To make it feasible to carry out calculations of liquid properties and local properties of liquids, like chemical shifts, without using any empirical information some preconditions had to be fulfilled. Computers had to become fast enough for extensive simulations and quantum chemical calculations and methods had (and still have) to be developed for the calculation of these properties with the necessary accuracy. Knowledge in quantum chemistry and in simulations was developed in different groups and had to be exchanged before a combination of the two fields could occur. On the simulation side the tools were available and the computers fast enough for reasonable computations around 1980. Although quite accurate quantum chemical calculations could be performed for molecules at that time, intermolecular interactions, which are of crucial importance for liquids, could not yet be obtained with the necessary accuracy for reasonably large systems. For this purpose quite huge basis sets are usually needed with many polarization functions as well as diffuse functions, but also electron correlation has to be included on a high level in most cases. This is not only true for the interaction energy, but also for electronic properties like electric field gradients (EFGs). It was only at the end of the eighties that quantum chemistry could fulfill these preconditions. For more details on this development see Ref.⁵ Some of the techniques developed are described in the next section.

2 TOOLS FOR CALCULATION OF PROPERTIES OF FLUIDS

Here we consider the tools available for calculation of solvent effects. The methods used can be grouped into three broad categories:

- (1) *Macroscopic treatment of the solvent*: In this approach, the solvent is treated using continuum models or reaction fields. This is the method that is commonly incorporated in quantum chemical packages.
- (2) *Microscopic cluster methods*: In these studies, the solvent molecules are explicitly treated when determining the molecular property of interest (for details see below and Figure 1). The necessary cluster size varies with the property considered as does the way in which the solvent molecule is treated. In some cases the main influence of the solvent molecules on the molecular property being determined is due to electrostatic interactions and therefore the solvent is modeled as a distribution of charges (electrostatic model), however in general the full electronic effects of the solvent should be considered.⁶
- (3) *Car-Parrinello simulations*: In this case the periodic bulk fluid and its dynamics are modeled using quantum chemical calculations on the fly. Various techniques are introduced to account for the periodicity.

We will focus on microscopic cluster methods for the following reasons. Firstly we doubt that studies using the first approach can reach predictive accuracy without including increasingly more microscopic features (so that this approach becomes more like the second category; see e.g., the polarizable continuum model (PCM) by Tomasi and co-workers.^{7,8}) The first approach also needs at least one empirical parameter and therefore will never be able to provide completely theoretical predictions. However, it should be noted that it is currently the only method that can be applied routinely by most scientists, and uses little additional computer time to that required for single molecule (gas phase) calculations. The third category is still very computer time intensive, and few examples of calculations of NMR related properties in liquids exist in the literature at this time. Moreover, in certain cases the density functional theory (DFT) method inherent to it might not yield the required accuracy.

2.1 Cluster Method

The cluster method involves the generation of clusters of molecules, and the treatment of each cluster as a supermolecule for which the required property of the central molecule is calculated using quantum chemistry. The fluid property is then determined from the ensemble average of its value for each of the clusters.

Liquid clusters are obtained using Monte Carlo (MC) simulations or from single configurations ('snapshots') of a classical simulation trajectory formed using molecular dynamics (MD) simulations.⁹ A molecule is randomly selected from the molecules in the MC or MD liquid snapshot, and the configuration of molecules nearby the central molecule is used to form the cluster. This is illustrated in Figure 1. Periodic boundary conditions are generally used to model the bulk fluid. In MC simulations, the liquid configurations are determined by random sampling with the statistics of the ensemble required. MD

Figure 1 A schematic diagram demonstrating how the cluster method is used to determine properties in liquids. Firstly a potential energy hypersurface is determined empirically or using ab initio methods. This is then used in MD or MC calculations of the bulk liquid. Finally, ‘snapshots’ of the liquid are taken and clusters of molecules are used in ab initio quantum mechanical calculations to determine values for the property of interest. Averaging over many snapshots and clusters results in the liquid state value

simulations involve solution of Newton’s equations of motion for each particle in the simulation box and the configurations obtained are representative of the microcanonical ensemble. Modifications to the equations of motion allow other ensembles to be sampled using MD simulations. Both MC and MD simulation techniques are thoroughly described in Allen and Tildesley.⁹

Once clusters have been generated from the snapshots, the properties of the central molecule are determined using the liquid cluster (or supermolecule) as the input structure to a quantum chemical calculation. For example, the deuterium NQCC for an atom in the central molecule is calculated quantum chemically with the cluster input as the structure for the quantum chemical calculation. This is repeated for many clusters sampled from the MC or MD simulation, and averaged to obtain the liquid state property.

Questions that must be addressed when using the cluster method are: how many snapshots of the fluid are required; how many molecules should be included in the supermolecule; how the molecules to be included in the supermolecule should be selected; and for clusters obtained from MD simulations, the time required between snapshots should be considered. Optimization of the number of surrounding molecules to be included in the cluster and the selection criteria are determined by sample calculations, and require a balance between the time taken and the accuracy required. For the properties of interest for this review, it is necessary to carry out a quantum chemical calculation to determine the property of the molecule in the liquid state cluster. The quantum chemical calculations are generally more computer time intensive than the MC or MD simulations, and therefore the number of clusters and their size are restricted. It is also important to optimize the time between snapshots so that convergence to the ensemble average property of the liquid is obtained using the minimum number of calculations.

The cluster method has been used to determine various liquid state properties. Algorithms have been developed to calculate properties including vibrations,¹⁰ NQCCs,¹¹ chemical shifts,¹² J-couplings,¹³ electronic spectra,¹⁴ and EPR (electron paramagnetic resonance) hyperfine couplings.¹⁵ In the last case the solvent is treated only in an electrostatic approximation. These algorithms have been applied extensively since these early papers and extended to study a wide range of liquids.

An approach that is related to the cluster method is the Quantum Cluster Equilibrium (QCE) method. This method has been applied to the calculation of NQCCs in fluids by Ludwig, Weinhold, Farrar and co-workers.^{16–29} The QCE approach uses standard quantum statistical thermodynamics to consider the chemical equilibria existing between the clusters and thus determines the probabilities of observing clusters in the liquid state at the required temperature, pressure and composition of the fluid.²⁷ In contrast to the conventional cluster method discussed above, in this approach all possible clusters that might be expected to be present in the liquid are generated, and the structures of these clusters are optimized using quantum chemical calculations. A canonical ensemble is assumed, and for each cluster the energies, harmonic vibrational frequencies and moments of inertia of the cluster at its equilibrium structure are calculated using quantum mechanics. Hence partition functions for each cluster and the total partition function can be determined. The cluster populations obtained are then used to determine expectation value of the property of interest, such as the NQCC. The NQCC of nuclei in the liquid state of water,¹⁹ formamide,¹⁶ N-methylformamide,¹⁷ N-methylacetamide,¹⁸ ammonia²⁴ and ethanol²⁶ have been determined in this way. Thermodynamic and structural properties, vibrational frequencies and chemical shifts have also been calculated using the QCE method.^{16,18,20,22–26,28,29} Limitations of the QCE method are discussed by Ludwig et al.¹⁹ and include the treatment of the low-frequency intermolecular vibrational modes by a harmonic approximation, approximation of the

molecular volume, the possibility of excluding significant clusters in the ensemble and the use of a mean-field approximation to treat residual cluster-cluster interactions which requires an empirical parameter. Advantages over the cluster method where clusters are selected from a molecular dynamics simulation, are that the accuracy does not depend on the accuracy of a model potential energy function and generation of the clusters takes negligible time.

2.2 Dynamic Properties

The above cluster method is very general and can be applied to calculate most static properties at any phase point. Similarly the QCE method is very general, although it may be difficult to extend it to non-hydrogen bonded systems and some problems exist with higher order temperature derivatives.²⁸ However, both methods are only able to calculate static properties. This is true even if the cluster method is combined with molecular dynamics (MD) simulations, because the simulation is only used to obtain the static clusters. Hence, for relaxation times or other dynamic properties other techniques are needed.

‘Mechanical’ dynamic properties like transport properties can be obtained by integration of the underlying time correlation function in equilibrium simulations (Green-Kubo integrals). Relaxation times are obtained similarly (see equation (2)), the only problem is the need of additional electronic properties like field gradients (for quadrupolar relaxation, which we take as an example in the following) at each step of the simulation. The required field gradient can in principle be calculated quantum chemically at any position of the simulation cell and at each time step. However, this is not practical today. Even if one reduced the ensemble to a cluster by use of a cutoff radius, the high accuracy needed in the quantum chemical calculation would make it unfeasible to perform such a calculation at each step. The same problem would occur if one desired a quantum chemical calculation of the intermolecular potential (i.e., the forces) at each step. The usual approximation invoked in this case is to calculate pair potentials only and to assume pair additivity for the simulation. The same approximation is possible for the electronic property of interest. That means that for quadrupolar relaxation, for example, a pair EFG hypersurface is calculated firstly, e.g., in the case of Neon a one-dimensional curve of the EFG at one Neon nucleus induced by the other Neon atom as a function of the distance. This pair function, obtained pointwise from quantum chemical calculations, is fitted to an analytical function and implemented in the simulation program to obtain the property at each step of the simulation (for details see Refs.^{30–32}). Another possibility would be to use Car-Parrinello types of methods³³ and to calculate the electrical property on the fly with the same density functional theory (DFT) procedure as used for the potential. To our knowledge this has not yet been done.

There are several levels of difficulty in obtaining the EFG in a liquid. The first calculations in the eighties were all for atomic ions^{30–32,34} or a rare gas³⁵ in aqueous solutions. In these cases the EFG is completely intermolecular and can be obtained with relatively crude approximations like Hartree-Fock (HF) calculations with small basis sets or even classical electrostatic models³⁵ as the solvent is very polar. The next step was the treatment of the relaxation of ²¹Ne in liquid Neon.³⁶ Here the solvent is also very simple, but one already

needs very high-level quantum chemical calculations as we are dealing with a pure dispersion interaction. A step further leads us to molecular systems. To our knowledge the quadrupolar relaxation of a molecular nucleus has not yet been studied computationally. In our groups we are currently doing this for the system D₂O/DMSO, but with an empirical force field. For this polar system with deuterium as the nucleus of interest, a HF calculation yields a sufficiently accurate EFG. The only calculated relaxation time for a molecular system using quantum chemistry we are aware of is a dipolar relaxation, which was calculated in a slightly different manner and will be discussed in the Results section.³⁷

2.3 Quantum Chemical Tools

If one is interested in obtaining completely non-empirical predictions, the interatomic potential has to be calculated quantum chemically. Except for very polar systems, dispersion energy always has a major contribution to the potential energy. This means that one has to include electron correlation on a reasonably high level and use quite large basis sets. If this is not possible one might use an empirical potential. The importance of inclusion of electron correlation for the calculation of the electric property applies equally when using a pair surface and using clusters. However, recourse to empirical approximations is usually not possible. This is the main reason why such calculations only became possible in the last decade. In the Results section we will show how improvements of the quantum chemical calculations influence the results for the example of the quadrupolar ²¹Ne relaxation. In the cluster method one typically needs 50 to 100 quantum chemical calculations for clusters that typically consist of 5 to 15 monomers. For an electric property surface one typically needs several hundred pair calculations. This is currently only possible for reasonably small monomers, but even then it would barely be possible with the methods available two decades ago. There were two developments in the eighties that assisted these calculations greatly. One was the improvement of DFT by the introduction of the generalized gradient approximation and some additional developments, and the other was the development of special basis sets to calculate local properties in a molecule or cluster.

The latter method is based on the idea that a local property like an EFG or a chemical shift needs a very accurate basis set close to the location of interest, smaller basis sets in the next neighborhood and only small basis sets far away (note that this is a similar philosophy to that which has been applied in the so called QM/MM methods, where distant molecular parts are only treated by molecular mechanics). We developed this strategy under the name Basis sets of high local quality in the early eighties for EFG calculations and showed in many papers that it works excellently for deuterium,^{38–43} but also reasonably well for other nuclei like N,^{44,45} Li,⁴⁶ O⁴⁷ and S.^{48,49} Chesnut et al. applied the same concept under the name Locally dense basis sets to chemical shifts,^{12,50–54} whereas Hinton et al.⁵⁵ call it Attenuated basis sets. Other groups have also applied it to chemical shifts.^{37,56} DiLabio et al.^{57–61} and Pratt et al.⁶² showed recently that the concept also works well for bond and dissociation energies, whereas Chesnut and Byrd⁶³ use it to get correlation energies in an additive scheme.

The DFT method, although much older, improved in the mid-eighties with the introduction of the generalized

gradient approximations and it started a triumphant advance in chemistry. Due to its lower scaling it is particularly suited to large systems such as the clusters in the cluster method. Bailey has shown recently in several papers,^{64–68} that it yields excellent EFGs for nuclei like D, B, O, N, S and Ge. This new finding has not yet been applied to liquid calculations. As shown by Schwerdtfeger et al.,⁶⁹ its suitability needs to be checked for each nucleus. The sum-over-states density functional perturbation theory method is an important method for the calculation of magnetic properties that was developed by Malkin et al.^{70,71} in the last decade.

3 RESULTS

3.1 Nuclear Quadrupole Coupling Constants

Some early studies of monatomic ions and atoms have been carried out with the goal of investigating quadrupole relaxation, and in these cases the NQCC was calculated assuming pair additivity (see below).

In the mid-1980s the first ab initio calculations of the NQCC and asymmetry parameter of deuterium (^2H or D) and oxygen (^{17}O) nuclei in water were carried out. The electric field about the isolated water molecule is not symmetric, therefore the EFG at each nucleus is non-zero and changes in the structure of the water molecule will influence the EFG. In addition, the strong intermolecular interactions in hydrogen bonded liquid water mean that the influence of neighboring molecules in the cluster will be important. Hence, liquid water is an interesting candidate for study. The first ab initio predictions of the NQCCs of liquid water did not use a cluster approach, but assumed that the water molecule was hydrogen bonded 75% of the time.^{72,73} In the early 1990s the cluster approach was used

to determine the D and ^{17}O NQCC and asymmetry parameters in liquid water.^{11,74,75} A number of potential models were used in MD simulations to generate clusters, including the ab initio MCYL potential energy surface of Lie and Clementi.⁷⁶ The NQCC was determined at the HF level, i.e., NQCCs for liquid water were determined by purely computational methods with no empirical parameters. Furthermore, a model for the dependence of the deuterium NQCC on the structure of the water cluster was developed¹¹ and has been used to identify a slight temperature dependence of the deuterium NQCC⁴³, consistent with experimental results. The HF ab initio calculations of the deuterium NQCC in single molecules indicate that a systematic error of 3% is expected due to limitations of the ab initio method used,⁴¹ therefore the best estimate of the NQCC should be corrected by this factor. In Figure 2 the temperature dependence of the experimentally determined NQCC is compared with that obtained using the model developed in Ref.¹¹ and corrected by the error due to the ab initio calculations. The recent experimental results are in good agreement with the calculated values.^{43,75} When the calculated value of the NQCC of ^{17}O , $\chi = 8.9 \pm 0.3$ MHz, was published in 1993 the value was somewhat higher than the best experimental results at that time. However, as is shown in Figure 3, the most recent experimental result that we are now aware of⁴ is in excellent agreement with the calculated value. Rather than determine the NQCC directly from relaxation times, Ropp et al.⁴ use the observed correlation between the chemical shift and the NQCC ($R^2 = 0.99$ for deuterium and $R^2 = 0.96$ for ^{17}O) for its determination and therefore do not rely on the assumptions necessary in the earlier works. For a review of the early calculations of NQCCs in the liquid state see.⁴³

Alternative approaches for the computational determination of the deuterium and ^{17}O NQCC and asymmetry parameter in

Figure 2 Experimental and calculated deuterium NQCCs. The results before 1980 have open symbols, whereas the more recent ones have crosses or star symbols. The symbol key for the experimental values is ordered by the year of publication. The calculated values are from Eggenberger et al.¹¹ The simulations were performed with the MCYL ab initio potential. The values were obtained from a model (see Ref.¹¹) which lead to statistical errors <1 kHz and they were empirically corrected, i.e., reduced by 3% such that the gas phase value is in agreement with experiment

Figure 3 Experimental and calculated NQCCs for ^{17}O in water versus the year of publication. All but one result (black square) were determined experimentally (open squares). The early results of Glaser¹⁰⁶ (labelled 1) were criticized by later authors, although it is in good agreement with the calculated value of Eggenberger et al.⁷⁴ (labelled 7) and the newest experimental value,⁴ labelled 8. The other experimental results are from the following references: 2 is from Ref.¹⁰⁷, 3 is from Ref.¹⁰⁸, 4 is from Ref.¹⁰⁹, 5 is from Ref.¹¹⁰ and 6 is from Ref.¹¹¹

liquid water have been taken by Moriarty et al.⁷⁷ and Ludwig et al.¹⁹ Moriarty et al. used HF theory to treat the central water molecule within a statistical mechanical bath of water molecules. The configurations of the liquid water cluster were generated using MC simulations. Their best results include configuration interaction and a zero point energy correction, and for deuterium $\chi = 228.2$ kHz and $\eta = 0.1605$. For ^{17}O , $\chi = 11.04$ MHz and $\eta = 0.8237$. Ludwig et al.¹⁹ used the QCE approach and for deuterium in liquid water obtained $\chi = 264$ kHz and $\eta = 0.134$. For ^{17}O , $\chi = 8.4$ MHz and $\eta = 0.855$.

Experimental studies have shown an interesting and surprising behavior for the deuterium NQCC of water in a mixture of water and DMSO.⁷⁸ Recently, we have shown that this behavior is not reproduced in computational studies using the cluster approach.⁷⁹ Experimental determinations of liquid state NQCCs are not straightforward and various approximations must be employed in interpretation of the experimental results. The disagreement between experiment and computation suggests that one of these approximations is not valid, but also may be due to deficiencies in the simulations. Studies are underway to clarify the current situation.

The cluster approach has also been used to calculate ^{17}O NQCC in liquid CO_2 .⁸⁰ The results were in excellent agreement with experiment and it was found that the NQCC is constant over a wide range of densities and temperatures between 298 K and 325 K, in the liquid and supercritical phase. The asymmetry parameter has a negligible contribution in equation (3). The same approach was used by Laaksonen and Wasylishen⁸¹ to determine the ^{14}N and deuterium NQCC of liquid ammonia and their temperature dependence. The ab initio calculations of the NQCC were carried out at the MP2 level with a 6-31 G** basis set and at this level of theory the gas phase deuterium NQCC is overestimated by approximately 10% and the ^{14}N NQCC by approximately 4%. For liquid ammonia, the calculated ^{14}N NQCC at 271 K was

$\chi = -3.67$ MHz and at 197 K $\chi = -3.43$ MHz. For the deuterium nucleus, $\chi = 264$ kHz at 271 K, $\chi = 255$ kHz at 197 K and the asymmetry parameter is insensitive to temperature with $\eta = 0.13 \pm 0.01$ over the range of temperature studied. These values are approximately 13% higher than recent experimental results for the deuterium NQCC in liquid ammonia of Hardy and Zeidler⁸² who obtained $\chi = 232$ kHz at 273 K. However, accounting for the 10% error due to limitations of the ab initio calculations results in excellent agreement between the computational and theoretical values. Furthermore an increase in the deuterium NQCC with temperature at a rate of 0.1 kHz K^{-1} was observed in both the experimental and computational results. Merkling et al.⁸³ have calculated the deuterium NQCC of the hydroxy-deuterium of methanol in carbontetrachloride at various compositions. Experimental studies show that the NQCC decreases with an increase in the methanol mole fraction of 0.1 after a maximum at that point. Although the computed values also show a decrease with increase in the methanol mole fraction, no maximum is observed. Furthermore, the computed NQCC values are 2–20% higher than the experimental results.

Ludwig, Farrar and Weinhold have carried out QCE calculations of NQCCs for a range of liquids. As discussed above, the QCE algorithm was used to determine the deuterium and ^{17}O NQCC and asymmetry parameter in liquid water with results that are in fair agreement with experiment. Ludwig, Farrar and Weinhold use a Calibrated quadrupole moment to correct the cluster results against the single molecule value, so no correction due to inadequacies of the ab initio calculation are necessary.¹⁹ The temperature dependencies of the NQCC and asymmetry parameter of the carbonyl deuterium, oxygen, amide trans deuterium and nitrogen nuclei in liquid formamide were also determined by Ludwig, Farrar and Weinhold.¹⁶ The trends in the temperature dependencies are found to be in good agreement with experimental results,^{3,16,84} however there are

significant discrepancies between the absolute values of the NQCCs (up to approximately 10%). The more recent experimental results for the carbonyl deuteron and the trans amide deuteron³ show deviations of 3% from the theoretical results, while deviations of up to 13% are observed between these experimental results and the earlier results of Ludwig et al.^{16,84} This indicates that the early experimental results may contain systematic errors. The new experimental results³ are determined using the correlation between the chemical shift and NQCC whereas the earlier experimental results used relaxation data.^{16,84} The differences between the two sets of experimental values highlight the difficulties in interpretation of the experimental data for determination of liquid state NQCCs. Studies on the temperature dependence of the NQCC and asymmetry parameter of nuclei in N-methylformamide¹⁷ and N-methylacetamide¹⁸ have also been carried out. Again, the temperature dependence of the ¹⁴N and deuterium NQCC are in good agreement with the qualitative behavior of the experimental results, however the absolute values differ. NQCCs in ammonia have also been determined using the QCE method,²⁴ however deviations from experiment suggest that the clusters selected in the study may not be an accurate representation of the liquid.⁸² Recently the QCE method has been used to determine the NQCCs of liquid ethanol²⁶ in the temperature range 250–350 K. The results obtained are in good agreement with experiment. In general, the temperature dependence of the NQCC that is observed in experiment can be reproduced using the QCE method. However, the absolute values of the NQCCs often differ considerably suggesting a systematic error in the experimental results or the computations. The necessity of invoking approximations in the experimental interpretations, and the variations in experimental results suggest that some of the experimental determinations are in error.

Using the cluster method accurate predictions for the NQCC of various nuclei and liquids have been obtained. The NQCC generally needs to be adjusted due to errors in the *ab initio* calculations of the gas phase NQCC,⁴³ or equivalently a Calibrated quadrupole moment needs to be used.¹⁹ These errors can often be quantified due to the availability of accurate experimental values of the NQCC for single molecules, but suggest that improvement of the *ab initio* cluster calculations is an important step in obtaining NQCCs using purely computational methods. The use of DFT may alleviate these difficulties due to its ability to determine accurate values of the NQCC in an efficient manner. Bailey and co-workers have recently used DFT to calculate NQCCs of gas phase molecules with considerable success^{64–68} however these are yet to be used in liquid state calculations as far as we are aware.

3.2 Relaxation Times

The history of a combined application of simulations and quantum chemical calculations for a better understanding of relaxation phenomena started just 20 years ago with an investigation on quadrupolar relaxation. In 1981 Engström and Jönsson³⁰ published a paper on the EFG fluctuation at the nucleus of a lithium ion in dilute aqueous solution. The results were obtained from Monte Carlo simulations on clusters of different sizes and used an EFG curve obtained from self consistent field (SCF) calculations. They used a pair approximation for the EFG, as is usually done for the potential and

estimated the error due to this approximation to be smaller than 5 to 10%. The estimate was based on calculations for $\text{Li}^+ + 2\text{H}_2\text{O}$ configurations. They found interesting information that contributed to the detailed understanding of the relaxation mechanism, e.g., that the first solvation shell is the main contributor, that the lateral motion of the water molecules in this shell is much more important than the rotational motion, and that an electrostatic approximation for Li^+ is not satisfactory due to the close neighbourhood of this shell to the central ion. Although they analysed the time scale of the fluctuations, they were not yet able to calculate the relaxation time itself, as they used the static MC method rather than the dynamic MD method. This work was extended a year later to the Na^+ and Cl^- ions and for the latter case it was found that rotational motion of the water molecules has a similar influence to the translational motion.³¹ In 1984 the work was further extended to MD simulations yielding, for the first time, relaxation times from first principles.³² The dynamics clearly showed that the decay of the EFG time correlation function is not mono-exponential, and the simulated relaxation rate (experimental values in parenthesis) for Li^+ was 0.007 s^{-1} (0.027 s^{-1}), for Na^+ was 22 s^{-1} (16.6 s^{-1}) and for Cl^- was 41 s^{-1} (25 s^{-1}), i.e., in good agreement with the exception of Li^+ . This work was recently extended by Odelius and Kowalewski.⁸⁵ They studied the dipole-dipole relaxation for Li^+ and were able to reproduce the experiment quite accurately, whereas the temperature behaviour of the quadrupolar relaxation with the EFG surface from Engström et al. showed a similar deviation as before with the deviation being a factor of 3 to 4 of the experimental value. The same system was also studied by Baumert et al.⁸⁶ by MD with an electrostatic approximation for the EFG, but in addition these authors compared the quadrupole couplings obtained from this approach and the *ab initio* cluster approach, finding a deviation up to a factor two and indirectly confirming the failure of the electrostatic approach for this system.

At approximately the same time that the early work of Engström et al. was performed, Schnitker and Geiger³⁵ used similar techniques in an MD study of the quadrupolar relaxation of ¹³¹Xe in water (published for the first time in a diploma work in 1982), although they applied an empirical potential and an electrostatic approximation for the EFG. The technique applied differs from that of Engström et al. insofar as the simple electrostatic model permits calculation of the EFG ‘on the fly’, i.e., in each step of the simulation, rather than requiring calculation of a pair EFG surface before the simulation and use pair additivity. In many respects they came to similar conclusions, e.g., that the decay is not mono-exponential and that the first hydration shell is mainly responsible for the relaxation. In contrast to simpler theories they found agreement between simulated and experimental relaxation rates roughly within the experimental uncertainty.

With a similar method Luhmer et al.^{87,88} calculated the quadrupole relaxation of ¹³¹Xe dissolved in benzene. They found that no complex formation was necessary to explain the relaxation as assumed by some authors previously, but that the molecular rotation of the quadrupole of benzene around a C_2 axis can reproduce the experimental relaxation nearly quantitatively. The influence of the cross-correlation was found to be negligible and the relaxation rates between 100 and 150 s^{-1} were in good agreement with experiments ($190\text{--}230 \text{ s}^{-1}$). These results are compared in a study of the dipolar relaxation of ¹²⁹Xe in benzene in a later paper⁸⁹

where, in contrast to the quadrupolar relaxation, it is found that the translational motion is more important than the rotation. Additional results of similar quality were obtained with the same approach for ^{131}Xe in 1,3- and 1,4-dioxane,⁹⁰ in tetrachloride, acetonitrile, and methanol,^{91,92} and in acetonitrile also for ^{21}Ne and ^{83}Kr .⁹³

The only study of a relaxation time in pure water we are aware of is by Lippens et al.⁹⁴ They studied the dipolar proton relaxation of liquid water in an empirical approach with the SPC and a polarizable SPC model. The relaxation time is 75% larger than the experimental value, a detailed analysis shows however, that the intermolecular part is quite accurate.

All the simulations discussed up to now are in agreement with experiment to within approximately a factor of two. The authors of these studies usually accept this as a good agreement. There are several problems with approximations (like the difficulty in obtaining a good estimate for the Sternheimer shielding), which make it difficult to get more accurate values in this approach. Linse and Halle³⁴ argue that continuum-solvent theories cannot give good results. In a study of noble gases in organic solvents Vaara et al.⁶ conclude that a pure electrostatic model is not good enough. These conclusions could be one reason to turn to methods that calculate the relaxation time from first principles, as performed first by Engström et al.³² with an EFG obtained from SCF calculations. Although for more accurate values one should include electron correlation.

The quadrupolar relaxation in liquid ^{21}Ne has been treated from first principles in three papers,^{36,95,96} which show the progress of the methods within a few years. This system is more difficult to handle because the EFG is completely intermolecular, but no electrostatic interaction occurs and hence electrostatic models are not possible. In addition the interaction is purely dispersive, i.e., the potential as well as the EFG has to be calculated with high-level correlation methods. In 1993 Eggenberger et al.³⁶ obtained values with deviations less than 20% from experiment. Although the authors discuss different error sources which might lead to fortuitous cancellations, the good agreement with experiment seduced them to assume that the error was not more than 10%, not including the error due to quantum effects at the temperatures below 33 K. Improved work in 1998 by Kirchner et al.⁹⁵ showed that the property is much more sensitive to changes in both the EFG and the potential than assumed. A better potential reduced the relaxation times by one third, whereas improving the EFG in addition increased the values by approximately 50% bringing them back close to the original results. In contrast, three-body and quantum effects were shown to induce changes of only 5 to 10% each. As a result the authors assumed that the results had, by far, not yet converged. Two years later Halkier et al.⁹⁶ were able to reach convergence (not including many-body and quantum effects) with coupled cluster calculations on the CCSD(T) level and huge basis sets for the EFG as well as for the potential. At 41 K a best estimate including quantum effects by a perturbational method is approximately 15% lower than the experimental value. Additional insights were gained by Kirchner et al.⁹⁵ from a detailed study of the self- and cross-correlation functions and a semi-quantitative model of the mechanism. There are two main effects that induce the relaxation. First an exchange between first shell and outer shell atoms with a correlation time of 5 to 0.5 ps for temperatures between 25 to 300 K and a fast process,

where an outer shell atom hits a first shell atom towards the central atom with a correlation time of 200 to 50 fs for the same temperature range. The first process is a random walk process showing a linear relation with the inverse temperature, whereas the second is a linear movement (vibration), inversely proportional to the square root of the temperature.

From the experience with the quadrupolar relaxation of liquid neon, the present authors believe that most of the work on spherical symmetric systems, where the EFG is completely intermolecular, probably profited from error cancellations. For the Li^+ ions the cancellation was perhaps just not as effective as for other systems.

The most complicated system investigated by similar microscopic techniques to those discussed here was published by Scheurer et al.³⁷ in 1999. They studied the shielding anisotropy, dipolar relaxation and nuclear Overhauser effect values in the protein ubiquitin. MD simulations for the protein molecule in water were performed with a molecular mechanics force field. 625 snapshots of the trajectory were taken to obtain dynamic information of the magnetic properties from SOS-DFPT (sum-over-states density functional perturbation theory) calculations. Model groups or simple charges replaced part of the molecule, whereas the quantum chemical part was treated using basis sets of high local quality. They were able to reproduce experimental relaxation times and nuclear Overhauser effect values to within 10 to 20%. In our group we are currently working on the deuterium quadrupolar relaxation of the water/DMSO system, where we previously obtained the NQCC (see above).

3.3 Chemical Shieldings

Whereas in most previous sections a comparison between different results was difficult, we are here in the fortunate situation that most work on chemical shieldings up to now was performed on water at ambient conditions. A collection of results, all published between the years 1994 and 2000, is presented in Figure 4 for protons and in Figure 5 for ^{17}O . The range of the results is as large or even larger than the solvent effect itself. We will discuss the different methods here. In this section we use shift for the difference between the liquid and gas isotropic chemical shielding, i.e., no absolute shieldings are discussed here.

Method 1 is the reference interaction site model combined with self consistent field calculations (RISM-SCF approach) by Hirata and co-workers.⁹⁷ The method is in principle non-empirical and treats the solvent and the solution on an atomic level. However this first application is based on an empirical potential (TIP3P-like). The authors discuss ways to improve the method, which evidently is not yet predictive.

Method 2 is a continuum method where the water molecule is immersed in a dielectric medium. The result is again unsatisfactory with the wrong sign for the ^{17}O gas-liquid shift as above. This work by Mikkelsen et al.⁹⁸ is cited because they extended this model (Method 3) by taking a cluster with a first solvation shell which as a whole was immersed in a dielectric medium. The results improved greatly with the protons yielding a nearly perfect agreement with experiment, but for the oxygen the solvent effect is only approximately half the experimental value. The authors suggested that their somewhat accidental result (using just one fixed first solvation shell) could be improved by selection

Figure 4 The solvent effect of water on the proton shift in water calculated with different methods (see text)

Figure 5 The solvent effect of water on the ^{17}O shift in water calculated with different methods (see text)

of clusters from simulations. This was indeed done by other authors, who also showed that the range of shifts obtained from different clusters is huge, making the method by Mikkelsen et al. not very reliable. The same authors published similar work on H_2S and HCN .⁹⁹ Method 4 by Nyman and Åstrand is a perturbational method that again does not yet give satisfying results.

Method 5 is the first work applying the cluster method. Chesnut and Rusiloski¹² used the CFF-91 force field for the simulation and the gauge including atomic orbital (GIAO) coupled HF method for the shift calculations applying locally dense basis sets. Their statistical error bars are quite large.

The solvent shifts are roughly half the experimental shifts. One reason for the inadequacy of the results might be the general force field applied here in contrast to most other work where potentials calibrated for water were used. It is hard to judge whether the quality of the quantum chemical method is adequate for the intermolecular contributions.

In method 6 by Cui and Karplus¹⁰⁰ a QM/MM method was applied to this problem for the first time. The flexible TIP3P model by Dang and Pettitt¹⁰¹ was applied in the MD simulations. DFT calculations on the B3LYP/6-311G(d,p) level were performed for 100 clusters. Their results include only the intermolecular component, which however are responsible for 90%

and 80% of the shift for protons and oxygen, respectively.¹⁰² The results given as method 7 were obtained with a larger basis set, but for 10 clusters only.

The next three methods are by Malkin et al.¹⁰² and apply the cluster method with different potentials. The quantum chemical method for the shift calculation is in all cases the SOS-DFPT with an IGLO-III basis set.¹⁰³ Method 8 uses the Dang and Pettitt potentials, as do methods 6 and 7. Method 9 corresponds to the potential by Bopp et al.¹⁰⁴ and method 10 to the MYCL potential of Lie and Clementi⁷⁶ obtained from ab initio quantum chemical calculations. Hence method 10 is the first one that uses no empirical information (with the exception of a very general empirical parameter in the SOS-DFPT method). The values presented in the figures were obtained from 10 clusters consisting of 9 water molecules. Test calculations showed that the absolute values of these shifts would increase by approximately 0.2 ppm and 1.2 ppm for H and ¹⁷O, respectively, if the cluster size was increased to 13 water molecules. The small number of clusters leads to relatively large statistical errors (the bars in the figures are standard errors). In fact all three values are identical within two standard errors and two of them for oxygen and one for hydrogen, respectively, also agree with the experimental shift within two standard errors. Due to the small number of clusters it could be that the configurations do not represent the distribution of configurations in the liquid well enough. The shifts are in fair agreement with the experimental value for oxygen, the agreement is worse for protons. It would be interesting to repeat this work with today's computer power for more clusters to give a better insight into the role of the potential.

Finally, method 11 is the recent work of Pfrommer et al.¹⁰⁵ This is probably the first application of Car-Parrinello simulations to the calculation of magnetic properties of liquids. Their calculation of chemical shieldings with the BLYP functional is not limited to clusters of a certain size, but is performed for the ensemble consisting of 32 molecules with periodic boundary conditions. The result for oxygen is in excellent agreement with experiment, but the absolute value of the proton shift is approximately 1.6 ppm too large. The statistical errors are very small, approximately the size of the rectangle in Figure 4 and only half that size in Figure 5.

Cammi et al.⁷ tested the newly developed PCM-GIAO method on the ¹³C, ¹⁵N and ¹⁷O shifts for the molecules CH₃CN and CH₃NO₂ in water with good success and gave a critical evaluation of the method. Ludwig et al.¹⁸ applied the QCE method to liquid N-methylacetamide and obtained excellent agreement with experiment for the temperature dependence of the chemical shifts of H, ¹⁷O and ¹⁴N and fair agreement of the shifts themselves for H and ¹⁷O.

We would like to make a few concluding remarks on this comparison of calculated with experimental shifts and between different methods. The experimental error is not known, but could be sizeable. The calculations do not include rovibrational corrections in an adequate manner, but it is assumed that their classical treatment is sufficient as it will almost cancel when the difference between liquid and gas value is calculated. There are still quite a few different error sources which might cancel, like the limited quality of the potential applied in the simulation, the limited basis set and the limited treatment of correlation in the calculation of the chemical shielding, limited representation of configuration space and limited cluster size.

Nevertheless the results show a great improvement in the last decade and it can be expected that such calculations will reach predictive quality in the coming decade.

3.4 J-Couplings

We are aware of only two recent papers on calculations of J-couplings in the liquid. Mikkelsen et al.⁹⁹ use a model where the solvent is represented by a dielectric medium, to study its influence on the HH⁻ and HS⁻ coupling in H₂S and the HC⁻, NC⁻ and NH⁻ coupling in HCN. They find dielectric effects of more than 10% and stress the importance of geometry relaxation as they may enhance as well as oppose the direct dielectric effect. Case et al.¹³ study dipeptides and ubiquitin. For the latter they apply the cluster method already applied to calculate the relaxation time of the same system³⁷ (see above). Their results show a reasonable scatter around an empirical Karplus curve.

4 CONCLUSIONS

Before 1990 only very few papers on the simulation of NMR properties in the liquid phase appeared. All of them were about relaxation processes for simple systems (atomic ions and rare gas atoms in polar solvents). One reason was that the computer speed and some quantum chemical tools were not yet available, but perhaps another was that simulations and quantum chemistry were completely different fields with only few people having the necessary knowledge in both fields. In the last decade the number of groups working on the subject has grown and approximately 50 papers are now available. The field is still in an experimental state, i.e., we need much more experience on the reliability of the methods. What influences do the potentials, the pair approximation in the MD cluster method or the harmonic approximations in the quantum cluster equilibrium theory have? However it has been shown that calculations of liquid properties and solvent effects have become feasible and we can see a new great area of computational chemistry evolving.

1 INTRODUCTION

In the beginning of the 1960s, NMR spectroscopists started to look for means to orient molecules with a particular goal in mind, i.e. to find a situation where the intermolecular direct dipolar couplings would average out whereas the corresponding intramolecular couplings would average to a nonzero value. Various methods were tried until, in 1963, Saupe and Englert¹ proposed that the sought-after properties can be reached by using liquid crystals as solvents.

The anisotropic orientational distribution of solute molecules in liquid crystals makes it possible to use the NMR observables (anisotropic couplings including both the direct dipole–dipole couplings and a contribution from the anisotropy of the indirect spin–spin coupling tensor, chemical shifts, and nuclear quadrupole splittings) for the determination of molecular structures, the anisotropies of nuclear shielding and spin–spin couplings, and quadrupole couplings for nuclei with spin ≥ 1 . In principle, the method is quite straightforward but in practice some complications may appear. In particular, the determination of molecular structures necessitates the introduction of the vibrational² and deformational^{3–5} corrections (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*). Since the anisotropic contribution of the spin–spin coupling tensor can only be separated from the experimental coupling when the direct dipole–dipole coupling is known, the corresponding effects have also to be considered here. To obtain reliable shielding anisotropies for protons and for nuclei with small anisotropy in general, various disturbing effects on the experimentally determined chemical shifts, such as local anisotropy due to solvent molecules, have to be taken into account.

A comprehensive review on the anisotropies of shielding and spin–spin coupling tensors determined using liquid crystalline solvents appeared in 1982.⁶ Since then, however, remarkable progress has taken place. This concerns spin–spin coupling anisotropy, in particular, where the inclusion of the deformational corrections leads to unambiguous, solvent independent results.

The NMR spectra observable from the spin- $\frac{1}{2}$ nuclei in molecules dissolved in liquid crystals resemble those in

isotropic liquids; relatively sharp, well resolved lines can be detected. Hence, analyses of spectra taken in the two phases are, in principle, similar (see *Liquid Crystalline Samples: Spectral Analysis*, and *Analysis of High-Resolution Solution State Spectra*). There are, however, also a few basic differences. Firstly, the anisotropic couplings between magnetically and chemically equivalent nuclei affect the structure of the spectrum. Thus, for example, the ^1H NMR spectrum of three methyl protons is a triplet and the six benzene protons give a spectrum very rich in resonance lines. Secondly, the dipole–dipole coupling constants are often large, of the order of kHz, and consequently the first-order approximation can usually be carried out only when the coupled nuclei are of different species.

2 LIQUID CRYSTALS

The liquid crystals most applicable in NMR spectroscopy are the thermotropic ones which have mesophases within certain temperature ranges.⁷ In a few cases, lyotropic liquid crystals have also been used. They are formed by mixing, for example, alkyl sulfates and the corresponding alcohols, sodium sulfate, and water.⁸

Thermotropic liquid crystals which are mainly used as solvents in NMR spectroscopy, can be classified into two main categories; nematic (N) and smectic (S). In the nematic phases, the molecules have only a short range positional order. However, if the liquid crystals consist of elongated molecules, as those used in the applications described in this context usually do, they tend to align with their long axes parallel to a common axis which defines the director (often called also the optic axis), $\mathbf{n}$, of the liquid crystal. The nematic phases are almost in all known cases uniaxial (rotational symmetry exists around the director) and apolar (the directions $\mathbf{n}$ and $-\mathbf{n}$ are equivalent). In the smectic phases the liquid crystal molecules possess long range order. A specific feature of smectic phases is the appearance of one-dimensional density waves or, as often called, layered structures. Smectic phases are divided into subgroups of which the smectic A phase (S_A) is the one used in the present applications. In this phase, the director coincides with the normal of the layer, and $\mathbf{n}$ and $-\mathbf{n}$ are equivalent. The structures of the nematic and smectic A phases are shown in Figure 1.

When a liquid crystalline sample is placed in an external magnetic field $\mathbf{B}$, the sample is magnetized so that the magnetization $\mathbf{M}$ is given by

$$M_\alpha = \mu_0^{-1} \chi_{\alpha\beta} B_\beta \quad (1)$$

Figure 1 Structures of thermotropic nematic (N) and smectic A (S_A) liquid crystalline phases. The direction of the director is shown by $\mathbf{n}$

2 ANISOTROPY OF SHIELDING AND COUPLING IN LIQUID CRYSTALLINE SOLUTIONS

where μ_0 is the permeability in vacuo and the $\chi_{\alpha\beta}$'s are elements of the diamagnetic (volume) susceptibility tensor, χ_m , which is diagonal in uniaxial phases.

The energy density, ρ_B , due to the magnetization $\mathbf{M}$ is:

$$\rho_B = - \int_0^B \mathbf{M} \cdot d\mathbf{B} = - \frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \theta) \right] \quad (2)$$

where $\chi_m = \frac{1}{3} \text{Tr} \chi_m$ is the isotropic susceptibility, $\Delta\chi_m$ is the anisotropy of the susceptibility tensor, and $P_2(\cos \theta) = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the second Legendre polynomial (θ being the angle between $\mathbf{B}$ and $\mathbf{n}$). Considering the condition of minimum energy density, one can conclude the following:

1. When $\Delta\chi_m$ is positive, ρ_B reaches a minimum with $P_2(\cos \theta) = 1$, i.e. the director is oriented parallel with the external magnetic field.
2. When $\Delta\chi_m$ is negative, ρ_B reaches a minimum with $P_2(\cos \theta) = -\frac{1}{2}$, i.e. when the director is oriented perpendicular to the external field.

Both types of thermotropic liquid crystals exist and have been used in studies of the properties of solute molecules. Furthermore, proper mixtures of liquid crystals with opposite signs of diamagnetic anisotropies have been utilized. (See *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*.)

3 THE HAMILTONIAN OPERATOR AND OBSERVABLES

When considering the NMR spectra of spin- $\frac{1}{2}$ nuclei in molecules partially oriented in liquid crystals, the transition frequencies are dependent upon the nuclear shielding tensor, σ_i , the indirect spin-spin coupling tensor, $\mathbf{J}_{ij}$, and the direct dipole-dipole coupling tensor, $\mathbf{D}_{ij}$ (see *Liquid Crystals: General Considerations*). Then the total Hamiltonian operator is (in energy units):

$$\hat{\mathcal{H}} = -\hbar \sum_i \gamma_i \hat{\mathbf{I}}_i \cdot (\mathbf{1} - \sigma_i) \cdot \mathbf{B} + \hbar \sum_{i < j} \hat{\mathbf{I}}_i \cdot (\mathbf{J}_{ij} + \mathbf{D}_{ij}) \cdot \hat{\mathbf{I}}_j \quad (3)$$

where $\hbar$ is Planck's constant divided by 2π , γ_i is the magnetogyric ratio of nucleus i , and $\mathbf{1}$ is the unit tensor. On the basis of perturbation theory one can conclude that the terms of the Hamiltonian operator which do not commute with the total spin component, $\hat{I}_z$, in the direction of $\mathbf{B}$ (defined as the z direction of the laboratory frame) can be safely neglected. Furthermore, taking the time average of the observables over the anisotropic molecular tumbling, the operator shown in equation (3) can be approximated by:

$$\begin{aligned} \hat{\mathcal{H}} = & -\hbar \sum_i \gamma_i (1 - \sigma_i) B \hat{I}_{iz} \\ & + \hbar \sum_{i < j} J_{ij} \left[\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \\ & + \hbar \sum_{i < j} (2D_{ij} + J_{ij}^{\text{aniso}}) \left[\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{4} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \end{aligned} \quad (4)$$

In the operator shown in equation (4), the shielding is represented as

$$\begin{aligned} \sigma_i = \langle \sigma_{izz} \rangle &= \frac{1}{3} \sum_{\alpha} \sigma_{i\alpha\alpha} + \frac{2}{3} \left(\sum_{\alpha, \beta} S_{\alpha\beta} \sigma_{i\alpha\beta} \right) P_2(\cos \theta) \\ &= \sigma_i^{\text{iso}} + \sigma_i^{\text{aniso}} \end{aligned} \quad (5)$$

The isotropic spin-spin coupling constant, J_{ij} , and the anisotropic contribution, J_{ij}^{aniso} , are

$$J_{ij} = \frac{1}{3} \sum_{\alpha} J_{ij\alpha\alpha} \quad (6)$$

and

$$J_{ij}^{\text{aniso}} = \left(\frac{2}{3} \sum_{\alpha, \beta} S_{\alpha\beta} J_{ij\alpha\beta} \right) P_2(\cos \theta) \quad (7)$$

In equations (5)–(7), $\sigma_{i\alpha\beta}$ and $J_{ij\alpha\beta}$ are the elements of the shielding and spin-spin coupling tensor, respectively, in the molecule fixed coordinate system while the $S_{\alpha\beta}$ terms in turn, are the elements of the Saupe ordering tensor⁹ which are defined as

$$S_{\alpha\beta} = \frac{1}{2} \langle 3 \cos \theta_{\alpha n} \cos \theta_{\beta n} - \delta_{\alpha\beta} \rangle \quad (8)$$

where $\theta_{\alpha n}$ is the angle between the director $\mathbf{n}$ and the α axis of the coordinate system, the $\langle \rangle$ brackets indicate a time average, and $\delta_{\alpha\beta}$ is the Kronecker delta. The dipole-dipole coupling constant, D_{ij} , appearing in the operator shown in equation (4) is defined (when the correlation of the molecular reorientational and vibrational motions is neglected) as

$$D_{ij} = - \frac{\mu_0 \hbar \gamma_i \gamma_j}{8\pi^2 r_{ij}^3} S_{ij} \quad (9)$$

where r_{ij} is the internuclear distance, and

$$S_{ij} = \frac{1}{2} \langle 3 \cos^2 \theta_{ijB} - 1 \rangle \quad (10)$$

is called the order parameter (with respect to the external magnetic field) of the axis passing through i and j , and θ_{ijB} is the angle between the ij direction and the magnetic field. Since the order tensor is traceless and symmetric, it consists of five independent elements which are usually chosen as S_{cc} , ($S_{aa} - S_{bb}$), S_{ab} , S_{ac} , and S_{bc} (a , b and c are the axes of the molecule fixed coordinate system). Utilizing the coordinate transformation equation

$$S_{ij} = \sum_{\alpha, \beta} \cos \theta_{ij\alpha} \cos \theta_{ij\beta} S_{\alpha\beta} \quad (11)$$

S_{ij} can be written as:

$$\begin{aligned} S_{ij} = & \left[\frac{1}{2} S_{cc} (3 \cos^2 \theta_{ijc} - 1) + \frac{1}{2} (S_{aa} - S_{bb}) (\cos^2 \theta_{ija} - \cos^2 \theta_{ijb}) \right. \\ & + 2S_{ab} \cos^2 \theta_{ija} \cos^2 \theta_{ijb} + 2S_{ac} \cos^2 \theta_{ija} \cos^2 \theta_{ijc} \\ & \left. + 2S_{bc} \cos^2 \theta_{ijb} \cos^2 \theta_{ijc} \right] P_2(\cos \theta) \end{aligned} \quad (12)$$

The number of the independent elements of the order tensor can be reduced by taking into account molecular symmetry. The values of the order tensor elements are obtained from the dipole-dipole coupling constants provided that at least one internuclear distance is known.

4 SHIELDING ANISOTROPY

For a moment let us forget the complications that may occur particularly when determining small anisotropies of nuclear shieldings, and concentrate on the principles of how the shielding anisotropy is obtained from an NMR spectrum of a molecule partially oriented in a liquid crystal. Let us choose as an example a molecule possessing at least a

threefold symmetry axis, e.g. acetonitrile (CH_3CN). In such a case, the molecular orientation is completely determined by one order tensor element. Thus the experimental chemical shift, δ^{exp} , can be expressed in the form (note that δ increases to high frequency whereas σ increases to low frequency; for simplifying notations the subscript i will be omitted):

$$\begin{aligned}\delta^{\text{exp}} &= \delta^{\text{iso}} - \frac{2}{3} \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] S P_2(\cos \theta) \\ &\equiv \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S P_2(\cos \theta)\end{aligned}\quad (13)$$

where $\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \equiv \Delta\sigma$ is the anisotropy of the shielding tensor [(x, y, z) is a molecule fixed coordinate system] and S is the order parameter of the molecular symmetry axis (which in the case of acetonitrile lies along the $-\text{C}\equiv\text{N}$ direction). Equation (13) contains two unknown parameters δ^{iso} and $\Delta\sigma$; the order parameter S is obtained from the experimental dipole-dipole couplings [defined in equation (9)] which do not contain an anisotropic contribution, J_{ij}^{aniso} , and are corrected for harmonic vibrations and preferably also for deformational contributions. Usually couplings of the type D_{HX} with ^1H as a coupling partner (D_{HH} in CH_3CN) are a safe choice.

The shielding anisotropy can be determined by changing either S or $P_2(\cos \theta)$. There exist several possibilities for both. They are described below.

4.1 Use of Isotropic–Nematic Phase Transitions

In this method, $\delta^{\text{iso}} = \delta^{\text{exp}}(\text{isotropic})$ is determined in the liquid crystal heated to the isotropic state (when $S \equiv 0$) and assumed not to be affected by the change of phase. Then the sample is cooled to the nematic state and $\delta^{\text{exp}}(\text{nem.})$ is measured. Consequently,

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(\text{nem.}) - \delta^{\text{exp}}(\text{isotropic})}{S P_2(\cos \theta)} \right] \quad (14)$$

4.2 Gradient Method

One disadvantage of the previous method is that the experiments have to be carried out at two different phases, isotropic and nematic. This can be avoided by working exclusively in a nematic or smectic phase and changing the molecular degree of order, i.e. the order parameter S . This is achieved by changing the temperature or concentration of the sample. When δ^{exp} is expressed graphically as a function of $S P_2(\cos \theta)$, the slope of the resulting straight line gives $\Delta\sigma$ and the intercept δ^{iso} .

4.3 Use of Smectic Phases

The smectic A phases of thermotropic liquid crystals often possess the property that once oriented in a magnetic field they keep the orientation for a long time. This makes it possible to change in a very straightforward way the angle between the director $\mathbf{n}$ and the magnetic field $\mathbf{B}$, i.e. the factor $P_2(\cos \theta)$ in equation (13), while S remains unchanged.¹⁰ The

shielding anisotropy is then obtained without changing solvent properties.

When the liquid crystal is heated to the isotropic state and then cooled in the magnetic field to the smectic state, the director orients (when $\Delta\chi_{\text{m}} > 0$) along the magnetic field and $\theta = 0$. Thus

$$\delta^{\text{exp}}(0) = \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S \quad (15)$$

The rotation of the sample (in a conventional electromagnet) around the tube axis by 90° [generally, the rotation angle is obtained from the ratio of the dipolar couplings: $D_{ij}(\theta)/D_{ij}(0) = P_2(\cos \theta)$] gives:

$$\delta^{\text{exp}}(90) = \delta^{\text{iso}} + \frac{1}{3} \Delta\sigma S \quad (16)$$

and consequently,

$$\Delta\sigma = \frac{\delta^{\text{exp}}(90) - \delta^{\text{exp}}(0)}{S} \quad (17)$$

In the smectic phases the degree of solute molecular orientation is usually high, when both S and the chemical shift difference [nominator in equation (17)] are large, leading to a good relative precision in $\Delta\sigma$. Figure 2, which shows the ^{199}Hg NMR spectrum of dimethylmercury ($\text{CH}_3)_2\text{Hg}$ at the orientation described above, illustrates the method.

4.4 Use of Mixtures of Thermotropic Nematic Liquid Crystals

4.4.1 Liquid Crystals with Opposite Diamagnetic Anisotropy

This method, called NEMIX, is comparable with the one described in Section 4.3. When two thermotropic nematic liquid crystals possessing opposite anisotropies of diamagnetic susceptibility, $\Delta\chi_{\text{m}}$, are mixed at a certain critical concentration ratio ($\Delta\chi_{\text{m}}$ of the critical mixture is equal to 0), the 90°

Figure 2 ^{199}Hg NMR spectrum of dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ in the smectic A phase of HAB: 0° , director parallel with the external magnetic field, 90° , director perpendicular to the external magnetic field. (Reproduced with permission of Heyden & Sons from J. Jokisaari and P. Diehl²⁶)

Figure 3 The experimental chemical shift, δ_F^{exp} , of the ^{19}F nucleus and the order parameter of the C_3 symmetry axis, S , for methyl fluoride (CH_3F) as a function of the liquid crystal composition in mixtures of ZLI 1167 and EBBA. The mixtures used in the NEMIX and ENEMIX methods are indicated by N and E, respectively

rotation of the liquid crystal director is achieved by changing the sign of $\Delta\chi_m$ with the aid of a slight temperature change or a small temperature gradient over the sample volume (see *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*). In the latter case, the NMR spectra corresponding to the two director orientations can be detected simultaneously.^{11,12} The shielding anisotropy can be calculated from equation (17). Figure 3 shows how the method works.

4.4.2 Liquid Crystals with Opposite Deformational Effects on Molecular Structure

The anisotropic forces that cause the orientation of solute molecules at the same time deform their structure leading to the solvent dependence of structure. It has appeared that ^{13}C -enriched methane ($^{13}\text{CH}_4$) is a convenient and practical reference, not only for chemical shifts but also for structural deformations. It has been found that in certain mixtures of thermotropic liquid crystals the methane molecule is not deformed.¹³ The components of the mixture may be selected so that they possess opposite diamagnetic anisotropies and, consequently, parallel and perpendicular orientations of the director with respect to the external magnetic field can be produced in a similar way to that discussed above. Figure 3 also demonstrates this method, which is called ENEMIX. In contrast to the NEMIX method and the method based on the utilization of smectic liquid crystals, the ratio of the S parameters corresponding to the two director orientations may not exactly equal -2 , whence

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(0) - \delta^{\text{exp}}(90)}{S(0) - S(90)} \right] \quad (18)$$

4.5 Use of Sample Spinning

4.5.1 Sample Tube Axis Perpendicular to the Magnetic Field

As discussed above, the liquid crystals director orients either along the external magnetic field or perpendicular to it depending upon the sign of the diamagnetic anisotropy. In a conventional electromagnet, the director orients perpendicular to the tube axis (when $\Delta\chi_m > 0$; if $\Delta\chi_m < 0$ the director orients along the tube axis and no change in the orientation can be achieved by spinning the sample tube). When the sample is spinning around the tube axis the liquid crystal experiences a viscous torque

$$N_v = \lambda_1 \Omega \quad (19)$$

where Ω is the angular speed and λ_1 a coefficient proportional to the viscosity of the solution. The magnetic torque opposes the viscous torque, and in equilibrium $N_B = N_v$. Thus the angle θ_0 between the magnetic field and the director is determined by

$$\sin 2\theta_0 = -\frac{2\mu_0\lambda_1}{B^2\Delta\chi_m} \Omega \quad (20)$$

The value of $SP_2(\cos \theta_0)$ can be determined from the dipolar coupling constants and the shielding anisotropy calculated as in the previous method. On the other hand, θ_0 can be varied by varying the angular speed Ω . There is, however, an upper limit for Ω , the so-called critical speed, $\Omega_c = -B^2\Delta\chi_m/2\mu_0\lambda_1$, above which no equilibrium state can be reached but the director rotates with the tube. When the experimental chemical shift is plotted as a function of $SP_2(\cos \theta_0)$, the shielding

anisotropy is obtained from the slope of the resulting straight line.

4.5.2 Variable Angle Spinning

Let us consider a general case where the spinning axis of a sample tube forms an angle β with the magnetic field. Transforming the susceptibility tensor into the principal axis system rotating around the magnetic field direction and taking a time average,¹⁴ the magnetic energy density can be represented in the form

$$\langle \rho_B \rangle = -\frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \beta) P_2(\cos \delta) \right] \quad (21)$$

where δ is the angle between the spinning axis and the liquid crystal director. From the condition of minimum energy density, one can conclude the following: (a) when $\Delta\chi_m > 0$ and $0 \leq \beta < \beta_m$ (β_m is the magic angle, 54.7°), the liquid crystal director orients parallel with the spinning axis, i.e. the angle between the director and the magnetic field equals β ; (b) when $\Delta\chi_m > 0$ and $\beta_m < \beta \leq \pi/2$, the directors are equally distributed in the plane perpendicular to the spinning axis; (c) when $\Delta\chi_m < 0$ and $0 \leq \beta < \beta_m$, the situation is similar to (b); and (d) when $\Delta\chi_m < 0$ and $\beta_m < \beta \leq \pi/2$, the situation is similar to (a).

The slope of the resulting straight line obtained by plotting the experimental chemical shift as a function of $SP_2(\cos \beta)$, or as a function of a dipolar coupling constant as shown in Figure 4, gives the shielding anisotropy.

4.6 Examples and Reliability of Results

4.6.1 Molecules Whose Orientation Can Be Described by One Order Parameter

Tables (1)-(3) show $\Delta\sigma$ values determined by applying various liquid crystals and methods described above. The examples are chosen so that they cover a wide range of values, and consequently yield the weaknesses on the one hand and the reliability on the other hand of liquid crystal NMR spectroscopy as applied to the determination of shielding anisotropies. Table 1 lists the proton shielding anisotropy values measured for acetonitrile (CH_3CN). As can be seen, they vary over a relatively wide range, and both positive and negative values have been reported. The $\Delta\sigma_{\text{H}}$ value seems to depend upon the method used, liquid crystal solvent, and reference method and substance. This is due to the fact that the measured shielding is affected by three different anisotropic contributions:

$$\sigma^{\text{exp}} = \sigma^{\text{mol}} + \sigma^{\text{local}} + \sigma^{\text{bulk}} \quad (22)$$

where σ^{mol} (the quantity of interest) arises from the electron distribution in the molecule, σ^{local} (the local effect) from the nearest neighbor molecules, and σ^{bulk} (the bulk effect) from the other parts of the sample. The greatest problem is caused by the local effects; obviously the solute and reference molecules do not probe exactly the same local fields, leading to an erroneous $\Delta\sigma$. Local effects in a smectic liquid crystal, and in mixtures of thermotropic nematic liquid crystals with opposite diamagnetic anisotropies, have been studied by using globular solutes (which do not orient in liquid crystals, i.e. $S = 0$) and found to be from -0.2 to -0.5 ppm for protons.¹⁵⁻¹⁷ These

Figure 4 Plot of δ^{exp} for the ^1H nucleus (referenced to internal TMS) as a function of D_{HH} for methyl iodide (CH_3I) in three liquid crystals: phase 4 ($\square$); ZLI 1167 (39.1%)/phase 4 (60.9%) ($\bullet$); and ZLI 1167 (57.6%)/phase 4 (42.4%) ($\times$). The data were produced on a VAS system by varying the angle between the spinning axis and the external magnetic field. The slope, κ , of the straight line yields the proton shielding anisotropy $\delta\sigma_{\text{H}} = (3/4) (K_{\text{HH}}/r_{\text{HH}}^3) \kappa$, where $K_{\text{HH}} = \mu_0 \hbar \gamma_{\text{H}}^2 / 8\pi^2$. (Reproduced with permission of Academic Press from T. Väänänen, J. Jokisaari, and M. Seläntaus³³). Note: the δ scale is opposite to the one used in the present text

experiments and the earlier ones^{18,19} mean that the anisotropic contribution of the local effects may be of the same magnitude as σ^{aniso} for protons, but also for other nuclei if their shielding anisotropy is not very large.

The first column of Table 2 shows that the shielding anisotropy of the methyl carbon, $\Delta\sigma_{\text{CH}_3}$ in acetonitrile, being of the order of 20 ppm, also depends markedly on the applied experimental method and liquid crystal solvent. On the contrary, the shielding anisotropies measured for the $-\text{C}\equiv\text{N}$ carbon, $\Delta\sigma_{\text{CN}}$, in acetonitrile as well as those for the ^{199}Hg nucleus in dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ (see Table 3) are virtually insensitive to all these factors. The small scatter arises from the internuclear distance chosen as a basis in calculating the order parameter S and from whether vibrational corrections are taken into account or not.

The experiments carried out until now and comparisons made with the values produced by other techniques or theoretical calculations provide strong support for the modified ENEMIX method giving the most reliable estimates for small $\Delta\sigma$ s.²¹

4.6.2 Molecules Whose Orientation Can Be Described by Two Order Parameters

In cases where molecules possess two perpendicular planes of symmetry as, for example, monosubstituted benzenes and heteroatomic five-membered rings, the experimental chemical shift can be represented in the form:

$$\delta^{\text{exp}} = \delta^{\text{iso}} - \frac{2}{3} \left\{ S_{zz} \left[\sigma_{zz} - \frac{1}{2} (\sigma_{xx} + \sigma_{yy}) \right] + \frac{1}{2} (S_{xx} - S_{yy}) (\sigma_{xx} - \sigma_{yy}) \right\} P_2(\cos \theta) \quad (23)$$

6 ANISOTROPY OF SHIELDING AND COUPLING IN LIQUID CRYSTALLINE SOLUTIONS

^bIGLO method with two different basis sets. Large basis set results on the right.

The shielding anisotropy, $\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})$, and the difference $(\sigma_{xx} - \sigma_{yy})$ are obtained separately only if the ratio $(S_{xx} - S_{yy})/S_{zz}$ can be varied. Consequently, none of the methods described above which are based on the change of direction of the liquid crystal director with respect to the external magnetic field, i.e. the variation of the $P_2(\cos \theta)$ factor, is applicable here. The variation of the ratio $(S_{xx} - S_{yy})/S_{zz}$ may be produced by changing the sample temperature or by using different liquid crystal solvents. Then one has to assume that the shielding tensor elements are not affected by the experimental conditions.

The determination of the ¹³C shielding anisotropies in molecules which are large in the liquid crystal NMR scale (when the number of magnetic nuclei increases, the NMR spectrum of an oriented molecule becomes very complex; in practice the upper limit for the number of active, interacting nuclei is 10–12), and contain several carbon atoms and ¹³C in natural abundance, is usually at least very cumbersome if not impossible from the proton coupled spectra. Therefore, a method has been proposed which uses a spin echo sequence $[90^\circ - \tau - 180^\circ - 2\tau - 180^\circ - \tau - \text{acquisition}]$ and phase-alternated broadband decoupling.³⁰ The echo sequence cancels the possible overlap of the solute signals by the solvent signals.

Table 3 ¹⁹⁹Hg Shielding Anisotropy in Dimethylmercury Determined by Various Methods in Different Liquid Crystals. For Comparison, Results obtained from Spin–Lattice Relaxation Time Measurements are also Included

$\Delta\sigma^{199}\text{Hg}$ (ppm)	Method	Liquid crystal	Comments

Figure 5 The ^{125}Te NMR spectrum of tellurophene ($\text{C}_4\text{H}_4\text{Te}$) in (a) ZLI 1167 (58%)/phase 4(42%), (b) EBBA and (c) ZLI 1167. (Reproduced with permission of Taylor & Francis from J. Jokisaari and T. Väänänen³¹)

The ^{13}C NMR spectrum yields the chemical shifts whereas the order parameters appearing in equation (23) are obtained from the ^1H spectrum.

The NMR spectroscopy of solute molecules in liquid crystals has not been applied very much to the investigations of shielding anisotropies of the so-called heavy nuclei. Most of the studies deal with the ^1H , ^{13}C , ^{19}F , and ^{31}P nuclei, and highly symmetrical molecules.⁶ This is somewhat surprising because the method is best when the shielding anisotropy is fairly large. There has been, however, some work carried out for ^{111}Cd , ^{113}Cd , and ^{199}Hg in molecules with C_3 symmetry, and one work for the ^{125}Te nucleus in a C_{2v} symmetric molecule, tellurophene ($\text{C}_4\text{H}_4\text{Te}$).³¹ The ^{125}Te NMR spectra of tellurophene in three liquid crystals are shown in Figure 5.

Equation (23) can be rewritten in the form

$$-\frac{3}{2} \left[\frac{\delta^{\text{exp}} - \delta^{\text{iso}}}{S_{zz}} \right] = \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] + \frac{\sigma_{xx} - \sigma_{yy}}{2} \frac{S_{xx} - S_{yy}}{S_{zz}} \quad (24)$$

Table 4 The Results of the ^{125}Te NMR Study of Tellurophene Dissolved in three Liquid Crystals.³¹ The Signs of δ^{exp} and δ^{iso} are Opposite to those in the Original Paper due to the Different Definition of the δ scale

Liquid crystal	δ^{exp} (ppm)	δ^{iso} (ppm) ^a	$(S_{xx} - S_{yy})/S_{zz}$ ^b	S_{zz} ^{b,c}
EBBA	2.50	-33.55	0.5033	0.0363
ZLI 1167/phase 4	48.51	-34.83	1.7478	0.0953
ZLI 1167	-85.02	-35.60	1.9992	-0.0592

The intercept of the straight line obtained by plotting the left hand side of equation (24) as a function of $(S_{xx} - S_{yy})/S_{zz}$ yields $[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})]$ whereas the slope gives $(\sigma_{xx} - \sigma_{yy})$. The results derived for ^{125}Te in tellurophene are collected in Table 4.

5 SPIN-SPIN COUPLING ANISOTROPY

The determination of reliable anisotropies, ΔJ_{ij} , of the spin-spin coupling tensors using NMR spectroscopy of molecules dissolved in liquid crystals may be a fairly difficult task. This is due to the fact that the experimental couplings, D_{ij}^{exp} , are dominated by the direct dipole-dipole coupling tensor elements, and moreover, in real molecules the dipole-dipole as well as spin-spin coupling tensors are averages over intramolecular motions. However, when performing proper analyses of data (sets of D_{ij}^{exp} values) preferably (often necessarily) produced in many liquid crystal solvents, most reliable and accurate ΔJ_{ij} values can be determined.

5.1 Quantitative Determination of J Anisotropy

The experimentally available couplings D_{ij}^{exp} can be expressed as a sum of several contributions (*Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*):

$$D_{ij}^{\text{exp}} = D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} + D_{ij}^{\text{h}} + D_{ij}^{\text{d}} + \frac{1}{2} J_{ij}^{\text{aniso}} \quad (25)$$

In equation (25), the first four terms on the right-hand side constitute the direct dipolar part of the coupling: D_{ij}^{e} is the dipole-dipole coupling corresponding to the equilibrium structure of the molecule; D_{ij}^{aff} is the contribution from the anharmonicity of the vibrational potential (the sum of these terms $D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} = D_{ij}^{\alpha}$ is the dipole-dipole coupling corresponding to the so-called r_{α} structure of the molecule; the anharmonic force constants are often not available and thus only the r_{α} structure can be determined); D_{ij}^{h} is the contribution from the harmonic vibrations; and D_{ij}^{d} (the so-called deformational contribution which is responsible for the solvent dependence of structure) from the correlation between

$$\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) = -1569 \pm 21 \text{ ppm}$$

$$\sigma_{xx} - \sigma_{yy} = 307 \pm 26 \text{ ppm}$$

^aObtained from a sample heated to isotropic state.

^bDetermined from the ^1H - ^{125}Te dipolar couplings by assuming the corresponding J^{aniso} to be negligible.

^cWith respect to the external magnetic field.

vibrational and reorientational motions (time averages of S_{ij} and r_{ij}^{-3} appearing in the definition of the dipole–dipole coupling, equation (9), cannot be taken independently).

In order to get a reliable value for J_{ij}^{aniso} (which is normally small and in many cases comparable in magnitude with the vibrational and deformational correction terms), the molecular structure should be determined as completely as possible with the aid of the D_{ij}^{exp} values. This necessarily means a full analysis of data taking into account the interactions (the anisotropic forces that tend to orient molecules) between the solute and solvent molecules. In such an analysis the number of unknown parameters often exceeds the number of D_{ij}^{exp} values obtainable from one experiment, i.e. the problem becomes underdetermined. This increasing number of parameters is a consequence of the deformational effects. For example, in order to be able to calculate deformational corrections to J^{aniso} , one should know the derivatives of the spin–spin coupling tensor with respect to the vibrational normal coordinates. These are not available, and consequently must be used as adjustable parameters.³² The problem of underdetermination can, however, be overcome by carrying out experiments in several liquid crystalline solvents.

Another uncertainty in the determination of J_{ij}^{aniso} may appear in cases of spin systems consisting of different nuclear species, for instance I and S spins. Thus, the NMR spectrum yields only the sum $|2D_{is}^{\text{exp}} + J_{is}|$. If the spin–spin coupling constant, J_{is} , cannot be determined under the same experimental conditions (the same solvent, temperature, concentration, etc.) as the sum, an additional uncertainty is introduced into D_{is}^{exp} , and consequently, also into J_{is}^{aniso} . In principle, J_{is} can be determined in liquid crystalline phases by performing, for instance, VAS (Variable Angle Spinning) experiments.³³

Let us consider the determination of the anisotropy of the ^{13}C – ^{19}F spin–spin coupling in the methyl fluoride (CH_3F) molecule. Due to the C_3 symmetry of the molecule, its orientation can be described by one order parameter, S , of the symmetry axis. Then the anisotropic contribution to the experimental coupling $D_{\text{CF}}^{\text{exp}}$ can be expressed in the form:

$$J_{\text{CF}}^{\text{aniso}} = \frac{2}{3} \Delta J_{\text{CF}} S P_2(\cos \theta) \quad (26)$$

where $\Delta J_{\text{CF}} = J_{\text{CFzz}} - \frac{1}{2}(J_{\text{CFxx}} + J_{\text{CFyy}})$ is the anisotropy of the coupling tensor $\mathbf{J}_{\text{CF}}$. When the experimental dipolar couplings are corrected for harmonic vibrations but the deformational corrections are neglected, ΔJ_{CF} appears to be solvent dependent to a very great extent, as shown in Table 5. This large scatter of results is removed when all the dipolar couplings and $J_{\text{CF}}^{\text{aniso}}$ are corrected for deformational effects and a joint analysis of nine experiments (44 couplings, $D_{\text{CF}}^{\text{exp}}$ in one liquid crystal could not be obtained, and 23 parameters) is carried out. This analysis results in $\Delta J_{\text{CF}} = 404 \pm 31$ Hz. The relative anisotropy, $\Delta J_{\text{CF}}/J_{\text{CF}}$, is -2.50 ± 0.20 (J_{CF} appears to be slightly dependent upon the liquid crystal solvent, its average value is -161.43 Hz) and should be compared with -2.70 obtained by Hartree–Fock theory (ab initio) and by a semiempirical finite perturbation method at the INDO MO level of approximation.³⁴ The first-order polarization propagator approach has led to the ΔJ_{CF} value of 296.41 Hz.³⁵ Consequently, the experimental results of a joint analysis and the theoretical results are in fair agreement.

Reinforcement for the workability of the method is provided by the studies on acetonitrile (CH_3CN) and methyl isocyanide

Table 5 The Anisotropy ΔJ_{CF} of the ^{13}C – ^{19}F Spin–Spin Coupling Tensor for Methyl Fluoride ($^{13}\text{CH}_3\text{F}$) in Various Liquid Crystals. The Dipolar Couplings are Corrected for Harmonic Vibrations but not for Deformational Effects. The Result of the Joint Analysis (which takes into account also the Deformational Effects) of Nine Sets of D_{ij}^{exp} Values (44 Couplings and 23 Parameters) is also given for Comparison³²

^bResults of the joint analysis. For details, see text.

^cTheoretical value obtained by first-order polarization propagator approach.³⁵

(CH_3NC). Table 6 clearly shows that when the harmonic vibrational and deformational effects are taken into account in the experimental dipolar couplings, the ΔJ values are in nice accord with the theoretical ones.

5.2 Qualitative Revelation of J Anisotropy

Molecular symmetry can place very restrictive conditions for the ratios of dipolar coupling constants. Consequently, this can be used to reveal whether D^{exp} includes a contribution from J^{aniso} or not. If the examination of the ratios $D_{ij}^{\text{exp}}/D_{kl}^{\text{exp}}$ shows that they differ from the corresponding ratios of direct dipolar couplings ($D^{\text{dir}} = D^{\text{exp}} - \frac{1}{2}J^{\text{aniso}} = D^e + D^{\text{ah}} + D^{\text{h}} + D^{\text{d}}$, see equation (26)), they (or at least some of them) may be affected by J^{aniso} .

Benzene is a good example of a molecule in which symmetry completely fixes the ratios of the dipolar couplings. The order parameter of each ij direction equals $-\frac{1}{2}S$ (S is the order parameter of the sixfold symmetry axis) and consequently the following equation is valid:

$$\frac{D_{ij}^{\text{dir}}}{D_{kl}^{\text{dir}}} = \frac{\gamma_i \gamma_j}{\gamma_k \gamma_l} \left(\frac{r_{kl}}{r_{ij}} \right)^3 \quad (27)$$

It follows from the hexagonal symmetry of benzene that $r_m = \sqrt{3}r_o$ and $r_p = 2r_o$ ($o = \text{ortho}$, $m = \text{meta}$, $p = \text{para}$). Thus for the nuclei of same isotopic species, $D_o/D_m/D_p = 1 : \sqrt{3}/9 : 1/8 \sim 1 : 0.1925 : 0.1250$. It has been found that the ^1H – ^1H couplings in benzene indeed fulfil these ratios (in particular, when the experimental couplings are corrected for harmonic vibrational and deformational effects) and thus the $J_{\text{HH}}^{\text{aniso}}$ values are obviously negligible.⁴ In contrast, remarkable deviations have been detected for the ^{13}C – ^{13}C couplings (corrected for harmonic vibrations).³⁹

Equation (27) is not only valid for benzene but more generally. Thus, if S_{ij} for the nuclei i and j is the same as S_{kl} for the nuclei k and l , in other words the axes passing through

Table 6 Anisotropies of the ^{13}C – ^{13}C and ^{13}C – ^{15}N Spin–Spin Coupling Tensors in Acetonitrile (CH_3CN) and Methyl Isocyanide (CH_3NC)

(a) Acetonitrile

1 INTRODUCTION

Nuclear magnetic shielding is a second-order molecular electronic property which provides a severe test of the accuracy of molecular quantum mechanical calculations. While electric dipole polarizability and hyperpolarizabilities provide tests of the wavefunction at the outer regions, nuclear shielding is very sensitive, especially to contributions from high angular momentum functions, in the regions close to a particular nucleus. Precise measurements of differences in shielding are easy to carry out. In most NMR studies the resonance frequencies are measured and a chemical shift is defined as $\delta = (\nu_i - \nu_{\text{ref}})/\nu_{\text{ref}}$. From the relationship between the resonance frequency ν_i , the external magnetic field B_0 , the magnetogyric ratio γ , and the nuclear shielding σ_i , i.e. $\nu_i = (\gamma/2\pi)(1 - \sigma_i)B_0$, we can write the chemical shifts in terms of the nuclear shielding as $\delta = (\sigma_{\text{ref}} - \sigma_i)/(1 - \sigma_{\text{ref}})$.

Reasonably accurate calculations are now available for nuclei in the first row of the Periodic Table in molecules with a small number of first row atoms and for hydrides of the second row, as may be seen in the articles on IGLO, LORG and SOLO and GIAO shielding calculations described by Kutzelnigg, Hansen and Pulay in this Encyclopedia (*Shielding Calculations: LORG and SOLO Approaches, Shielding Calculations: IGLO Method, Shielding Theory: GIAO Method*). In making a comparison of theoretical ab initio values at the equilibrium molecular geometries with experimental chemical shifts, it is necessary to have absolute quantities (absolute shielding values) to compare with rather than shielding differences or chemical shift values. Accurate chemical shift measurements can be carried out by simultaneous measurement of two frequencies in the same physical sample in the field. If we know the absolute shielding value corresponding to the first frequency, then the accurate chemical shift between the two provides the absolute shielding of the second, or indeed of any number of systems whose chemical shifts can be related to the absolute shielding of any

one system. But how do we establish the absolute shielding value of the very first one?

2 ABSOLUTE SHIELDING SCALES BASED ON THE PROTON IN LIQUID WATER

The absolute proton shielding in a spherical sample of pure liquid H_2O at 34.7°C , $\sigma = 25.790 \pm 0.014$ ppm, has been established by two experiments. The first was a simultaneous measurement of the frequencies of an electronic transition and a nuclear magnetic transition in atomic hydrogen. The second was a simultaneous measurement of NMR frequencies of protons in a spherical sample of liquid water at 34.7°C and in a spherical bulb filled with atomic hydrogen in the same magnetic field. The first experiment established the g -factor of the bare proton; the second experiment allows the determination of the absolute nuclear magnetic shielding of protons in liquid water.^{1,2}

One standard technique for establishing an absolute shielding scale for a nucleus M is by combining the results of two experiments. The first is an atomic beam magnetic resonance experiment or an optical pumping experiment which measures the ratio of γ for the M nucleus to γ for the electron in the free M atom. Since the (electron) γ can be calculated from the known electron magnetic moment and electronic g -value of the atomic state, the value of $\gamma(M, \text{free atom})$ may be obtained precisely. The second is an NMR experiment which measures the ratio of the Larmor frequencies of M and ^1H in an infinitely dilute $M_{(\text{aq})}^{n+}$ ion in aqueous solution. This provides the ratio $\gamma(^1\text{H}, \text{H}_2\text{O}, \text{liq.})/\gamma(M, M_{(\text{aq})}^{n+})$. The key here is that $\gamma(^1\text{H}, \text{H}_2\text{O}, \text{liq.})$ is known precisely for pure liquid water from experiments and is assumed to be the same in the infinitely dilute aqueous solution of $M_{(\text{aq})}^{n+}$ ion, so $\gamma(M, M_{(\text{aq})}^{n+})$ can be obtained. Then, from the definition of the nuclear magnetic shielding σ relative to the bare nucleus, $\gamma = (1 - \sigma)\gamma_0$, where γ_0 is the magnetogyric ratio of the bare nucleus,

$$\frac{\sigma(M, \text{free atom}) - \sigma(M, M_{\text{aq}}^{n+})}{1 - \sigma(M, M_{\text{q}}^{n+})} = 1 - \frac{\gamma(M, \text{free atom})}{\gamma(M, M_{\text{aq}}^{n+})} \quad (1)$$

Since $\sigma(M, \text{free atom})$ is theoretically known³ the absolute shielding of M in the aqueous solution of $M_{(\text{aq})}^{n+}$ is thereby established.

This method is applicable when the aqueous solution of the metal ion is a convenient reference and extrapolation to infinite dilution is possible. The ratio $\gamma(M, \text{free atom})/\gamma(M, \text{liq. ref.})$ has to be known to 1 part in 10^5 if the $\sigma(M, \text{liq. ref.}) - \sigma(M, \text{free atom})$ is to be determined to ± 10 ppm. The absolute shielding scales for Li, Na, K, Rb, Cs, Zn, Cd, Ga, Hg, and Pb were determined in this way and are summarized in Table 1 in 'Multinuclear NMR' edited by Mason.⁴

3 ABSOLUTE SHIELDING INFORMATION FROM SPIN-ROTATION CONSTANTS

With the gauge origin at the nucleus in question, σ^P in Ramsey's expression is related to another molecular property,

Table 1 Absolute σ_0 ^{15}N Shieldings

Molecule	$\sigma_0(^{15}\text{N}$ in the molecule, 300 K) (ppm)
N_2	-61.6
NNO	99.5
NNO	11.3
HCN	-20.4

the nuclear spin-rotation tensor. The nuclear spin-rotation tensor arises from the coupling of the magnetic moment of a nucleus with the magnetic field generated by the molecular rotation at that nucleus. Ramsey⁵ and Flygare⁶ have shown that

$$\sigma_{\text{gg}}^{\text{p}} = (m_{\text{p}}/2m g_N) C_{\text{gg}}/B_{\text{gg}}^{(\text{e})} - (\mu_0/4\pi)(e^2/2m) \times \sum_N Z_{N'} [R_{NN'}^2 - (R_{NN'}^2)_{\text{gg}}]/R_{NN'}^3 \quad (2)$$

in which m_{p} and m are the masses of the proton and the electron, g_N is the g -factor for the nucleus of interest, C_{gg} and $\sigma_{\text{gg}}^{\text{p}}$ are the diagonal components of the spin-rotation tensor and the paramagnetic shielding tensor in the principal axis system of the molecular moment of inertia, while $B_{\text{gg}}^{(\text{e})}$ is the rotational constant at the equilibrium configuration.

The $\sigma_{\text{gg}}^{\text{p}}$ values can be related to the components along the principal axes of the shielding tensor by a rotational transformation using the known molecular geometry. The second term in the equation is the nuclear contribution which depends only on the coordinates and atomic number of all the other nuclei N' in the molecule. The total absolute shielding can then be determined by adding the diamagnetic contribution σ^{d} , which is obtained from theory, calculated at the nucleus of interest N as the gauge origin:

$$\sigma^{\text{d}} = (\mu_0/4\pi)(e^2/3m) \left\langle \psi^0 \left| \sum 1/r_i \right| \psi^0 \right\rangle \quad (3)$$

It is very important to calculate the nuclear terms using the same structure as that used for calculating diamagnetic terms.

Experimental values of spin-rotation constants are available from molecular beam magnetic and electric resonance experiments and also from high-resolution microwave spectroscopy. In the first two types of experiments the radiofrequency spectrum corresponding to the reorientation of the ^{15}N nuclear moment in a magnetic field, or the interaction of the electric dipole moment of the molecule with a strong external electric field, is composed of transitions from many J and M_J states which may be individually resolved. In the third type of experiment, a specific purely rotational transition is observed. Vibrationally averaged constants are obtained, usually for the ground vibrational state, occasionally for a vibrationally excited state as well. The exact relation between σ^{p} and C holds for a vibrationless molecule at the equilibrium nuclear configuration. Experimentally one usually obtains $\langle C \rangle_{v=0}$ components of the vibrationally averaged spin-rotation constant.

The first absolute shielding scale which was compiled in an internally consistent way is the one for ^{19}F in a small set of molecules whose chemical shifts have been measured in the limit of zero pressure at room temperature.⁶ To establish the first absolute shielding for ^{19}F in a molecule,⁷ Hindermann and

Cornwell corrected the observed spin-rotation constant in HF to the equilibrium configuration, from which they obtained σ_e^{p} . The latter combined with the theoretical value of σ_e^{d} gave σ_e , which was then converted to σ_0 at room temperature by making the rovibrational correction. Once the absolute σ_0 for HF was known, they could then find the absolute σ_0 for their secondary reference molecule (SiF_4) by measuring the chemical shift between HF and SiF_4 at the zero-pressure limit. The absolute σ_0 for the other molecules on their scale were then determined from measured chemical shifts from SiF_4 . Since all the measured chemical shifts correspond to the zero-pressure limit, Hindermann and Cornwell's scale is a list of absolute σ_0 (i.e., for the isolated molecule) at room temperature. In addition, they found the absolute shielding $\sigma(\text{liq.}, T)$ of CFCl_3 . With this connection, other measurements of shifts relative to liquid CFCl_3 can be converted to absolute $\sigma(\text{liq. or soln.}, T)$ by other workers.

In general, once the absolute shielding of a primary reference molecule (in this case the HF molecule) has been established, the absolute ^{19}F shielding of a series of other molecules can be systematically determined. What is required are simultaneous accurate chemical shift measurements between the primary reference molecule and all the other molecules in the isolated molecule limit. Frequently, the primary reference molecule is not a convenient internal reference and a secondary reference molecule is used instead. In this case, the SiF_4 molecule is ideal, it is relatively inert, and has a long ^{19}F relaxation time in the gas phase so that the signal is sharp. To extend the ^{19}F absolute shielding scale, observed resonance frequencies in gas samples were reduced to the zero-density limit at 300 K using previously measured density and temperature-dependent chemical shifts for each gas. The results corresponding to a rovibrationally-averaged isolated molecule at 300 K are expressed relative to SiF_4 as a standard. The values of $[\sigma_0(300 \text{ K}) - \sigma_0^{\text{SiF}_4}(300 \text{ K})]/[1 - \sigma_0^{\text{SiF}_4}(300 \text{ K})]$ were obtained by dividing the frequency differences by the resonance frequency of SiF_4 . The shielding differences $[\sigma_0^{\text{A}}(300 \text{ K}) - \sigma_0^{\text{SiF}_4}(300 \text{ K})]$ were obtained for a large number of molecules^{8,9} and were found to be identical to Hindermann and Cornwell's values for all of their molecules (six) which were included in the new set. Based on $\sigma_0(\text{HF}, 300 \text{ K}) = 410.0 \text{ ppm}$, absolute $\sigma_0(\text{SiF}_4, 300 \text{ K}) = 363.2 \text{ ppm}$. The absolute σ_0 for a large number of F-containing molecules have been determined from the ^{19}F chemical shift limit at 300 K, $[\sigma_0(\text{A}, 300 \text{ K}) - \sigma_0(\text{SiF}_4, 300 \text{ K})]$.^{8,9} Neat liquid CFCl_3 and C_6F_6 provide the connection for converting chemical shifts measured in other laboratories using these references into absolute shielding values; $\sigma(^{19}\text{F}$ neat liq. CFCl_3 , spherical, 300 K) = 188.7 ppm; $\sigma(^{19}\text{F}$ neat liq. C_6F_6 , spherical, 300 K) = 355.5 ppm.

How large can the errors be if the corrections shown in Figure 1 are not carried out, i.e. if $\langle C_{\text{gg}} \rangle_{v=0}/\langle B_{\text{gg}} \rangle_{v=0}$ are used to calculate $\langle \sigma_{\text{gg}}^{\text{p}} \rangle_{v=0}$ directly? The difference between the vibrational average of the ratios $\langle C_{\text{gg}}/B_{\text{gg}} \rangle_{v=0}$ and the ratio of the vibrational averages $\langle C_{\text{gg}} \rangle_{v=0}/\langle B_{\text{gg}} \rangle_{v=0}$ can be as much as 10% in molecules containing hydrogen. Incomplete knowledge of the first and second derivatives of C with nuclear configuration presently makes it impossible to correct for this error, as Hindermann and Cornwell had done for HF. The thermal average of σ^{p} can be approximated by using the spin-rotation tensor for the ground vibrational state. However, when a low-frequency vibration exists and the spin-rotation constants

Figure 1 Building up an absolute shielding scale from the absolute shielding of one primary reference whose spin-rotation constant is accurately known. The following notations are used: * denotes the primary reference molecule, A any other compound, subscript 0 the isolated molecule, and subscript e the equilibrium configuration

for the first excited vibrational state are substantially different from those of the ground vibrational state (such as in NNO), a proper thermal average has to be carried out. There are also rotational (centrifugal distortion) corrections which have to be made.

Given the possible sources of error which we have mentioned above, some discrepancies may be observed in comparing shielding values derived from spin-rotation constants with differences in thermal averages of shielding observed in nuclear magnetic resonance spectroscopy in the zero-pressure limit. However, the precision of most available spin-rotation constants is still such that the sources of errors discussed above are not limiting.

Ab initio calculations of the diamagnetic part of the shielding are generally reliable since these depend only on the ground-state wavefunctions. The changes resulting from configuration interaction are very minor, no more than a few tenths of a ppm in σ^d , over the Hartree–Fock value. Where ab initio calculations are not available, it is possible to estimate σ^d to within 1–2 ppm even without wavefunctions. Flygare has proposed an easy method for evaluating σ^d which has been shown to be sufficiently reliable for evaluating the average and the components of σ from the spin-rotation tensor.^{10,11} The success of this method is due to the fact that most of σ^d is given by the diamagnetic shielding of the free atom and the rest can then be approximately calculated by the method of atomic dipoles. It has been found that the method of Flygare and co-workers is accurate to within 1–2 ppm. Let us consider this method briefly.

By formally partitioning the sum of $1/r_j$ over all j electrons into two sums, one over electrons ‘on’ nucleus N and the other

over all electrons ‘on’ all the other nuclei, N' , Flygare has been able to write the average diamagnetic shielding in terms of a free atom term, a contribution of the electronic point charges centered at the other nuclei, and a third term which arises if the point charges are not centered on the N' nucleus but are displaced by a distance $\langle \rho \rangle_{N'}$:

$$\sigma_{av}^d = \sigma^d(\text{free atom}) + (\mu_0/4\pi)(e^2/3m) \sum_{N'} Z_{N'}/R_{N'} - (\mu_0/4\pi)(e^2/3m) \sum_{N'} R_{N'} \cdot \langle \rho \rangle_{N'}/R_{N'}^3 \quad (4)$$

The second term in the above equation is identical in form and opposite in sign to the nuclear terms in equation (1) and the last term is a small correction. Thus, the absolute shielding σ can be written in the Flygare method, as

$$\sigma_{av} = \sigma^d(\text{free atom}) - (\mu_0/4\pi)(e^2/3m) \times \sum_{N'} R_{N'} \cdot \langle \rho \rangle_{N'}/R_{N'}^3 + \frac{m_p}{2m_e g_N} \cdot \frac{1}{3} \sum \frac{C_{gg}}{B_{gg}^{(e)}} \quad (5)$$

This applies to the equilibrium configuration, with extension to thermal averages requiring some corrections which may be a few ppm.

Using the Flygare approximation for the diamagnetic shielding then leads to

$$\sigma_{av} \simeq \frac{m_p}{2m_e g_N} \cdot \frac{1}{3} \sum \frac{C_{gg}}{B_{gg}^{(e)}} + \sigma^d(\text{free atom}) \quad (6)$$

The diamagnetic shieldings of the free atoms are well known from the tabulations of Malli and Froese.³ For a spherical top molecule,

$$\left. \begin{aligned} \sigma_{av} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{av}}{B} + \sigma^d(\text{free atom}) \\ \sigma_{||} - \sigma_{\perp} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{||} - C_{\perp}}{B} \end{aligned} \right\} \quad (7)$$

and for a linear molecule

$$\left. \begin{aligned} \sigma_{\perp} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{\perp}}{B} + \sigma^d(\text{free atom}) \\ \sigma_{||} &= \sigma_{||}^d \end{aligned} \right\} \quad (8)$$

since $\sigma_{||}^p$ is identically zero for a linear molecule.

The spin-rotation tensor has been used to determine the ^{15}N absolute shielding in NH_3 , ^{19}F in HF , ^{13}C and ^{17}O in CO , and ^{31}P in PH_3 , and these absolute shieldings have been used to establish all other absolute shieldings in various molecules containing these nuclei. Gas-phase studies provide the relative differences at the zero-density limit and these can be converted to $\sigma_0(300\text{ K})$ values absolutely. If the commonly used liquid reference is also measured relative to this one molecule, then all past and future measurements of chemical shifts relative to this liquid reference can be converted to absolute shieldings. As we have seen above, rovibrational corrections should be calculated and added to theoretical σ_e

before comparing with the experimental values $\sigma_0(300\text{ K})$. For some molecules this latter value is not very different from the zero-point vibrational average shielding $\sigma_0(0\text{ K})$. Similarly, the observed spin-rotation constants should be corrected for rovibrational effects before using the identity to obtain σ_e . Nevertheless, the agreement between absolute shielding values derived from spin-rotation constants and those from gas-phase measurements in the zero-pressure limit is remarkably good as shown in Figure 2, which indicates the reliability of the spin-rotation constants.

Figure 2 Experimental absolute shielding values of ^{19}F from gas-phase measurements in the zero-density limit. The gas-phase measurements are converted to absolute shielding by using HF as the primary reference molecule. These are compared with the individual absolute shielding values derived from independent measurements of the ^{19}F spin-rotation constants in various molecules

The ^{15}N absolute shielding scale is based on the spin-rotation tensor in the primary reference molecule, NH_3 . The spin-rotation-derived shielding for NH_3 is 264.54 ppm.¹² Nitrogen-15 chemical shifts in the gas phase taken to the zero-pressure limit lead to absolute $\sigma_0(^{15}\text{N})$ shieldings in the N_2 , NNO , and HCN molecules,¹³ see Table 1. At the same time, the absolute shielding of the liquid references were obtained: $\sigma(^{15}\text{N}, \text{NH}_3, \text{liq.}, 300\text{ K}) = 380.4\text{ ppm}$; $\sigma(^{15}\text{N}, \text{CH}_3\text{NO}_2, \text{liq.}, 300\text{ K}) = -135.8\text{ ppm}$.

The ^{17}O absolute shielding scale is based on the spin-rotation tensor in C^{17}O , $C_\perp = 30.4 \pm 1.2\text{ kHz}$ which leads to $\sigma(^{17}\text{O}, \text{CO}) = -42.3 \pm 17.2\text{ ppm}$.¹⁴ The gas-phase measurements of ^{17}O chemical shifts in H_2O , CO_2 , NNO , OCS , OF_2 , and CO lead to the absolute $\sigma_0(^{17}\text{O})$ shielding values¹⁴ shown in Table 2.

The ^{13}C shielding scale is based on the primary reference ^{13}C in the $^{13}\text{C}^{16}\text{O}$ molecule in which $C_\perp = 32.70 \pm 0.12\text{ kHz}$ in the $v = 0, J = 1$ state¹⁵ is in good agreement with the previous value of $32.59 \pm 0.15\text{ kHz}$. Rovibrational corrections on the spin-rotation constant to obtain $\sigma_e(^{13}\text{C in } ^{13}\text{C}^{16}\text{O}) =$

Table 2 Absolute σ_0 ^{17}O Shieldings

Molecule	$\sigma_0(^{17}\text{O in the molecule, 300 K})$ (ppm)
H_2O	344.0
CO_2	243.4
NNO	200.5
OCS	107.9
OF_2	-473.1
CO	(-42.3 ± 17.2)

3.0 ± 0.9 and then rovibrational corrections on the latter lead to $\sigma_0(^{13}\text{C in } ^{13}\text{C}^{16}\text{O}, 300\text{ K}) = 1.0 \pm 1.2\text{ ppm}$.¹⁶ With measurements of ^{13}C chemical shifts in the low-density gas phase under conditions such that intermolecular effects and bulk susceptibility effects are less than 0.05 ppm, the $[\sigma_0 - \sigma_0(\text{CO})]$ have been obtained for a large number of molecules ranging from CH_4 where $\sigma_0(^{13}\text{C}, \text{CH}_4, 300\text{ K}) = 195.1\text{ ppm}$ to $\text{CH}_2=\text{C}=\text{CH}_2$ where $\sigma_0(^{13}\text{CH}_2, 300\text{ K}) = 115.2\text{ ppm}$, $\sigma_0(^{13}\text{C}=\text{C}, 300\text{ K}) = -29.3\text{ ppm}$. The independent spin-rotation-derived absolute shieldings in $^{13}\text{CH}_4$, D^{13}CN , and O^{13}CS are completely consistent with the values of σ_0 obtained for these molecules based on $\sigma_0(^{13}\text{CO}) = 1.0 \pm 1.2\text{ ppm}$.

The $\sigma_0(^{13}\text{C in the molecule, 300 K})$ values for a large number of molecules have been published by Jameson¹⁶ and Jameson (Table 16).¹⁷ A missing value from the latter is isopentane $\cdots (\text{CH})\text{CH}_3$, for which $\sigma_0(^{13}\text{C in the molecule, 300 K}) = 165.0\text{ ppm}$. These measurements also provide $\sigma(^{13}\text{C}, \text{TMS liquid, spherical, 300 K}) = 184.1\text{ ppm}$ and $\sigma(^{13}\text{C}, \text{C}_6\text{H}_6 \text{ liquid, spherical, 300 K}) = 55.7\text{ ppm}$, which are convenient references for converting chemical shift measurements to absolute shieldings.

The ^{31}P absolute shielding scale is based on the primary reference molecule PH_3 , in which the spin rotation tensor $C_\perp = -114.90 \pm 0.13\text{ kHz}$ and $C_\parallel = -116.38 \pm 0.32\text{ kHz}$ (where the quoted errors are for 99% confidence limits),¹⁸ leading to $\sigma_0(^{31}\text{P}, \text{PH}_3, 300\text{ K}) = 594.45 \pm 0.63\text{ ppm}$. If the spin-rotation tensor is rovibrationally corrected, one gets¹⁹ $\sigma_e(^{31}\text{P in the PH}_3 \text{ molecule}) = 599.93\text{ ppm}$ and $(\sigma_\parallel - \sigma_\perp)_e = -64.5\text{ ppm}$.

The PF_3 molecule serves as a suitable secondary reference since its chemical shift has a smaller dependence on density. Extrapolation of gas-phase mixtures in argon to the zero-density limit provides the absolute shieldings²⁰ listed in Table 3. At the same time the absolute shielding of ^{31}P in convenient reference liquids has been obtained: $\sigma(^{31}\text{P}, 85\% \text{ H}_3\text{PO}_4 \text{ aq., spherical, 300 K}) = 328.35\text{ ppm}$ and $\sigma(^{31}\text{P}, \text{P(OMe)}_3 \text{ liquid, spherical, 300 K}) = 187.54\text{ ppm}$. A ^{33}S absolute shielding scale has been derived from the spin-rotation constant $C_\perp = 870 \pm 50\text{ Hz}$ in the OCS molecule, which leads to $\sigma_0(^{33}\text{S}, \text{OCS molecule}) = 843 \pm 12\text{ ppm}$.²¹ The ^{33}S chemical shift measurements in the gas phase lead (without full corrections for intermolecular effects) to the values shown in Table 4. A convenient liquid reference is CS_2 for which $\sigma(^{33}\text{S}, \text{CS}_2, \text{liquid, spherical, 300 K}) = 581\text{ ppm}$.

Although the proton absolute shielding for water was the first to be established, proton shifts have not been systematically measured in the gas-phase zero-pressure limit and connected to either liquid water or liquid TMS. This situation should be remedied soon as improving proton shielding calculations need some good experimental tests. There are, however, absolute shieldings that can be individually derived

Table 3 Absolute σ_0 ^{31}P Shieldings

Molecule	$\sigma_0(^{31}\text{P}$ in the molecule, 300 K) (ppm)
PMe_3	391.71
OPF_3	363.43
PF_3	222.69
PCl_2Me	138.65
PCl_3	111.29
P_4	-551.5
PH_3	(594.45 ± 0.63)

Table 4 Absolute σ_0 ^{33}S Shielding Values

Molecule	$\sigma_0(^{33}\text{S}$ in the molecule, 300 K) (ppm)

OCS	(843 ± 12)

from measured spin-rotation constants by the methods already described, and these are shown in Table 5.

Table 5 Absolute σ_0 Proton Shieldings

Molecule	$\sigma_0(^1\text{H}$ in the molecule, 300 K) (ppm)	Other values (ppm)
CH_3F	28.27 ± 0.5	
PH_3	27.89 ± 0.15	
NH_3	32.10 ± 0.02	
H_2	26.363 ± 0.004	
CH_4	30.80 ± 0.23	30.611 ± 0.024
HCl	31.16 ± 0.09	
HF	28.64 ± 0.01	28.51 ± 0.20
H_2S	31.26 ± 0.40	
SiH_4	27.52 ± 0.44	27.63 ± 0.03

The errors quoted include only those arising from the uncertainty in the spin-rotation tensor itself. Other values reported in the last column are based on a variety of chemical shift measurements which are indirectly connected to liquid water whose absolute shielding is $\sigma(^1\text{H}, \text{H}_2\text{O}, \text{liq.}, \text{spherical}, 34.7^\circ\text{C}) = 25.790 \pm 0.014$ ppm.

4 THE CONNECTION BETWEEN ABSOLUTE SHIELDING SCALES OF TWO NUCLEI

Spin-rotation constants of any two nuclei in the same molecule can be related to one another provided that both nuclei relax entirely by the spin-rotation mechanism. In the gas phase, in the exchange-narrowing limit, there is a single characteristic correlation time τ which is identical for both nuclei.

The nuclear spin relaxation time characteristic of this mechanism is given by

$$(1/T_1)_{\text{SR}} = \frac{2}{3}(J(J+1))4\pi^2 C_{\text{eff}}^2 \tau \quad (9)$$

with C in units of rad s^{-1} , so that for two nuclei k and k' in the same molecule, in the same gas sample,

$$T_1(k)/T_1(k') = C_{\text{eff}}^2(k')/C_{\text{eff}}^2(k) \quad (10)$$

For linear molecules $C_{\text{eff}}^2 = C_{\perp}^2$. For spherical tops

$$C_{\text{eff}}^2 = C_{\text{av}}^2 + \frac{4}{45}(\Delta C)^2 = \left[\frac{1}{3}(2C_{\perp} + C_{\parallel}) \right]^2 + \frac{4}{45}(C_{\parallel} - C_{\perp})^2 \quad (11)$$

A nucleus in the center of a spherical top is a favorable choice since all $C_{\text{gg}}^{(k)}$ are equal by symmetry and only C_{av}^2 enters into the relaxation expression. If both nuclei k and k' relax entirely by spin rotation, and if C_{eff}^2 is known for one nucleus, e.g. ^{19}F in SeF_6 or TeF_6 , then C_{av} for the central nucleus (and thus the shielding) can be obtained from the measured ratio of relaxation times in the gas phase. This is supported by empirical observations for CH_4 in various buffer gases, in which the ratio of measured ^{13}C and ^1H relaxation times in the gas phase was found to be independent of buffer gas, temperature, or density, and was within experimental error of the inverse ratio of the C_{eff}^2 values from molecular beam data. These molecular beam data, in turn, were consistent with the ^{13}C shielding scale (based on $C_{\perp}$ in CO) and the ^1H shielding scale (based on γ of the H atom).

It is also possible to determine C_{eff}^2 from the density dependence of T_1 in the region of the minimum. However, for most systems, the minimum T_1 occurs at such low densities that appropriate measurements are feasible only for ^1H and ^{19}F nuclei which have the highest NMR sensitivity, and which also have well-established shielding scales based on spin-rotation constants from molecular beam and high-resolution microwave measurements.

This method was used to establish the ^{77}Se and ^{125}Te shielding scales by concurrent measurement of the ^{19}F and ^{77}Se (or ^{125}Te) spin-relaxation times in SeF_6 (or TeF_6) molecules in the dilute gas phase,²² and also the ^{29}Si shielding scale based on both SiH_4 and SiF_4 molecules.²³ The sample was gaseous (e.g. SeF_6 or TeF_6 , or an equimolar mixture of SiH_4 and SiF_4) contained in a sealed glass tube at a well-regulated temperature. Inversion-recovery experiments were set up in both the observe channel and the decoupling channel, the decoupling channel having been modified so that it could be tuned to ^{19}F as well as ^1H .

In one cycle, one-eighth of the total number of transients were taken and stored for each delay time for one nucleus and then the other. The next cycle went through the delay list for one nucleus and the other, acquiring the next eighth and so on. Thus the T_1 experiments were undertaken in the same molecule in the same sample essentially simultaneously. Only the magnitude of C could be obtained from the experiments. The signs were assigned on the basis of the σ values obtained. Defined with the gauge origin at the nucleus in question, σ^{P} is usually negative for most heavy nuclei. For SeF_6 the two possible values of σ^{P} which can be calculated from C are 1559.7 or -2160.7 ppm, from which we choose the latter, i.e. $C(^{77}\text{Se})$ is negative. For TeF_6 the two possible values of σ^{P} are 2570 or -3070 ppm and we choose the latter, which with a negative $g(^{125}\text{Te})$ implies that $C(^{125}\text{Te})$ is positive.

Although the relationship between σ^p and C is exact only for the rigid isolated molecule at its equilibrium configuration, we have used rovibrationally averaged values at room temperature for all quantities. The errors in σ associated with this are smaller than the rovibrational corrections to shielding (-8 and -9 ppm, respectively, for ^{77}Se and ^{125}Te in SeF_6 and TeF_6) since the vibrational corrections to C and σ^p tend to increase slightly the magnitudes of both. Hence, σ_0 (^{77}Se in SeF_6 molecule, 300 K) = 1437.8 ± 64 ppm, σ_0 (^{77}Se in H_2Se molecule, 300 K) = 2401 ± 64 ppm, and σ_0 (^{125}Te in TeF_6 molecule, 300 K) = 3790 ± 130 ppm.

These values are based on 3298 ppm and 6580 ppm for σ^d of the free Se and Te atoms, respectively, including relativistic corrections. Using the absolute shielding values for ^{77}Se in $\text{SeF}_6(\text{g})$ and for ^{125}Te in $\text{TeF}_6(\text{g})$, and the known gas-to-liquid shifts for SeF_6 and TeF_6 , the absolute shielding for the reference liquids $\sigma(^{77}\text{Se}, \text{Me}_2\text{Se}, \text{liq.}) = 2069$ ppm and $\sigma(^{125}\text{Te}, \text{Me}_2\text{Te}, \text{liq.}) = 4333$ ppm are obtained. Concurrent measurement of ^{29}Si and ^1H spin-relaxation times in a sample of SiF_4 gas provides the ratio $C_{\text{av}}^2(^{29}\text{Si})/C_{\text{eff}}^2(^1\text{H})$, and concurrent measurement of ^{29}Si and ^{19}F spin-relaxation times in SiF_4 gas provides the ratio $C_{\text{av}}^2(^{29}\text{Si})/C_{\text{eff}}^2(^{19}\text{F})$. The spin-rotation tensors are independently known for ^1H and ^{19}F in these molecules. Using $g_{\text{Si}} = -1.1106$ and the theoretical value for the diamagnetic shielding σ^d free Si atom = 874.1 ppm, and choosing positive signs for $C(^{29}\text{Si})$ in both molecules, leads to $^{29}\sigma_0(^{29}\text{Si}$ in SiH_4 molecule, 300 K) = 475.3 ± 10 ppm and $\sigma_0(^{29}\text{Si}$ in SiF_4 molecule, 300 K) = 482.0 ± 10 ppm.

The T_1 experiments in SiH_4 and SiF_4 provide two completely independent determinations of very nearly the same point (separated by only 6.7 ppm) on the ^{29}Si shielding scale. The coincidence of these two truly independent results is remarkable. Since a large part of $C_{\text{eff}}^2(^1\text{H}$ or $^{19}\text{F})$ is the isotropic average $C_{\text{av}}^2(^1\text{H}$ or $^{19}\text{F})$ which is directly related to $\sigma_{\text{av}}(^1\text{H}$ or $^{19}\text{F})$, the values are constrained to be consistent with the absolute shielding scales of both ^1H and ^{19}F and also the 6.7 ppm ^{29}Si shielding difference between SiH_4 and SiF_4 . All these conditions are well satisfied within realistic error estimates of ± 10 ppm. The ^{19}F shielding scale is well established, with several independent determinations based on the spin-rotation constants in a number of small molecules agreeing with the chemical shifts in the zero-pressure limit. The ^1H shielding scale is also well established on the basis of hydrogen atomic beam data. It is satisfying to find that the Si shielding scale is consistent with these. Finally, the measured ^{29}Si chemical shifts in SiH_4 and SiF_4 gas relative to neat liquid Me_4Si lead to $\sigma(^{29}\text{Si}, \text{Me}_4\text{Si}, \text{liquid, spherical}) = 368.5 \pm 10$ ppm.

In favorable systems, simultaneous measurements of T for two spin- $\frac{1}{2}$ nuclei in the same molecule in the gas phase provide a means of determining the absolute nuclear shielding scale of the second nucleus from that of the first. This method

can be applied when the spin-rotation tensor of the first nucleus is independently known or can be calculated from its known shielding tensor. The latter can be obtained by measurement of the chemical shift anisotropy and the isotropic absolute shielding based on some primary reference (such as ^1H in the H atom, ^{13}C in CO, ^{15}N in NH_3 , ^{17}O in CO, ^{19}F in HF, ^{31}P in PH_3 , or ^{33}S in OCS). In a linear molecule only the isotropic shielding is necessary since $\sigma_{\parallel}$ is entirely diamagnetic. For spherical tops the $(\Delta C)^2$ term is 4/45-times as small as the C_{av}^2 term, so that even when $(\Delta C)^2$ and $\Delta\sigma$ are unknown an estimate may be adequate. An appropriate molecule in which two nuclei relax nearly exclusively by spin-rotation in the gas phase effectively provides a bridge between the absolute shielding scales of these nuclei.

Finally, a method of obtaining the absolute shielding directly from the measured anisotropy $\Delta\sigma \equiv (\sigma_{\parallel} - \sigma_{\perp})$ in a linear molecule takes advantage of the symmetry requirement that the paramagnetic shielding contribution along the axis parallel to the molecular axis vanishes: $\sigma_{\parallel}^p = 0$. A theoretically calculated diamagnetic term $\sigma_{\parallel}^d$ provides the rest of the required information:

$$\sigma_{\perp} = \sigma_{\parallel}^d - \Delta\sigma, \quad \sigma_{\parallel} = \sigma_{\parallel}^d \quad (12)$$

so that the absolute average shielding is

$$\sigma = \sigma_{\parallel}^d - \left(\frac{2}{3}\right) \Delta\sigma \quad (13)$$

albeit containing some unwanted intermolecular effects in $\Delta\sigma$ which is usually obtained from a condensed-phase measurement. One can therefore establish a shielding scale for a nucleus by choosing an appropriate linear molecule. Some examples are shown in Table 6. The absolute shieldings obtained from the anisotropy differ slightly from those obtained in the gas in the zero-pressure limit, from which we see that intermolecular effects are 1 to -8 ppm in the solid. It should be noted that the above relationships hold only for a linear molecule, not for a quasilinear or pseudolinear molecule. Any off-axis atoms break the symmetry and lead to $\sigma_{\parallel}^p \neq 0$. For example, $\text{CH}_2=^{13}\text{C}=\text{CH}_2$ has $\sigma_{\parallel}^p = -250$ ppm for the central ^{13}C . Furthermore, $\sigma_{\parallel}^p = 0$ holds for a linear molecule only at the level of the nonrelativistic theory of shielding.

5 MAGNITUDES OF THE CORRECTIONS LINKING THE SHIELDING IN THE CONDENSED PHASE TO THE ISOLATED MOLECULE AT ITS EQUILIBRIUM GEOMETRY

The exquisite sensitivity of the shielding to the electronic environment is what makes the NMR chemical shift a very

Table 6 Absolute Shielding (ppm) Derived from the Shielding Anisotropy

SeCSe	506	294	-212	-43.3	

powerful tool in studying structure, intermolecular effects, and dynamic averaging. For the purpose of comparing with theoretical *ab initio* calculations of the shielding, however, this exquisite sensitivity to the environment appears at first to be a distinct disadvantage. Nevertheless, if one knows the precise relationship between the quantities being calculated (the shielding at some specific set of nuclear coordinates) and the quantities being measured, then the appropriate comparisons against theory can still be made. In fact, a more complete comparison becomes possible when the true connection between the experimental milieu and the theoretical constructs is understood. Since it is never possible to observe a molecule as a fixed arrangement of nuclei (even in the molecular beam where no neighbor effects need to be considered, there is always at least the zero-point vibrational motion), let us consider the nature of the connection between what is measured and what can be calculated. In this respect, the NMR chemical shift is in by far a more advanced stage compared with other molecular electronic properties such as electric dipole polarizability, electric field gradient tensors, etc. It is partly a theoretical advantage, but more important an experimental advantage, that NMR spectroscopy provides. The very high resolution that is possible under the conditions of isotropic averaging in gases and solutions makes it possible to measure chemical shifts of the order of parts per billion. The more advanced temperature control of experiments in NMR spectroscopy, compared with other forms of spectroscopies, combined with the high resolution, has made it possible to measure the temperature dependence of the shielding in a nearly isolated molecule over a 200 K range almost routinely. The small chemical shifts that are the differences in shielding between two molecules differing only in the isotopic masses of some of the nuclei can be measured to a few ppb as well.

Both of these phenomena are related to the dynamic averaging of the vibrating molecule through its various nuclear configurations, each configuration having its appropriate shielding value for a particular nucleus. There are also intermolecular effects, again associated with shielding values that change with nuclear configurations, this time the configurations of supermolecules including not only the molecule bearing the NMR nucleus but all the neighboring interacting molecules. Solvent shifts are a manifestation of this, as are adsorption shifts, as well as a portion of the discrimination between different locations of the same amino acid residues in a protein. The dynamic averaging is discussed further in *Isotope Effects on Chemical Shifts and Coupling Constants* and some aspects of the intermolecular shifts are discussed further in the article on *Gas Phase Studies of Intermolecular Interactions and Relaxation*. In this article, we merely take note of the mechanisms that give rise to the phase-dependent and temperature-dependent differences and how large the corrections are.

Let us first consider an isolated or nearly isolated molecule, i.e. one in which the frequency of collisions with other molecules is still enough to allow the molecule to sample its many rotational and vibrational states while being observed in the NMR spectrometer but not frequent enough to lead to a measureable intermolecular contribution. As the molecule undergoes vibrations, the distances between nuclei change in a periodic fashion, bonds being alternately compressed and expanded, bond angles being alternately enlarged and made smaller, with torsions or frustrated internal rotations possibly occurring as well. For each frozen configuration the

shielding of an NMR nucleus in the molecule is different. In the context of the Born–Oppenheimer approximation, the nuclei are moving slowly enough relative to the electronic motion that it is possible to talk about a shielding surface, a highly multidimensional mathematical surface akin to the intramolecular potential energy surface, which describes the shielding at each configuration of the collection of nuclei that make up the framework of the molecule. Of course, the parts of this shielding surface that are sampled during the vibrations are those regions that correspond to the deep pockets in the intramolecular potential energy surface (PES), located at what we call the ‘equilibrium’ molecular geometry. Thus, it would seem that for the most part, the only interesting regions that we should concern ourselves with are those in the immediate vicinity of the single deep pocket in the PES. This may indeed be the case for the dynamic averaging in small molecules such as diatomics and methane. However, as soon as torsion angles come into the picture, the nature of the averaging changes. Wider excursions are possible, perhaps passing through *cis*-eclipsed, *gauche*, *gauche'*, *trans*-staggered, etc. Even in a simple molecule like NH₃, the umbrella inversion has to be considered in its entirety—no minor small amplitude excursions here! Thus, it becomes necessary to think in terms of not a single shielding tensor associated with a particular nucleus in a molecule, but a continuum, of such tensors changing smoothly with nuclear displacements away from the lowest energy point in the deep pocket. Some shielding surfaces are shown in the article on *Isotope Effects on Chemical Shifts and Coupling Constants*, and the consequences of the dynamic averaging are discussed there as well.

How large are the shielding changes in going from the equilibrium geometry to the dynamically-averaged shielding? This depends on the molecule. For the ¹⁹F shielding in the F₂ molecule, the difference is of the order of 40 ppm; for the ¹⁵N in the N₂ molecule it is smaller, about 3 ppm, and for ¹H in the HF molecule it is around 0.3 ppm. Most of the dynamic averaging effects lead to a decreased shielding, but instances of increased shielding can also be found. At the time when the theoretical calculations were only good to within 50 ppm for ¹³C in various molecules, for example, the direct comparison of the shielding calculated in a molecule rigidly fixed at its equilibrium geometry with the chemical shift measurements in solution could be excused. With the present theoretical capability discussed in the articles by Hansen and Kutzelnigg in this Encyclopedia, the real test of the quality of a calculation is really in the shape of the surface in the immediate vicinity of the equilibrium geometry, not just the value at a single one point on the surface. The rationale for determining absolute shielding scales is to be able to compare shieldings rather than differences of shieldings between two different molecules, thereby disallowing any fortuitous agreements in chemical shifts while the shieldings themselves could be far off. We go further at this point and make note not only of the absolute shielding of a nucleus in the particular molecule, but the dynamic average over a portion of the shielding surface for this nucleus; the shape of the surface itself is being tested. Typical magnitudes of the vibrational corrections that arise from this dynamic averaging are shown in Table 7.

Most of the time, we observe molecules in some medium rather than in the zero-pressure limit in the gas phase. Most of the full shielding tensor information is obtained in the solid

Table 7 Vibrational Corrections from Dynamic Averaging

	$[\sigma_0(T) - \sigma_e]$, theor. (ppm)
^1H in HF	-0.4

^{19}F in HF	-9.7
^{31}P in PH_3	-12.8
^{77}Se in H_2Se	-58.9

state or in liquid crystal solutions. It is therefore important to understand the ways in which that which we are measuring is affected by the surrounding molecules. We know that medium effects can be large because the gas-to-liquid shifts have been measured in pure substances. The magnitudes of some of these are shown in Table 8, where the chemical shift between the liquid and the vapor in equilibrium with it have been measured at the same temperature. We also know that intermolecular effects in physisorption can be large. Now, this is strictly an intermolecular effect, not involving a change in chemical structure. For ^{129}Xe nuclei of xenon atoms physisorbed in zeolites, the adsorption shifts are of the order of several hundred ppm! In other words, a xenon atom adsorbed in a zeolite cavity or channel has a shielding that differs from that in the gas phase by several hundred ppm. (See *Adsorbed Species: Spectroscopy and Dynamics*.) This is strictly an intermolecular effect, not much different from the solvent effect in solution, with the only difference being that the solvent is stationary while the solute is relatively free to move. This too is a result of dynamic averaging, just as in solutions. This is clearly a many-body type of situation and the interpretation involves making some approximations.

Table 8 Gas-to-Liquid Shifts

		$T(\text{K})$	$[\sigma(\text{liquid}, T) - \sigma(\text{vapor}, T)]$ (ppm)

	H_2Se	300	-120
^{125}Te in	TeF_6	300	-2.0
^{129}Xe in	Xe	244	-200

A simpler situation is found in the gas phase. Intermolecular effects can be treated in the gas phase by the method of Buckingham and Pople by considering a virial expansion of the molecular electronic property, in this case the NMR shielding, in powers of density, i.e. $\sigma(T, \rho) = \sigma_0(T) + \sigma_1(T)\rho + \sigma_2(T)\rho^2 + \sigma_3(T)\rho^3 + \dots$, where $\sigma_0(T)$ is the temperature-dependent shielding in the nearly isolated molecule. By making measurements of the shielding in gas samples of various densities at various temperatures, it is possible to obtain directly the second virial coefficient of nuclear shielding, $\sigma_1(T)$. This is a dynamic average which has a precise interpretation, as shown below.

$$\sigma_1(T) = \int_0^\infty 4\pi R^2 dR [\sigma(R) - \sigma(\infty)] \exp^{-V(R)/kT} \quad (14)$$

In other words, the dynamic averaging occurs over an intermolecular shielding surface, $[\sigma(R) - \sigma(\infty)]$, with various weighting factors, as determined by the intermolecular potential energy, $V(R)$, surface. In a sense, this is entirely analogous to the averaging which occurs in vibration, except that the pockets are very deep in the intramolecular potential surface, whereas they are relatively shallow for intermolecular surfaces. Thus a very wide range of distances are included, and the temperature dependence is explicitly seen in the integration. The intermolecular shielding surface looks rather similar to the shielding surface of a nucleus in a diatomic molecule, except that all parts of the intermolecular surface are important other than at very very close range where the repulsive interactions dominate so strongly that such configurations are not effectively sampled.

This shielding surface is also amenable to theoretical calculations. In effect, the system under consideration is a supermolecule made up of the interacting molecules at all possible orientations and separations. A direct comparison of an intermolecular surface to an intramolecular one is not possible. However, the known differences in shielding sensitivities of nuclei across the Periodic Table allow us to scale the chemical shifts of one type of nucleus relative to another. For example, proton shifts are about 20 ppm to the fluorine shifts of about six hundred ppm. If we do this, then we can put an intramolecular shielding surface on the same plot as an intermolecular shielding surface, keeping their magnitudes in the same proportion as the well-known relative magnitudes of the ranges of their chemical shifts. One such example is shown in Figure 3, where the intramolecular shielding surface for the ^{23}Na nucleus in the NaH molecule is superimposed on the intermolecular shielding surface for the isoelectronic system, the ^{21}Ne nucleus in a Ne atom interacting with a He atom. On an absolute scale the shielding surface for ^{21}Ne in Ne-He has a much steeper change than the ^{23}Na shielding surface, but only because the nuclei on the right-hand side of the Periodic Table have much larger expectation values for the $1/r^3$ value of the electrons. When this is taken into account, it is seen that intramolecular shielding surfaces involve a much greater response of the nucleus to the changing electronic environment (bond extension or compression) than the response of the nucleus to the approach of a neighboring solvent molecule described by the intermolecular shielding surface.

If the shielding of a nucleus in a molecule surrounded by six neighbors, say, can be considered as a sum of six pairwise contributions between itself and each neighbor molecule,

Figure 3 The intramolecular shielding surface for ^{23}Na in NaH and the intermolecular shielding surface for ^{21}Ne in NeHe

and if each pairwise intermolecular shielding function is known (similar to the ^{21}Ne shielding function for NeHe in Figure 3), then dynamic averaging amounts to sampling all such configurations of molecule and neighbors and calculating the intermolecular shielding for each configuration. This has been done for ^{129}Xe shielding in zeolite NaA. The same intermolecular shielding function that reproduces the $\sigma_1(T)$ for xenon in the gas phase reproduces the chemical shifts between the Xe, Xe_2 , Xe_3 , ..., Xe_8 clusters trapped inside the cages of zeolite NaA.^{24,25} In principle, chemical shifts in condensed phases can be obtained by a similar dynamic averaging.

1 INTRODUCTION

There are a number of methods in solid state NMR spectroscopy which can be used to obtain information about the chemical shift tensor. The method of choice is usually a function of the equipment available, the complexity of the sample, the information desired, and the state of the sample at ambient temperatures. This article serves as an overview of the various methods, and deals with the requirements and limitations in terms of both sample and instrumentation for each technique, as well as with the information that can be obtained. A more detailed description for some of these techniques can be found in other portions of the Encyclopedia, as listed in Section 10. It should be noted that no effort is made to include listings of chemical shift tensor data that have been measured. The reader is referred to compilations of this type of data, the most recent being Duncan's book.¹

Before the description of the methods, a brief introduction concerning the Zeeman interaction, chemical shielding, dipolar coupling, and quadrupolar interactions that must be considered is presented. Again a more detailed discussion concerning these interactions is presented elsewhere in this Encyclopedia or can be obtained from a number of books.²⁻⁵

2 MAGNETIC INTERACTIONS

2.1 Zeeman Interaction

In the presence of a magnetic field, a nucleus possessing a spin ($I \neq 0$) will be in one of $2I + 1$ energy levels, defined by the magnetic moment of the nucleus and the strength of the static magnetic field, B_0 . The NMR experiment measures the transitions between these levels. The direction of the applied magnetic field is taken by convention to be along the

z direction, and the difference in energy between any two of the allowed states, in frequency units (Hz), can be given as

$$\nu_0 = \gamma_I B_0 / 2\pi \quad (1)$$

This frequency ν_0 is known as the Larmor frequency, and is a function of the field strength and the magnetogyric ratio, γ , of the nucleus.

2.2 Chemical Shielding

The chemical shielding interaction separates the resonance frequencies of nuclei based on their electronic environment. The magnetic field experienced or 'seen' by the nucleus of an atom in a molecule is affected by the electrons that surround that nucleus. The chemical shift tensor is a reflection of this orientation-dependent interaction of the electronic environment of a nucleus with the external magnetic field. In general, a different value of the chemical shift will be observed for a nucleus for each orientation of that molecule in the magnetic field. The dependence of the chemical shift on the molecular orientation will be further elaborated upon in the next section.

In the most general terms this chemical shift interaction is represented by a 3×3 Cartesian matrix,

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & \delta_{zz} \end{bmatrix} \quad (2)$$

The interaction can be decomposed into three parts: the isotropic, the symmetric, and the antisymmetric portions,

$$\delta = \delta_{\text{iso}} + \delta_{\text{sym}} + \delta_{\text{anti}} \quad (3)$$

The isotropic matrix gives the position of the center of the spectrum, while the symmetric matrix defines the lineshape observed. The antisymmetric portion has no observable effect on the lineshape, at the current level of technology and will not be further considered in this work. Often the first two terms are combined and given as

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{xz} & \delta_{yz} & \delta_{zz} \end{bmatrix} \quad (4)$$

The resonance frequency that is observed in high-resolution NMR spectroscopy is one-third of the trace of the matrix shown in equation (4), or $\delta_{\text{iso}} = (\delta_{xx} + \delta_{yy} + \delta_{zz})/3$.

There exists some frame in which the matrix in equation (4) is diagonal; in this case the three diagonal elements are known as the principal values of the chemical shift tensor (or tensor components), and are designated as δ_{11} , δ_{22} , and δ_{33} . Convention states that $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with δ_{11} being in the high-frequency or least shielded direction. The remaining three terms are the Euler angles which define the directions of these principal values in the molecular frame. The axis system in which the symmetric chemical shift matrix is diagonal is known as the principal axis system (PAS).

2.3 Dipolar Coupling

Interactions also exist between magnetic nuclei. The interaction of two spins through space is known as a direct or dipolar coupling. This interaction has a $1/r^3$ dependence on the separation of the two spins and a linear dependence on the γ values of the two spins involved, as shown in equation (5) for the general case of two different spin- $\frac{1}{2}$ nuclei, I and S , e.g., ^{13}C and ^1H .

$$D = \frac{\gamma_I \gamma_S \hbar}{r_{IS}^3} \quad (5)$$

The dipolar interaction is also orientation-dependent; in this case the tensor is axially symmetric and has a trace of zero. The fact that the dipolar tensor is traceless means that the dipolar interactions average to zero in high-resolution NMR spectra. The unique component of the dipolar tensor is along the vector connecting the two spins, generally designated as D_{zz} and is equal to $2D$, and the two identical components, D_{xx} and D_{yy} , with the value of $-D$, are in the plane perpendicular to this vector.

In the case of solid state NMR studies of organic compounds, most typically carbon is the nucleus of interest. Only 1.1% of all carbon nuclei are ^{13}C , which is the magnetic isotope of carbon. The remainder of the carbon nuclei have no magnetic moment and as such are nondetectable. For this reason, dipolar couplings between directly bonded carbons only occur in approximately one of every 10 000 pairs. Magnetic isotopes of low natural abundance, such as carbon, are said to be 'rare' or dilute spins. This is also the case for a number of other nuclei, with ^{15}N being a second important case of a rare spin. However, as more than 99% of all hydrogen nuclei are protons (^1H) with $I = \frac{1}{2}$, dipolar couplings both between protons and between the rare spins and the protons play an important role in organic compounds. These ^1H - ^1H and ^1H - ^{13}C dipolar interactions are very large (tens of kHz) and can completely obscure the chemical shift information. Fortunately, these interactions can be removed by a technique known as proton dipolar decoupling, which is the use of irradiation at the proton frequency during the observation period. Decoupling can be used to remove unwanted dipolar interactions in all cases where the rare spin being observed is coupled to an abundant spin system.

There are also several decoupling schemes that remove the dipolar interactions between nuclei of an abundant spin while allowing for the observation of the chemical shift information of that same spin. These techniques are grouped together as multiple pulse decoupling techniques,⁶ and are most commonly used when observing ^1H or ^{19}F .

Finally, dipolar couplings between two (and occasionally three or more) spins can be used to obtain information about both the orientation of the PAS and the distance between the spins. A molecule can be selectively enriched with two magnetic isotopes to achieve an isolated spin pair; alternatively, compounds can be enriched in one position and the second spin of the dipolar pair can be one of high natural abundance, but uncommon (^{19}F or ^{31}P), or a spin- $\frac{1}{2}$ pair may exist naturally (^{31}P - ^{31}P).

2.4 Quadrupolar Effects

For the quadrupolar nuclei, i.e. those with spins ≥ 1 , the observed lineshape is typically dominated by the nuclear quadrupole interaction, given for a spin I in equation (6):

$$\mathbf{Q} = \frac{eQ}{2I(2I-1)\hbar} \mathbf{V} \quad (6)$$

Again the interaction is anisotropic, with the factor eQ being the quadrupole moment and $\mathbf{V}$ the electric field gradient (EFG) tensor. The EFG tensor has a PAS just like the chemical shift tensor; the EFG tensor is traceless, and does not appear directly in liquid spectra due to rapid, isotropic molecular tumbling in solution. The quadrupole coupling constant, $\chi = e^2 Qq/h$, ranges from 100 kHz to tens of MHz depending on the nuclei (i.e., ^2H , ^{14}N , or ^{17}O) and the symmetry about the nuclei.

Due to the fact that quadrupolar coupling terms are usually orders of magnitude larger than the span of the chemical shift values, the lineshapes obtained are typically only fitted using the isotropic chemical shift along with the quadrupolar parameters. Therefore, the principal values of the chemical shift tensor have only been obtained for a small number of quadrupolar nuclei.¹ Due to this lack of reported measurements of the principal values, no further discussion on quadrupolar nuclei will be presented in this article.

When quadrupolar nuclei are coupled to spin- $\frac{1}{2}$ nuclei, there exists a dipolar coupling; this situation will be included in the section on dipolar spectra.

3 EXPERIMENTAL CONSIDERATIONS

3.1 Cross Polarization

The first step in all the experiments that will be discussed is to take the magnetization of the spin of interest from its equilibrium position, aligned with the magnetic field, to the xy plane. This is commonly done using one of two methods: by application of a 90° pulse (also known as a Bloch decay or BD) or by cross polarization (CP).⁷

The experiment of choice is typically CP, in which the signal of the low abundance spin system is enhanced via magnetization transfer from a second magnetic nucleus which has both a higher natural abundance and a higher γ value. Again the most common nucleus used for magnetization transfer is the proton. The CP method has two advantages over BD: there is a signal enhancement of the rare spin by up to a factor of the ratio of the γ value of the high abundance spin to that of the rare, lower γ spin, and the relaxation times, which dictate how fast a repetition rate can be used in the signal averaging process, are typically faster for the more abundant spin.

In the BD experiment, a 90° pulse is used to take the magnetization of the spins directly into the xy plane, followed by an observation period during which the decay of magnetization in this plane as it returns to its equilibrium position along the magnetic field direction is recorded. The BD experiment is used in cases without an abundant spin system, i.e. systems without protons.

In order to obtain signals from only protonated carbons or signals from only nonprotonated carbons, the techniques of short CP or contact times (SCT) and dipolar dephasing (DD) can be used.^{8,9} With short contact times (about 40 μ s), only carbons with directly bonded protons develop magnetization, resulting in a spectrum containing only signals of these carbons. With DD, time is allowed for magnetization transfer to develop to all carbons, followed by a period during which the magnetization of the strongly coupled spins, i.e. the protonated carbons, is allowed to decay. The magnetization dephasing is much slower for the weakly dipolar-coupled (nonprotonated and mobile methyl carbons) spins. After this dephasing period a normal acquisition shows only signals from these weakly dipolar-coupled carbons.

3.2 Magic Angle Spinning

Magic angle spinning (MAS)^{10,11} is a technique used in conjunction with high power decoupling to obtain high-resolution or solution-like spectra from a solid powder sample. With MAS the chemical shift interaction is averaged to its isotropic value and dipolar interactions are removed by rapid rotation of the sample at an angle of 54.7°, the magic angle, with respect to the B_0 . The average chemical shift δ of a given nucleus in a sample that is rotating about an angle θ with respect to the external magnetic field is given by

$$\begin{aligned} \delta = & \delta_{\text{iso}} + \frac{1}{2}(3 \cos^2 \theta - 1) \\ & \times \left[\frac{1}{2}(3 \cos^2 \beta - 1)(\delta_{33} - \delta_{\text{iso}}) \right. \\ & \left. + \frac{1}{2} \cos^2 \beta \cos 2\alpha(\delta_{11} - \delta_{22}) \right] \end{aligned} \quad (7)$$

where α and β are two of the three Euler angles which specify the orientation of the PAS in the frame of the spinning system, and the δ quantities are the various elements of the chemical shift tensor. At $\theta = 54.7^\circ$, the term $(3 \cos^2 \theta - 1)$ is zero, and the pattern collapses to a single line at the frequency given by the isotropic chemical shift, δ_{iso} , provided that the rotation frequency, ω_r , is larger than the width of the powder pattern.

4 SAMPLES: POWDERS VERSUS SINGLE CRYSTALS

4.1 Powder Samples

So-called powder techniques (both one- and two-dimensional) are performed on powdered or microcrystalline samples, or on samples that have molecules in a statistical distribution of all possible orientations with respect to the magnetic field. The principal values of the chemical shift tensor define the spectral lineshape obtained for the case of a decoupled spin- $\frac{1}{2}$ nucleus. The resultant lineshapes as shown in Figure 1 can be used to obtain the principal values of the chemical shift tensor. The change in intensity across the powder pattern can be explained by representing the chemical shift as an ellipsoid centered at the nucleus. The distance from the center to the outside of the ellipsoid represents the magnitude of the chemical shift with the static magnetic field in that direction while the three axes of the ellipsoid are the directions giving rise to the three principal values. While there are only two directions which give

Figure 1 Examples of chemical shift powder patterns for one spin- $\frac{1}{2}$ nucleus: (a) symmetric system, (b) axially symmetric system, and (c) general asymmetric tensor. Arrows indicate the position of the principal values of the chemical shift tensor

rise to each of the three principal values there are multiple directions that give rise to the values between the principal values.

For the case of nuclei with highly symmetric electronic environments, for example the carbon in methane, CH_4 , the electronic environment does not change as a function of the orientation of the molecule in the magnetic field, and thus the chemical shift is the same in all orientations. This situation occurs when the symmetry at the nucleus is tetrahedral or greater and gives rise to an isotropic chemical shift powder pattern, shown in Figure 1(a), where the three principal values are all equivalent and equal to the value observed in high-resolution NMR spectroscopy. The entire width of the powder pattern is due to residual broadening effects.

The next case is where two of the three principal values are equivalent (known as an axially symmetric tensor) which occurs in cases where there is a threefold symmetry axis through the nucleus, e.g. N of NH_3 . The unique principal value lies along the threefold axis and is designated $\delta_{\parallel}$ while the degenerate components are in the plane perpendicular to the axis and are designated $\delta_{\perp}$. These two values can be read from the extremes or breakpoints of the powder pattern, as indicated in Figure 1(b).

The most general case is when the symmetry elements present at the nucleus are all less than threefold, resulting in all three of the principal values being different, as shown in Figure 1(c). In general, only the three principal values of the

chemical shift tensor can be measured from a powder sample. However, in some cases, the symmetry of the molecule at the nuclei of interest can indicate the directions of one or more of the principal values of the tensor (but not which principal value is in that direction). The more the electronic environment varies, the broader the powder pattern.

The techniques that can be used to obtain the principal values of the chemical shift tensor for decoupled spin- $\frac{1}{2}$ nuclei using a powder sample are divided into two broad categories: the one-dimensional (1D) methods, discussed in Section 5, and the two-dimensional (2D) methods, covered in Section 6.

4.2 Single Crystals

In a single crystal there is no longer a distribution of all possible orientations with respect to the external magnetic field as in a powder sample. Instead of seeing broad powder patterns which are independent of the orientation of the powder sample in the magnetic field, the NMR signal from a single crystal placed in a magnetic field is a series of narrow lines, one for each magnetically inequivalent nucleus. When the crystal is rotated, the position of these lines change. The manner in which the position of a given line in the spectrum changes as a function of the crystal orientation in the magnetic field, again for decoupled spin- $\frac{1}{2}$ nuclei, is given by the expression

$$\delta = \delta_{11} \cos^2 \alpha \sin^2 \beta + \delta_{22} \sin^2 \alpha \sin^2 \beta + \delta_{33} \cos^2 \beta \quad (8)$$

where α and β are the Euler angles which relate the PAS to the magnetic field direction. Knowing the crystallographic orientation of the single crystal as mounted in the NMR probe, this information can be used to determine the orientation of the PAS in the molecular frame.

Aside from the advantage that the entire chemical shift tensor is determined, a second advantage is that single crystal NMR data are the most precise. The estimated errors in the principal values are in the order of 1 ppm or less, whereas the errors in the powder techniques are generally in the range of 3 ppm or more. Intermolecular interactions and/or structural distortions in crystals can lead to very small shifts in these principal values and/or orientations between two nuclei, and these effects, while immeasurable by powder techniques, can be observed by single crystal NMR.¹²

While this experimental method provides the most information, it is also the method with the most limitations. The most severe limitation is that a relatively large single crystal (several mm in all dimensions) of the compound of interest must be obtained, a feat not always possible. This automatically limits the possibilities to room temperature solids from which single crystals can be grown and transferred into the NMR probe. However, if a suitable crystal can be grown, it is the method of choice.

Single crystal studies have been completed on dilute spin systems, mainly ^{13}C , as well as on abundant spins such as ^1H or ^{19}F . For ^{13}C , the cross polarization method in combination with high-power proton decoupling is used; for the abundant spins, multipulse decoupling techniques are necessary.

Just as the powder techniques are divided among 1D and 2D methods, so are the single crystal methods. In Section 7, the experimental techniques for obtaining the chemical shift information from a single crystal will be presented.

5 ONE-DIMENSIONAL POWDER TECHNIQUES

5.1 Static Powder Sample

The simplest, most straightforward experimental method for obtaining the principal values of the chemical shift tensor is to record the spectrum of a static solid sample and measure the principal values from the breakpoints in the powder pattern, as indicated in Figure 1.² The sample can be a solid without any molecular reorientation at room temperature, or it can be a sample at a temperature low enough both to take the sample into the solid state and to stop any molecular reorientation. Most typically, the CP technique in conjunction with high-power decoupling is used to obtain the powder pattern of common, low natural-abundance spin- $\frac{1}{2}$ nuclei such as ^{13}C or ^{15}N or a high natural-abundance, but uncommon, nucleus such as ^{31}P . Powder patterns can also be obtained for common, high natural-abundance spin- $\frac{1}{2}$ nuclei (e.g., ^1H) with the use of multiple pulse decoupling techniques.

The use of static powder samples has one severe limitation. In molecules containing several nonmagnetically equivalent nuclei, e.g., several different carbons, overlap between the powder patterns can make the determination of the principal values impossible. This is demonstrated by the powder pattern of 1,2,3,6,7,8-hexahydropyrene, given in Figure 2 along with the best fit to the lineshape due to the aromatic carbons. In this case there are three magnetically inequivalent aromatic carbons, with the powder patterns labeled A, B, and C in the decomposed simulation. The portion of the spectral lineshape not fitted is due to the aliphatic carbons.

Even though there have been numerous techniques introduced which help to overcome this limitation concerning sample complexity, the use of a static powder sample is still very common as it is the only technique applicable for certain samples. While variable temperature probes could, in theory, be built to perform many of the experiments that will be discussed below, the majority of the probes that have been built for these techniques can only handle room-temperature solids. On the other hand, it is fairly simple to equip a NMR probe for a static sample with variable temperature capabilities to solidify a liquid and perform a static powder measurement on the sample.

NMR probes have also been constructed to interface with closed cycle cryogenic units, capable of reaching temperatures as low as 4 K.^{13,14} This allows the study of not only samples that are liquids or gases at room temperature, but also molecules isolated in an inert environment. Molecules not stable under normal conditions for any reasonable length of time can be generated and quickly deposited on the cold tip of the cryogenic unit, or molecules can be generated photochemically after deposition of a precursor species. For these situations, the only option for obtaining any information on the principal values of the chemical shift tensor is to measure a static powder pattern.

5.2 Variable Angle Sample Spinning

The problem of overlapping tensor patterns can be somewhat alleviated by partially averaging the lineshape by spinning the sample at an angle other than the magic angle, a technique

Figure 2 Static powder pattern of 1,2,3,6,7,8-hexahydropyrene with best-fit simulation of the aromatic region. Simulation is decomposed into the three components, where A is the lineshape of the substituted aromatic carbons, B is the pattern of the condensed or bridgehead aromatic carbons, and C is the pattern of the protonated aromatic carbons. (Reproduced by permission of the American Chemical Society from N. K. Sethi, R. J. Pugmire, and D. M. Grant, *Prepr. Am. Chem. Soc., Div. Fuel Chem.*, 1987, **32**, 155)

known as variable angle sample spinning or VASS.^{15,16} As described in Section 3.2, if a sample is spinning at an angle of 54.7° relative to the external magnetic field, and the spinning rate is greater than the width or anisotropy of the pattern, each pattern is collapsed to a relatively narrow line at the isotropic chemical shift, according to the expression in equation (7). If the chosen angle is not the magic angle then the pattern is scaled by the $3 \cos^2 \theta - 1$ term, where the angle between the spinning axis and the external magnetic field is given as θ . For angles less than the magic angle the pattern is scaled, and for angles greater than the magic angle the pattern is inverted about the isotropic chemical shift as well as scaled. Representative VASS spectra of 1,2,3,6,7,8-hexahydropyrene are shown in Figure 3 for four different angles. It should be noted that the powder pattern for each individual spin is scaled differently, and therefore the resultant patterns are not just scaled versions of one another but are distinctive lineshapes. Experimentally, it has been demonstrated that recording five spectra, one at the magic angle and four at other angles, and simultaneously fitting the four off-angle spectra while locking the isotropic values to those obtained by the magic angle spectrum, gives good results.¹⁷

One of the major advantages of the VASS technique is that it removes the overlap that is nearly always observed between the δ_{33} component of unsaturated carbons and the aliphatic carbon

Figure 3 VASS powder patterns of 1,2,3,6,7,8-hexahydropyrene taken at specified angles θ with respect to the static magnetic field direction, along with best fit simulations of the aromatic region. (Reproduced by permission of the American Chemical Society from N. K. Sethi, R. J. Pugmire, and D. M. Grant, *Prepr. Am. Chem. Soc., Div. Fuel Chem.*, 1987, **32**, 155)

signals. Also, less time is required to obtain a spectrum with the same signal-to-noise (S/N) ratio as a static powder pattern due to the scaling of the powder pattern. Because a number of different spectra can be recorded and fitted simultaneously, the number of tensors that can be fitted is slightly increased relative to the number of tensors that can be obtained from a static powder pattern.

5.3 Slow Magic Angle Spinning

Another method that can be used to alleviate the problem of overlapping powder patterns is to spin at the magic angle but at speeds less than the width of the patterns, a technique that is known as the Herzfeld–Berger method.^{18,19} The resulting spectrum is a series of narrow lines spaced about isotropic chemical shift at integer multiples of the spinning speed for the width of the powder pattern, as shown in Figure 4(b) for the carbons in 1,2,3-trimethoxybenzene. Combining this spectrum with the spectrum taken at a higher speed MAS, shown in Figure 4(a) for 1,2,3-trimethoxybenzene, the center or isotropic chemical shift peaks can be identified, and the various sidebands can then be matched to the proper centerline. The intensities of these spinning sideband (ssb) patterns can

Figure 4 (a) MAS spectrum of 1,2,3-trimethoxybenzene (shown in inset) at a spinning rate of 6.0 kHz. (b) Spinning sideband pattern obtained for 1,2,3-trimethoxybenzene at a spinning rate of 1106 ± 5 Hz

then be analyzed by several methods to yield the principal values of the chemical shift tensor.

This procedure has not been used very widely as it requires a careful measurement of the integrated intensities and the use of a more complex analysis than needed for static patterns, and the errors in the principal values obtained from this technique are typically greater than those from the other methods. Experimentally, it is crucial that the spinning speed be constant (± 10 Hz); however, with modern spinning speed controllers this is very feasible. The limitation in the number of magnetically inequivalent spins is determined by the width of the lines; if a compound contains several spins with similar isotropic chemical shifts, overlap can prevent accurate line intensities being obtained.

More recently, the Herzfeld–Berger method has been combined with DANTE pulse sequences²⁰ to saturate selectively one or more of the ssb patterns to simplify the spectra of complex compounds.²¹ After the initial preparation of magnetization by a normal CP sequence, a DANTE sequence centered at the frequency of one of the peaks of the ssb pattern to be destroyed is added. This sequence leaves the magnetization of the other spins unaffected. Several DANTE sequences at different frequencies can be added, with the limitation that the spin–lattice relaxation time (T_1) be of sufficient length that the magnetization for the desired spins does not relax back to thermal equilibrium during the time it takes to apply the saturation sequences.

This concept of producing selective 1D spectra can be considered an alternative to the 2D approach of obtaining all

the ssb patterns separated in 2D space, as presented in the section on 2D methods. This same approach is also used in the next section in conjunction with spinning at two different angles.

5.4 Switched Angle Spinning

A one-dimensional version of the 2D switched angle sample spinning (SASS) experiment to be discussed in the next section was introduced in 1990.^{22,23} By combining the principles of switched angle spinning with some type of selective irradiation scheme, a spectrum containing only the powder pattern(s) of the selected spin(s) can be obtained. The magnetization of the selected spin is selectively prepared or inverted with the sample spinning at the magic angle using a technique such as the DANTE sequence in the case of Maciel’s work²³ or selective soft rf pulses as done by Ashida et al.²² It is necessary that spinning be conducted at the magic angle in order to be able selectively to irradiate one spin while not affecting the magnetization of the remaining spins. The spinner axis is then changed to a different angle before the detection period, resulting in a scaled powder pattern containing only the signals of the selected spin. There is, however, a limit to how selective a pulse can be; if there are two or more signals closely spaced, it is impossible selectively to irradiate only one of them.

The experiment was undertaken in a 1D manner in the belief that conducting a number of 1D experiments in such a way as to obtain the spectra of all spins may be more time-efficient than conducting a 2D experiment in some cases. This judgment is very dependent on the nature and number of the nuclei in the sample.

6 TWO-DIMENSIONAL POWDER TECHNIQUES

The various 2D techniques that have appeared in the literature are discussed in this section. However, before discussing the specifics of each technique, some comments general to 2D spectroscopy are necessary. First, all 2D spectral techniques can be described in terms of the preparation of a magnetization period, followed by an evolution time, t_1 , possibly a mixing time, and then an acquisition time, t_2 . The evolution time is increased by a constant time increment between successive spectra in the 2D experiment, and the signal acquired during the acquisition time is a function of both the evolution time and the acquisition time. In all the cases outlined below, the techniques were described for the observation of dilute spin- $\frac{1}{2}$ nuclei, and the preparation period consisted of a normal CP sequence to take the magnetization into the transverse plane. A general 2D pulse sequence, using CP for signal enhancement, is shown in Figure 5.

While these 2D techniques can be divided in a number of ways, in this article the techniques that obtain the isotropic dimension during the evolution time will be discussed first, followed by those which use MAS during the acquisition time to obtain the isotropic information in the second dimension.

As the spectral presentation of the individual powder patterns as ridges in a 2D contour plot, with the projection on the two axes being an isotropic spectrum and a normal powder pattern, is the same in the majority of these techniques, sample spectra are not included for each technique. Instead only one

Figure 5 A schematic representation of the times in a general 2D pulse sequence, along with a typical 2D pulse sequence for both the ^1H (decoupler) and observe nucleus channels, using CP for the preparation of the magnetization. The pulse sequence shown is the basic 2D chemical exchange scheme. The mixing period is optional

representative spectrum of this type is included. Representative spectra obtained for the 2D methods that present the chemical shift information in a different manner are also included. Also, no information is provided on the details of the phase cycling used in the methods; the reader is referred to the original references for this information.

6.1 Magic Angle Hopping

Magic angle hopping (MAH)²⁴ was one of the first 2D techniques which provided isotropic chemical shifts, i.e. a normal MAS spectrum in the first dimension, with the individual powder patterns separated in the second dimension. The MAH experiment is carried out with a static sample at the magic angle with respect to the external magnetic field. The sample is successively hopped by 120° about this axis, using a computer-controlled stepping motor such that the sample spends one-third of the evolution time in each of the three orientations. Between these three periods the prepared magnetization is stored along the magnetic field direction with a 90° pulse; the sample is reoriented or hopped, followed by the return of the magnetization to the xy plane with a second 90° pulse. The timing of the pulses and the hopping of the sample during the evolution time are shown in Figure 6(a). As there is no spinning of the sample, the isotropic chemical shift dimension has no spinning sidebands.

The major difficulty in this experiment is the requirement of rapidly and accurately reorienting the sample during each scan. The original work reported a hopping time of 150 ms; subsequently, in a paper reporting several modifications to the original experiment,²⁵ the hopping time was reduced to under 60 ms with the use of a dc servo motor. The shortening of this hopping time is important as the magnetization that is prepared and subsequently stored along the magnetic field by the 90° pulse is decreased by normal T_1 relaxation mechanisms. The accuracy in setting the angles is reflected in how complete the averaging process is, and it therefore affects the width of the lines observed in both the isotropic chemical shift spectrum and in the 2D space, placing a limitation of the resolution obtainable.

The reported modifications of the MAH experiment also included a larger sample volume to allow for the measurement of a 2D spectrum in under 24 h, and an increase in the signal collected in each scan by incorporating the last one-third of the evolution time into the acquisition dimension, as discussed in the next technique.

6.2 Magic Angle Turning

One of the most recent 2D techniques for the separation of the overlapping powder patterns was introduced by Gan in 1992²⁶ and is known as the magic angle turning (MAT) method. Gan's technique is a very simple method which can, in principle, be undertaken on a normal MAS probe without any additional equipment. The MAT method is based on the fact that continuous, very slow, spinning at the magic angle can be used in place of the three discrete 120° hops in the MAH experiment. Instead of mechanically hopping the sample by 120° , Gan proposed that the pulses in the evolution period be separated by a time equal to one-third of the rotor period, as shown in the pulse sequence in Figure 6(b).

A second modification from the previous MAH method is that the acquisition period was started immediately after the last pulse instead of waiting a time period of one-third of the evolution period. This modification of acquiring the complete echo instead of starting the acquisition at the top of the echo increases the signal intensity by nearly a factor of $\sqrt{2}$. A consequence of this modification is that the 2D space is no longer a square but has the powder patterns at an angle defined by $\tan^{-1}(1/3)$, and it must be sheared or rotated by this angle in order to obtain normal projections of the isotropic chemical shift spectrum.

This technique was subsequently refined, and the power of the method demonstrated²⁷ using a probe designed specifically for the experiment. The probe, designed around a large volume rotor (about 5 cm^3), has a maximum spinning rate of about 200 Hz, and is very stable at spinning rates as low as 22 Hz. Normal commercial MAS probes, on the other hand, are optimized for stable spinning at speeds in the kHz to tens of kHz range and it is usually difficult to maintain stable spinning at very low speeds. The modification of the pulse sequence, designated the triple echo MAT and shown in Figure 6(c), consists of an addition of three echo pulses to Gan's proposed pulse sequence in order to remove phase imperfections and anomalies in the 2D base plane. The lowered spinning speed also simplifies the fitting of the powder patterns obtained as slices of the 2D space, as they are identical to a static powder pattern at these speeds. It was shown that the spectral lineshape is affected at speeds as low as 44 Hz, requiring that the data be fitted instead of being able to read the break points directly from the lineshape. The large volume sample allows for a typical 2D spectrum to be obtained in less than 24 h, making it feasible for this technique to be used on a routine basis.

This paper also demonstrated that the method can be combined with the techniques of SCT to obtain spectra containing signals from only the protonated carbons, and DD for spectra containing only patterns from nonprotonated carbons. A typical 2D spectrum obtained using the triple echo MAT method, along with the individual powder patterns obtained, is shown in Figure 7 for 2,6-dimethoxynaphthalene, which has six inequivalent aromatic carbons.

6.3 $5-\pi$ Pulse

The $5-\pi$ pulse experiment²⁸ is another method related to the MAT and MAH techniques. In this experiment, as in MAT, the sample is also spinning slowly at the magic angle. However, instead of storing the selected magnetization along

Figure 6 (a) The evolution and acquisition time of the MAH pulse sequence for both the observe and decouple channel. (b) The evolution and acquisition time of the original MAT pulse sequence. (c) The evolution and acquisition time of the triple echo MAT pulse sequence. Δ indicates the echo time. (d) The evolution and acquisition time of the 5- π pulse method. The shaded pulses are the ones which move as a function of the evolution time, τ . For (b)–(d), the decoupler remains on for the entire evolution and acquisition periods. In all cases 0 marks the start of the evolution period, T signifies the length of a rotor period, and a normal CP sequence used to prepare the magnetization

the static field direction during the course of the experiment, the magnetization is kept in the transverse plane and a series of five π pulses are used to achieve the same effect. This method can be thought of as a constant time version of the MAT experiment.

As shown in Figure 6(d), two of the five π pulses are at the fixed times of $T/3$ and $2T/3$ during the evolution period, where T must be an integral number of rotor periods. Each π pulse changes the sign of the phase angle describing the precession of the magnetization up until the application of the pulse. The position of the first, third, and fifth π pulses are set at times $T/6 - \tau$, $T/2 - \tau$, and $5T/6 - \tau$, where τ is the evolution variable which ranges from $-T/6$ to $T/6$. At $\tau = 0$, the five π pulses are evenly spaced at increments of $T/6$, such that the accumulated phase is zero, resulting in the complete suppression of the chemical shift. When $\tau \neq 0$ the pulses are no longer evenly spaced, and the phase accumulation is proportional to $\omega_{\text{iso}}\tau$. Thus, the evolution dimension displays an isotropic chemical shift spectrum. The spectrum in the

acquisition dimension is either a ssb or a static powder pattern depending on the spinning speed used.

This technique has an advantage over the MAH and MAT experiments in terms of increased sensitivity by avoiding the need to project the magnetization to the longitudinal direction. However, the 5- π pulse method does suffer from a loss of signal at longer evolution times (and therefore lower rotation frequencies) if the T_2 value of the spin is short in comparison to the total time T between the preparation of the magnetization and the start of the acquisition period.

6.4 Stop and Go

In the 2D technique known as stop and go or STAG²⁹ the sample, at the magic angle with respect to $\mathbf{B}_0$, is taken from being stationary during the preparation and evolution of the magnetization to high speed spinning during the acquisition period, as shown in the pulse sequence used in Figure 8(a). The

Figure 7 (a) A 2D MAT spectrum of 2,6-dimethoxynaphthalene (shown in inset). (b) The projection in the isotropic chemical shift dimension. (c) The individual powder patterns taken from the 2D spectrum in (a) at the indicated isotropic chemical shifts

air used for spinning is controlled with a solenoid valve that is electronically opened and closed by the pulse programmer controlling the NMR experiment. At the end of the evolution period the magnetization is stored along the magnetic field, in the manner discussed in the previous 2D methods, the air flow is started, and the sample is allowed to come to a relatively high spinning speed. Once the desired spinning speed has been

reached, the stored magnetization is returned to the xy plane for detection. In the original paper the time required to start the spinner and achieve a spinning speed of 1.7 kHz was in the range of 3–5 s.

The spectra obtained are identical to those of the original MAH spectrum, with the exception that there are now spinning sidebands observed in the spectra as the sample is spinning

Figure 8 The 2D pulse sequence used in the STAG, S^3 , and SAS 2D experiments. A normal CP preparation period was typically used. The $\pi/2$ pulses store the evolved magnetization along the field direction during the switching time and then return it to the transverse plane. (a) For STAG, the sample is stationary during the preparation and evolution periods and is spinning at the magic angle during the acquisition period. (b) In S^3 , the spinning speed is increased by a factor of 5–10 during the mixing time. (c) In SAS, the spinning speed remains constant but the spinner axis changes relative to the external magnetic field. The length of time taken to accomplish these changes (the length of the switching period) is discussed in the text

during acquisition. The limitations of this method are also the same; namely this approach is only applicable to spin systems with T_1 relaxation times long compared with the time taken to bring the sample from the static condition to the maximum spinning speed.

6.5 Switched Speed Spinning

The switched speed spinning (S^3)³⁰ experiment is similar to that of the STAG method except that the spinning speed is only reduced by a factor of ca. 5–10 during the preparation and evolution time of the 2D experiment instead of being completely stopped, and is shown in Figure 8(b). The experiment was performed on an unmodified MAS probe using a commercially available spinning system and the spinner speed was controlled by a system which delivered a flow rate of air proportional to an applied voltage, with the change in this voltage being under the control of the NMR pulse programmer. This results in the anisotropic information being in the form of an ssb pattern instead of a static powder pattern. The fact that the spinning speed is only reduced and not completely stopped should be less demanding on the spinning system.

6.6 Switched Angle Spinning

The next technique has been discussed in the literature under two different names: dynamic angle spinning (DAS) and switched angle spinning (SASS). The method was introduced independently by two different groups shortly after the

introduction of the MAH experimental technique.^{31,32} This technique also requires reorientation of the sample, however this time a rapidly spinning sample is taken between the magic angle and a second angle during each scan, as shown in Figure 8(c).

In this technique the sample is held at the magic angle during the evolution period of a 2D experimental scheme. The evolved magnetization is then stored along the static magnetic field while the spinning axis is changed from the magic angle to any other angle. Following the angle switch, the stored magnetization is returned to the transverse plane for detection. The second angle used can be any other angle, resulting in patterns that are scaled by the argument $\frac{1}{2}(3 \cos^2 \theta - 1)$ according to equation (7).

The initial papers on this technique employed switching times on the order of 0.5–2 s. There is now a commercial probe available for SASS measurements with angle switching times on the order of 100 ms, allowing for more widespread use of this method.

Subsequent development of SASS has led to two methods which shorten the time required for the measurement of the chemical shift tensor information. The first involves a technique by which the second dimension, the dimension containing the anisotropic information, can be shortened.³³ In the initial experiment, as in all of the 2D methods discussed, one dimension contains the isotropic chemical shifts and the other contains the separated powder patterns. The projection of the 2D space onto the axis in the second dimension will result in the static powder pattern, as this dimension contains not only the anisotropic information but also the isotropic, i.e. the powder patterns are still offset from each other by the difference in their isotropic chemical shift. However this offset can be removed, resulting in all of the powder patterns being centered at the same frequency. This allows the spectral width in the second dimension to be shortened from that necessary to observe the normal static powder pattern to a spectral width set by the widest of the separated, scaled powder patterns.

The second method introduced to shorten the time necessary to obtain the chemical shift information was the use of the SASS principle in conjunction with selective irradiation or inversion in a 1D experiment,^{22,23} as discussed in Section 5.4.

6.7 TOSS–Reverse TOSS

The TOSS (Total Suppression of Spinning Sidebands) sequence was originally introduced by Dixon et al.^{34,35} to suppress spinning sidebands in normal MAS spectra, resulting in a spectrum containing only the centerband frequencies. The TOSS sequence consists of a series of four π pulses, applied at precise fractions of a rotor period which allow the intensities of the centerband to add while the magnetization of the sidebands are canceled. This technique improves spectral resolution and simplifies MAS spectra, especially those taken at high fields or at low spinning speeds. However, the price is that information about the anisotropic portion of the chemical shift tensor is lost.

However, the anisotropic information can be restored in a 2D experiment by following a normal TOSS sequence with an evolution time and then applying the ‘mirror image’ of the TOSS sequence to reverse the averaging before the start of the acquisition period. The TOSS–reverse TOSS pulse sequence³⁶

Figure 9 (a) The observe channel portion of 2D pulse sequence used in the TOSS–reverse TOSS technique. The separation between the π pulses is discussed elsewhere.^{34–36} (b) The observe channel portion of 2D pulse sequence used in the synchronous application of π pulses with MAS method. The spacing of the four π pulses has been discussed by Tycko et al.⁴⁰ The rotor period is equal to τ . The decoupler remains on during the evolution and acquisition times in both sequences

is shown in Figure 9(a). The sample is spun at the magic angle at a relatively slow rotation frequency. During the evolution period, the effect of the TOSS sequence is such that the magnetization is evolving, containing only the isotropic information, without sidebands, while after the reverse TOSS sequence is applied the evolution once again contains the anisotropic information in the form of an ssb pattern. This information is then collected during the acquisition dimension.

6.8 Magic Angle Spinning with Synchronous Application of rf Pulses

The synchronous application of rf pulses during a MAS experiment in order to reconstruct the anisotropic information averaged by the spinning was first introduced by Lippmaa et al.³⁷ Subsequent improvement³⁸ led to the application of a train of six π pulses per revolution of the spinner in a 1D experimental format and the adaptation of the method to a 2D experiment utilizing four 2π pulses per rotor cycle to decrease the sensitivity of the experiment to pulse imperfections.³⁹ However, in none of the above do the breakpoints in the lineshapes correspond directly to the principal values of the chemical shift tensors, and the reported principal values are not in close agreement with those obtained by other techniques.

Tycko et al.⁴⁰ modified the basic method to render the intensities of the powder patterns obtained in the 2D space undistorted, making the measured principal values of the tensor more reliable, using a series of four or six π pulses as shown in Figure 9(b). The spacing of the four or six π pulses was chosen such that the isotropic scaling factor was zero.

This method, unlike many of the other 2D methods such as MAH, STAG, and SASS, is not demanding mechanically. Instead, the experiment can be performed on a normal MAS probe on a spectrometer system equipped with the ability to synchronize the application of the pulses with the spinning. However with this method it is more difficult to obtain very accurate principal values, due to the sensitivity of the technique to both the timing and quality of the rf pulses. This technique, along with the TOSS–reverse TOSS and the $5-\pi$ pulse method, also does not suffer from the loss of signals from nuclei with shorter T_1 relaxation times.

6.9 Chemical Shift–Chemical Shift Correlation

Chemical shift–chemical shift correlation (CS–CS) spectroscopy⁴¹ is a modification of the 2D exchange NMR experiment,⁴² using the basic pulse sequence shown in Figure 5 in which the stationary sample is reoriented by 90° along an axis perpendicular to the external magnetic field during the mixing time of the experiment. The projections in either dimension give the powder pattern of the sample in each of its two orientations relative to the external magnetic field. For a random powder sample, these two projections are identical. The 2D space, however, contains a unique representation of each tensor in the shape of a triangle for an axially symmetric tensor or a hexagon for a general asymmetric tensor, with the position of the corners defined by the principal values of the tensor. These shapes can be understood by considering the case of a single molecule. In the case of an axially symmetric tensor, if the molecule is in a position with respect to the external magnetic field such that its chemical shift is $\delta_{\parallel}$, then a 90° rotation of this molecule must give a chemical shift of $\delta_{\perp}$. Likewise, if the signal in the first orientation is at $\delta_{\perp}$, after a 90° rotation it must be either $\delta_{\parallel}$ or $\delta_{\perp}$, resulting in the triangular pattern observed in the 2D space. For the case of an asymmetric tensor, a 90° rotation from an orientation which has a chemical shift of any one of the three principal values must take the molecule into an orientation that has a chemical shift of either one of the two remaining principal values, creating a hexagonal pattern in the 2D correlation space.

One of the applications of this method is in sorting out the principal values of overlapping powder patterns, as is demonstrated for coronene in Figure 10. Coronene has

Figure 10 Contour plot of the 2D CS–CS correlation spectrum of coronene (shown in inset)

three magnetically inequivalent sets of carbons. At room temperature the molecule is rotating rapidly about an axis perpendicular to the plane of the molecule, averaging all

the three tensors to axial symmetry. From the normal 1D powder pattern (the projection on either axis) and the isotropic chemical shifts obtained from a MAS spectrum, it is difficult to determine which $\delta_{\parallel}$ and $\delta_{\perp}$ should be paired for each of the three tensors. The patterns in the 2D space, however, clearly indicate how the six principal values are paired to obtain the three tensors.

6.10 Variable Angle Correlation Spectroscopy

In this experimental approach, known by the acronym VACS^Y,⁴³ the approach used to separate the anisotropic information is different from the above techniques. The data are not acquired as a typical 2D data set, i.e., with the evolution time being incremented between individual spectra. Instead, the experiment, performed under the conditions of high-speed spinning, involves collecting a series of VASS spectra taken at different angles. Selected intensities of the signal as a function of time and the spinning angle are then chosen to create a 2D data set for normal 2D FT processing, as shown schematically in Figure 11.

Figure 11 Representation of the strategy employed for obtaining 2D VACS^Y data. The arrows represent the individual FIDs recorded, each at a different spinning axis angle. The grid of points (n_a, n_i) are the points needed for the 2D FT in the acquisition and evolution dimension. Interpolation between the acquired data points is used to obtain signal intensity at all the grid points that fall inside the wedge formed by the minimum and maximum angles. (Reproduced by permission of the American Institute of Physics from L. Frydman, G. C. Chingas, Y. K. Lee, P. G. Grandinetti, M. A. Eastman, G. A. Barrall, and A. Pines, *J. Chem. Phys.* 1992, **97**, 4800)

The dwell time of the VASS spectra is chosen as the time needed in the isotropic direction for sufficient resolution in this dimension. The dwell time in the acquisition dimension is then a function of the range of angles used, and from this information the spinning angles at which spectra are obtained can be calculated. The intensities at certain points in the grid of (n_a, n_i) points shown in Figure 11 are then obtained, using interpolation as necessary; these intensities are then processed using the normal 2D FT methods. Figure 12 shows plots of the different data processing stages in the procedure of obtaining a 2D isotropic–anisotropic chemical shift spectrum of glycine.

Figure 12 Plots of VACS^Y data for glycine ($\text{H}_2\text{NCH}_2\text{COOH}$). (a) Set of 75 FIDs recorded for a grid defined by the dwell time in the isotropic dimension being four times that in the anisotropic dimension. (b) 2D data set after interpolation onto the (n_a, n_i) grid. (c) Spectrum obtained after the 2D FT of data set in (b). (Reproduced by permission of the American Institute of Physics from L. Frydman, G. C. Chingas, Y. K. Lee, P. G. Grandinetti, M. A. Eastman, G. A. Barrall, and A. Pines, *J. Chem. Phys.*, 1992, **97**, 4800)

7 SINGLE CRYSTAL TECHNIQUES

7.1 Crystal Rotation Methods

All the early single crystal studies were undertaken using the 1D crystal rotation method.^{2,3} In this method, the crystal is mounted in the probe on a goniometer. A succession of spectra are recorded with the crystal being rotated by a number of degrees between spectra. This rotation is continued until the sample has been rotated by 180° . The step size used depends on the number of lines and how closely they are spaced; a typical step size is on the order of $5\text{--}10^\circ$. The crystal orientation is then changed by 90° and the process is repeated. Finally the third rotation pattern is obtained for a third axis, perpendicular to the first two rotation axes. A representative rotation pattern of pyrene is shown in Figure 13.

Figure 13 Rotation pattern obtained for one orientation of a single crystal of pyrene (shown in inset). One molecule in the unit cell is sampled nearly in the molecular plane by this rotation; in this case the difference between the in-plane components is small and the lines only move slightly. The other molecule is rotated in and out of the molecular plane and therefore shows a much greater range of chemical shift values as a function of the rotation angle. (Reproduced by permission of the American Chemical Society from C. M. Carter, D. W. Alderman, J. C. Facelli, and D. M. Grant, *J. Am. Chem. Soc.*, 1987, **109**, 2639)

Once the three rotation patterns are obtained, the line positions of each magnetically inequivalent spin must be followed as its position changes from one spectrum to the next, according to the expression given in equation (8). This process can be accomplished in a number of ways, one of which has been to fit the data using a least-squares Simplex fitting routine. Along with the fitting of peaks to different nuclei in one rotation pattern, a connection must be made to the lines in the other two rotation patterns.

Using this method there is a limit to the number of magnetically inequivalent nuclei in the unit cell. As there are more nuclei, the probability that the lines may not all be resolved increases and the large number of line crossings and the crowding often result in rotation patterns that cannot be interpreted, even with small step sizes. This limit has been estimated to be in the range of about 15–20 nuclei and is dependent on the width of the range of chemical shifts for the tensors. As two chemically equivalent nuclei with different orientations in the unit cell will give rise to different chemical shifts, this limitation is very restrictive especially in cases where there is more than one molecule per unit cell.

7.2 2D Crystal Correlation Methods

A 2D technique was introduced in 1985 which allowed for the study of more complex single crystals.^{44,45} This method

is a modification of the Jeener chemical exchange pulse sequence,⁴² with the normal CP sequence for the preparation of the magnetization added. As in the CS–CS method discussed in Section 6.9, the single crystal sample is reoriented during the mixing time of the experiment. This results in a 2D spectrum where the projection onto the axis in one dimension is the spectrum obtained for the first orientation of the crystal, while the projection in the second dimension is the spectrum obtained in the second orientation. In the 2D space there are a number of peaks which correlate a given chemical shift in one dimension (or crystal orientation) with a line position in the second orientation, eliminating the need to determine the best fit in the correlation of the resonance frequencies from one spectrum to the next in a rotation pattern.

In order to obtain all the information contained in a single axis rotation pattern, it has been shown that four 2D correlation spectra are needed. In each of these spectra the two orientations are related by a 45° rotation. The four spectra are taken with the sample between 0° and 45°, 45° and 90°, 90° and 135°, and finally between 135° and 180° (which is 0°). The position of the resonance lines in these four spectra can be connected by placing the four spectra in a square, where the axes corresponding to common crystal position are placed together.

The goniometer used for obtaining rotation patterns is replaced by a device capable of being rotated between two positions using a motor-driven string. The unit has four holes for a lever arm, positioned precisely at 45° increments about the sample. However, the sample must be remounted for each of the three sets of four 2D spectra which are needed for the complete determination of the chemical shift information.

This method was modified in 1989 to include a multiple-axis sample reorientation mechanism⁴⁶ to remove the need for remounting the crystal, as this remounting process introduces errors in the data if the three mounted orientations are not exactly perpendicular. This mechanism is designed to move between any pair of six orientations (X, XY, Y, YZ, Z, and ZX) which were selected such that all the information necessary completely to characterize the chemical shift tensor can be obtained. To determine the chemical shift tensor it is necessary to record only six 2D spectra, corresponding to the X–XY, XY–Y, Y–YZ, YZ–Z, and Z–ZX direction pairs. A representative set of the six 2D spectra is shown in Figure 14 for a single crystal of acenaphthene,⁴⁷ which has four molecules per unit cell with two crystallographically unique molecules. The symmetry of the molecule and the crystal combine to give rise to a total of 36 resonances, which can be analyzed to give the 14 unique chemical shift tensors.

In this figure the connectivity of the peaks due to one of the 14 carbons is shown. The spectra shown in Figure 14 were analyzed to obtain all 28 chemical shift tensors, with a standard deviation of 0.52 ppm between the actual peak positions in the 2D spectra and the expected positions based on the best parameters of the chemical shift tensor. To date, the chemical shift tensors have been obtained for crystals containing up to 72 magnetically inequivalent carbons.

8 DIPOLAR TECHNIQUES

Dipolar couplings can be used to assign the orientation of the PAS to the molecular frame for the nuclei coupled, as well

Figure 14 Set of six 2D multiple-axis reorientation spectra obtained for a single crystal of acenaphthene. The connectivity of peaks for one of the 14 magnetically inequivalent carbons is shown. The labels X, Y, Z, XY, YZ, ZX refer to the directions discussed in the text (Reprinted with permission from R. J. Iulicci et al., *J. Am. Chem. Soc.*, **117**, 2336. Copyright (1995) American Chemical Society)

as to provide information on the separation of the two spins. In practice, this technique is used on compounds which have been specifically labeled in two positions, or in compounds in which there is an isolated pair of spin- $\frac{1}{2}$ nuclei, for an example a ^{31}P - ^{31}P pair. Dipolar couplings also exist between a spin- $\frac{1}{2}$ and a quadrupolar nucleus. The lineshape obtained from a static powder sample containing such a spin pair contains not only the chemical shift information of one (for the case of a heteronuclear dipolar coupling) or both (homonuclear) spins, but also contains information on the orientation of the PAS of the chemical shift tensor with respect to the dipolar vector.

If one were to consider a single molecule in some orientation with respect to the static magnetic field, the chemical shift of a given spin in this molecule specifies the observed line position, that can be designated as ν . If this nucleus were coupled to a second spin, the result would be to see two lines spaced symmetrically about ν , with the separation dependent on D as given by the expression in equation (5) and the position of the dipolar vector. This situation is nicely shown in single crystal studies of compounds containing an isolated spin- $\frac{1}{2}$ pair.

This example can be extended to a spin- $\frac{1}{2}$ pair in a powder sample where the chemical shift of the spins involved is isotropic. In this case the dipolar coupling dominates the lineshape, and a Pake doublet, shown in Figure 15(a), is obtained. The Pake doublet consists of two axially symmetric patterns, with the central peaks being separated by D or $1.5D$ for the cases of heteronuclear and homonuclear spin pairs, respectively.

Now, if the spins have an appreciable anisotropy in their chemical shifts, the lineshape and the analysis of the dipolar pattern is more complicated. A detailed description of the mathematical treatment of the lineshape of dipolar spectra in this case is given in the literature⁴⁸ as well as in a recent review article on dipolar coupling.⁴⁹ Also, more details can be obtained in other sections of this Encyclopedia. For the purpose of this overview, however, the sensitivity of the lineshape relative to this orientation of the vector between the two spins in the PAS of the chemical shift tensor can be

Figure 15 (a) Typical dipolar spectra resulting for the coupling of two spin- $\frac{1}{2}$ nuclei in the absence of any anisotropy in the chemical shift. (b) The dipolar pattern for two spin- $\frac{1}{2}$ nuclei with anisotropy in the chemical shift as a function of the orientation of the internuclear vector with respect to the chemical shift tensor principal axes, where α is the angle between δ_{33} and the dipolar vector, and β the angle between δ_{11} and the projection of the dipolar vector into the plane defined by δ_{11} and δ_{22} . (b) is reproduced by permission of Academic Press from W. P. Powers and R. E. Wayslishen in *Annu. Rep. NMR Spectrosc.*, 1991, **23**, 1

nicely demonstrated with the set of simulated spectra shown in Figure 15(b). The simulations in Figure 15(b) are for the same principal values and dipolar coupling, with only the two angles relating the PAS to the dipolar vector being varied.

As mentioned earlier, a dipolar coupling also exists between a spin- $\frac{1}{2}$ nucleus and a quadrupolar nucleus, and a dipolar spectrum can be obtained by observing the spin- $\frac{1}{2}$ nucleus. The complete chemical shift tensor of the spin- $\frac{1}{2}$ nucleus is obtained, along with the information of the EFG tensor of the quadrupolar nuclei.

Finally, there have been a number of 2D techniques that can be grouped together as separated local field (SLF) techniques, which can provide the chemical shift information in one dimension and information on the dipolar couplings in a second dimension. The SLF technique, first introduced in 1976,⁵⁰ can be used to orient the principal values of a rare spin based on the dipolar coupling between that rare spin (S) and an abundant spin (I), typically a ^1H . In SLF, multipulse decoupling is applied during the evolution time of the 2D experiment to decouple all ^1H - H dipolar interactions, leaving the ^1H - X interactions although they are scaled. The initial experiments were applied to single crystals and to oriented samples.

The basic ideas presented by Waugh were extended to unlabeled static powder samples,⁵¹ with the shape of the spectra in the 2D space containing the information on the PAS; however, with powders, the patterns become very complicated if there are even two different dipolar interactions. The SLF technique has also been used with slow magic angle spinning and has been extended to the determination of the complete chemical shift of a nucleus coupled to two other spins,^{52,53} as well as to being used to extend some of the 2D powder techniques into 3D techniques to gain the information on the orientation of the PAS.⁵⁴

9 SUMMARY

As stated in the Introduction, the method of choice is primarily dependent on the sample. A single crystal study is the method of choice based solely on the amount of information obtained. The more recent 2D multiple axis reorientation method has opened up the field of single crystal studies to systems approaching 100 inequivalent nuclei. However, the limitation in obtaining a suitable sample, i.e., a large enough crystal of sufficient quality, eliminates this method as a choice for a majority of substances.

If a material is a solid at or near room temperature, but one for which a single crystal cannot be obtained, the method of choice is often determined by the equipment available. If there are more than three or four inequivalent nuclei, the experiment of choice will typically be a 2D method. In the last 12 or so years there has been an explosion of 2D and even a few 3D techniques in solid state NMR designed to obtain chemical shift information. While some of these techniques require specialized probes, several can be undertaken on any modern solid state NMR system equipped with a normal MAS probe, provided that only temperatures near ambient are needed. Though some standard MAS probes are capable of reaching temperatures down to 77 K, attaining very low temperatures at high spinning speeds for long periods of times is not easily or economically achieved.

When the sample of interest is a solid only at very low temperatures, or a sample that is stable only at very low temperatures for any reasonable time period, the choices are limited to the 1D techniques which typically take less time. However, samples that are suitable for study by 1D techniques are only the simpler compounds, i.e. those containing only three or four inequivalent nuclei. There have been efforts to use selective techniques, mainly short contact times, to look at only the protonated nuclei, or dipolar dephasing techniques to observe only the nonprotonated nuclei, but these methods have been shown to be of limited usefulness. The alternative is to use compounds selectively enriched at the nuclei of interest and study only that particular spin.

The lowest temperatures can only be achieved with the use of cryogenic equipment which does not allow for sample spinning, limiting the choice to the study of a static powder sample. It should be mentioned that there are several articles in the literature on MAS probes at temperatures in the region of 4 K, but they do not seem to be used routinely and there are no examples, to the knowledge of the author, on the use of such equipment in the study of molecules which are gases at room temperature. With the use of closed-cycle cryogenic units, it is economically feasible to achieve temperatures as

low as 8–10 K on a routine basis. The static sample limits the application of the cryogenic apparatus to studies of very simple cases, or to cases where isotopic labeling has been undertaken. However, this technique is the only method available for the study of reactive species trapped in inert gas matrices, a technique known as matrix isolation. The use of matrix isolation methodology, while very limited in NMR, is more widespread in other forms of spectroscopy.

Finally, for samples where a single crystal study is not possible, but an experimental determination of the PAS orientation is desired, dipolar techniques can be employed. If two dipolar coupled spins exist, or if a sample can be made to contain such a pair using selective enrichment, the orientation of the PAS can be determined for the spins involved. Dipolar spectroscopy has been used at ambient temperatures as well as at cryogenic temperatures.

1 INTRODUCTION

Shortly after its first detection in condensed matter in 1945,^{1,2} it became evident that NMR was an extremely sensitive probe of the local electronic environments of magnetic nuclei. Some of the first observations of NMR uncovered a chemical effect on the relative resonance frequencies of identical nuclear isotopes which has come to be known as the chemical shift, and because of this effect NMR has evolved into one of the premier spectroscopic techniques for chemical structure analysis. The primary use of NMR consists of measuring the isotropic chemical shifts of nuclei imbedded in molecules dissolved in solution; however, important information about the anisotropy of this interaction is available from the spectra of solids.³⁻⁵

Certain characteristics of the anisotropic chemical shift, the principal values of the chemical shift tensor for example, can be obtained from the spectra of powdered samples and, to a lesser extent, from molecules dissolved in liquid crystal solvents. Nevertheless, single crystal samples are preferred, when available, as they allow direct measurements of the complete chemical shift tensor. Single crystals are especially useful for studies of large molecules where the many overlapping powder patterns in traditional one-dimensional (1D) spectra are uninterpretable and where selectively labeling each individual site is impractical. Although progress has been made in extracting principal values from powdered samples of large molecules using two-dimensional (2D) NMR methods,⁶ direct measurements of tensor orientations can be made only on single crystals.

This article is written as an introduction to the techniques that are available for measuring chemical shift tensors in single crystals. Although many aspects of the techniques are quite general, the emphasis here will be on measurements of ¹³C chemical shift tensors in organic systems.

The first measurement of a ¹³C chemical shift tensor was made in the very early days of ¹³C NMR by Lauterbur⁷ on the carbonate ion of single crystal calcite (CaCO₃). This particular sample proved to be ideal because all magnetic nuclei were at

low abundance and thus the dipolar broadening was negligible. A few other systems were exploited where similar dilution occurred naturally or was introduced by substitution of ²D for ¹H, but progress along these lines was limited. It was only after the introduction of the combined cross polarization and high-power dipolar decoupling techniques⁸ that ¹³C chemical shift tensor measurements became more generally applicable. One of the first demonstrations of these now widely used techniques was in the measurement of ¹³C chemical shift tensors in single crystal durene (1,2,4,5-tetramethylbenzene).⁹

2 NUCLEAR SHIELDING AND THE CHEMICAL SHIFT TENSOR

The fundamental equation relating the NMR resonance frequency and the magnetic field strength is well known to all students of magnetic resonance

$$\nu_0 = |\gamma/2\pi|B_0 \quad (1)$$

For ¹³C, this frequency corresponds to 50 MHz in a typical field of 4.7 T.

Due to the electronic circulation set up in a molecule by the applied magnetic field, the effective field experienced by a particular nucleus is not exactly equal to B_0 . The electronic 'currents' induce a small shielding field B_s which must be added to B_0 to obtain the effective field at the nucleus

$$B_{\text{eff}} = B_0 + B_s \quad (2)$$

This vector addition is shown schematically in Figure 1.

Although B_s is called the shielding field, it does not necessarily oppose B_0 and thus deshieldings or paramagnetic shifts are possible. In general, the direction of B_s is not parallel to B_0 but the two are related through the shielding tensor which is represented as the 3×3 matrix σ

$$B_s = -\sigma \cdot B_0 \quad (3)$$

Figure 1 The relationship between the applied field B_0 , the shielding field B_s and the effective field B_{eff}

2 CHEMICAL SHIFT TENSORS IN SINGLE CRYSTALS

The matrix σ is usually called a second rank Cartesian tensor although it also contains zeroth and first rank parts as well.

Since B_s is very small compared to B_0 , equation (2) can be closely approximated by adding only the component of B_s that is either parallel or antiparallel to B_0 to obtain

$$B_{\text{eff}} = B_0 - \frac{B_0}{B_0} \cdot \sigma \cdot B_0 \quad (4)$$

The above approximation is equivalent to *truncation* or restriction to the *secular* terms of the chemical shift Hamiltonian in first-order perturbation theory. It should be pointed out that σ can be decomposed into a sum of second rank symmetric and first rank antisymmetric constituents

$$\sigma = \sigma^S + \sigma^A \quad (5)$$

Since σ^A leads to components of B_s which are perpendicular to B_0 , it does not contribute to B_{eff} in first order and thus its effect on the resonance frequency of the nucleus can be ignored.

The effect of shielding is thus to change the precession frequency of the nucleus from ν_0 to the frequency given by

$$\nu = |\gamma/2\pi| B_{\text{eff}} \quad (6)$$

In practice, the frequency of the bare nucleus is not known, and measurements of the frequency ν are always made relative to a reference frequency ν_{ref} , which for ^{13}C is usually taken as the resonance of liquid tetramethylsilane (TMS). The frequency difference between sample and reference can be written as

$$\nu - \nu_{\text{ref}} = |\gamma/2\pi| \frac{B_0}{B_0} \cdot (\sigma^S - \sigma_{\text{ref}} \mathbf{1}) \cdot B_0 \quad (7)$$

where σ_{ref} is the isotropic chemical shielding constant of the reference compound and $\mathbf{1}$ is the unit matrix. The symmetric difference matrix $(\sigma^S - \sigma_{\text{ref}} \mathbf{1})$ is defined as the chemical shift tensor, and is assigned the symbol δ in order to avoid its confusion with the shielding tensor σ .

It is customary to report chemical shifts not as frequencies, since these always depend on B_0 which varies from one spectrometer to the next, but as fractions of ν_{ref} . If the chemical shift F is defined as $(\nu - \nu_{\text{ref}})/\nu_{\text{ref}}$, then

$$F = \frac{B_0}{B_0} \cdot \delta \cdot \frac{B_0}{B_0} \quad (8)$$

Equation (8) is the master equation for the chemical shift in a single crystal, as it gives the observed shift in terms of the elements of δ and the orientation of B_0 .

For elements with sufficiently low atomic numbers, the chemical shift tensor δ can be represented in a Cartesian coordinate system as a 3×3 symmetric matrix

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \quad (9)$$

The matrix δ is called the Cartesian representation of the chemical shift tensor and is completely defined by

six independent numbers. It will be seen below that other representations are possible.

The average value of δ is known as the isotropic chemical shift

$$\delta_{\text{iso}} = \frac{1}{3}(\delta_{xx} + \delta_{yy} + \delta_{zz}) \quad (10)$$

and it is only this part of the chemical shift tensor which can be directly measured in solution samples due to rapid isotropic tumbling of the molecules. The isotropic chemical shift is also called the zeroth rank part of δ since it transforms as a scalar quantity, i.e., it is invariant under rotation.

A Cartesian tensor can be expressed in a different coordinate system by performing a similarity transformation on the matrix δ

$$\delta' = \mathbf{R} \delta \mathbf{R}^T \quad (11)$$

where $\mathbf{R}$ is a unitary matrix. The element R_{ij} is given by the direction cosine of the i th new coordinate axis with respect to the j th old coordinate axis. For instance, $R_{12} = \cos \gamma_{x'y}$ where $\gamma_{x'y}$ is the angle between the new x axis and the old y axis.

A number of coordinate systems are necessary in single crystal work. The *laboratory frame* is a coordinate system whose z axis lies along the direction of the static magnetic field. Rather than working in the laboratory frame, it is usually more convenient to work in a coordinate system called the *sample frame* whose orientation is fixed with respect to the single crystal sample. The sample frame will always be the coordinate system in which tensors are measured. A third coordinate system is that defined by the symmetry elements of the crystal and this will be called the *crystal frame*. The orientation of the crystal frame relative to the sample frame can usually be found by diffraction methods. For molecules containing high symmetry, it is often useful to define a coordinate system based on molecule symmetry elements called the *molecular frame*. For molecules of low symmetry, coordinate systems can be defined based on the local symmetry of a particular nuclear site and these will be called *local frames*. Finally, there is an important coordinate system known as the *principal axis* system which is unique to each tensor. The principal axis system is discussed below.

The relationships between all of these reference frames, except for that between the sample frame and laboratory frame, are determined by the crystal and molecular structure, and therefore they are not under experimental control. It is clear from equation (11) that once the tensor is known in one of these reference frames, it can be expressed in any of the other frames provided the unitary matrix $\mathbf{R}$ is available.

For any symmetric second rank tensor such as the chemical shift tensor δ , there exists a unitary matrix $\mathbf{S}$ that transforms δ into a coordinate system in which it is diagonal

$$\mathbf{S} \delta \mathbf{S}^T = \mathbf{\Lambda} \quad (12)$$

where $\mathbf{\Lambda}$ is a diagonal matrix with elements λ_1 , λ_2 , and λ_3 . This special coordinate system is called the principal axis system and the diagonal tensor elements are called the principal values. Multiplying both sides of equation (12) by $\mathbf{S}^{-1} = \mathbf{S}^T$ yields

$$\delta \mathbf{S}^T = \mathbf{S}^T \mathbf{\Lambda} \quad (13)$$

Equation (13) is readily recognized as an algebraic eigenvalue equation and the eigenvalues (principal values) and eigenvectors (principal axes) can be found by solving the secular equation

$$|\delta - \mathbf{\Lambda I}| = \begin{vmatrix} \delta_{xx} - \lambda_1 & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} - \lambda_2 & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} - \lambda_3 \end{vmatrix} = 0 \quad (14)$$

A convention for labeling the principal values is generally followed in which they are designated δ_{11} , δ_{22} , and δ_{33} in order of decreasing chemical shift. An alternative to the Cartesian representation of a chemical shift tensor is its representation as three principal values and the three Euler angles that orient the principal axis system with respect to one of the coordinate systems defined above. Other useful representations of the chemical shift tensor are described elsewhere.¹⁰

Recalling equation (8), the chemical shift F observed when the magnetic field is oriented with direction cosines $\cos \gamma_x$, $\cos \gamma_y$, and $\cos \gamma_z$ relative to the sample frame axes can be explicitly written as the quadratic form

$$\begin{aligned} F &= [\cos(\gamma_x) \cos(\gamma_y) \cos(\gamma_z)] \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \begin{bmatrix} \cos(\gamma_x) \\ \cos(\gamma_y) \\ \cos(\gamma_z) \end{bmatrix} \\ &= \cos^2(\gamma_x) \delta_{xx} + \cos^2(\gamma_y) \delta_{yy} + \cos^2(\gamma_z) \delta_{zz} \\ &\quad + 2 \cos(\gamma_x) \cos(\gamma_y) \delta_{xy} + 2 \cos(\gamma_y) \cos(\gamma_z) \delta_{yz} \\ &\quad + 2 \cos(\gamma_z) \cos(\gamma_x) \delta_{zx} \end{aligned} \quad (15)$$

It is seen from equation (15) that if the chemical shift tensor δ is known in the sample frame, the chemical shift can be calculated for any orientation of $\mathbf{B}_0$. Alternatively, if the chemical shift F is known for six suitably chosen directions of $\mathbf{B}_0$, the elements of δ can be obtained by solving a system of linear equations.

Equation (15) takes on a particularly simple form when expressed in the principal axis system

$$F = \cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} \quad (16)$$

Provided that the reference frequency is chosen such that the three principal values δ_{11} , δ_{22} , and δ_{33} are positive, a connection can be made between equation (16) and the equation of an ellipsoid with semiaxes a , b , and c

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \quad (17)$$

The direction cosines of a radius vector $\mathbf{r}$ taken from the origin to a point on the surface of the ellipsoid are given by $\cos^2(\gamma_x) = x^2/r^2$, $\cos^2(\gamma_y) = y^2/r^2$, and $\cos^2(\gamma_z) = z^2/r^2$. Substituting these into equation (17) yields

$$\frac{r^2 \cos^2(\gamma_x)}{a^2} + \frac{r^2 \cos^2(\gamma_y)}{b^2} + \frac{r^2 \cos^2(\gamma_z)}{c^2} = 1 \quad (18)$$

Finally, by making the identities $a^2 = 1/\delta_{11}$, $b^2 = 1/\delta_{22}$, and $c^2 = 1/\delta_{33}$, equation (18) can be rearranged to give

$$\cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} = \frac{1}{r^2} \quad (19)$$

Figure 2 The chemical shift tensor representation ellipsoid

The surface described by equation (19) is called the representation ellipsoid¹¹ of the chemical shift tensor and is illustrated in Figure 2.

The semiaxes of the ellipsoid are given by $1/\sqrt{\delta_{11}}$, $1/\sqrt{\delta_{22}}$, and $1/\sqrt{\delta_{33}}$. Comparing equation (16) and (19), it is seen that when $\mathbf{B}_0$ is oriented along $\mathbf{r}$, the length of the radius vector is given by $r = 1/\sqrt{F}$.

The representation ellipsoid thus allows a geometrical interpretation of the chemical shift tensor, and the *mmm* (D_{2h}) symmetry of this object reflects the symmetry of the chemical shift interaction.

In order to understand the effect of crystallographic symmetry on the chemical shift, it is necessary to define some terminology. Nuclear sites related by the rotation or reflection symmetry operations of the space group of the crystal are called *crystallographically equivalent* sites. Those sites that are related by inversion or translation are called *magnetically equivalent* sites. This definition of magnetic equivalence is in contrast to that used in solution NMR where sites related by any symmetry element of the molecule are magnetically equivalent due to the rapid isotropic tumbling of the molecule. As the operations of either inversion or translation do not change the orientation of the representation ellipsoid, a set of magnetically equivalent sites gives rise to a single peak in the spectrum. On the other hand, the representation ellipsoids of crystallographically equivalent sites are oriented differently in the absence of accidental coincidence of the symmetry elements of the representation ellipsoid with those of the space group. Therefore, multiple peaks occur in the spectrum of a single crystal sample when the magnetic field is in a general orientation with respect to a lattice of crystallographically equivalent sites. Two tensors are said to be *congruent* if they are each associated with nuclear sites which are crystallographically equivalent. Congruent tensors have identical principal values, but differ in the orientations of their respective principal axes.

3 THE SINGLE AXIS ROTATION METHOD

In the case of a crystal containing only one set of magnetically equivalent nuclei, the measurement technique is straightforward since the spectrum of such a crystal contains a single peak in any orientation of the field. Six 1D spectra can be obtained with the magnetic field oriented along six different directions. The chemical shift derived from each spectrum, along with the corresponding direction cosines describing

the orientation of the magnetic field, is then substituted into equation (15) to obtain a set of six equations from which the tensor elements are extracted.

The spectrum of a sample containing multiple sets of magnetically equivalent nuclei has a corresponding multiplicity of peaks. In this case the six 1D spectra described above would be useless, since there would be no way to determine which peak in each of the spectra was from a particular set of magnetically equivalent nuclei. One solution to this problem is to acquire many 1D spectra which differ by small angle rotations of the crystal so that the paths of the lines can be traced from one spectrum to the next to form a *rotation pattern*.

Consider a rotation of the crystal about an axis that makes an angle β with the magnetic field $\mathbf{B}_0$. The arbitrary sample frame can be oriented such that the x axis is parallel to the rotation axis and the magnetic field $\mathbf{B}_0$ lies initially in the xy plane. If the crystal is rotated through an angle α , the direction cosines of the field with respect to the sample frame are given by

$$\cos(\gamma_x) = \cos(\beta) \quad (20)$$

$$\cos(\gamma_y) = \sin(\beta) \cos(\alpha) \quad (21)$$

$$\cos(\gamma_z) = \sin(\beta) \sin(\alpha) \quad (22)$$

It can easily be shown by substituting equations (20)–(22) into equation (15) that the chemical shift F is given by

$$F = A + B \cos(\alpha) + C \sin(\alpha) + D \cos(2\alpha) + E \sin(2\alpha) \quad (23)$$

where

$$A = \frac{1}{2} \sin^2(\beta) (\delta_{yy} + \delta_{zz}) + \cos^2(\beta) \delta_{xx} \quad (24a)$$

$$B = 2 \sin(\beta) \cos(\beta) \delta_{xy} \quad (24b)$$

$$C = 2 \sin(\beta) \cos(\beta) \delta_{zx} \quad (24c)$$

$$D = \frac{1}{2} \sin^2(\beta) (\delta_{yy} - \delta_{zz}) \quad (24d)$$

$$E = \sin^2(\beta) \delta_{yz} \quad (24e)$$

From equation (23) it is seen that if the chemical shift is observed at five different angles α , for a given angle β , the coefficients A , B , C , D , and E can be extracted. However, these five coefficients are insufficient to determine fully the six tensor elements and it is apparent that the complete chemical shift tensor cannot be measured from a single rotation pattern.

The most frequently used measurement technique is to obtain three patterns by rotating the crystal about a single axis perpendicular to $\mathbf{B}_0$ in the laboratory frame as depicted in Figure 3.

Figure 3 Schematic representation of a simple experimental set-up for obtaining single axis rotation patterns

The three rotation patterns are obtained first with the x , then the y , and finally the z sample frame axis along the rotation direction. The rotation pattern about the x axis is easily obtained from equations (23) and (24) by setting the angle β equal to $\pi/2$

$$F(\alpha_x) = \frac{1}{2}(\delta_{yy} + \delta_{zz}) + \frac{1}{2}(\delta_{yy} - \delta_{zz}) \cos(2\alpha_x) + \delta_{yz} \sin(2\alpha_x) \quad (25)$$

The other two rotation patterns can be found by cyclic permutation of the sample axis labels x , y , and z

$$F(\alpha_y) = \frac{1}{2}(\delta_{zz} + \delta_{xx}) + \frac{1}{2}(\delta_{zz} - \delta_{xx}) \cos(2\alpha_y) + \delta_{zx} \sin(2\alpha_y) \quad (26)$$

$$F(\alpha_z) = \frac{1}{2}(\delta_{xx} + \delta_{yy}) + \frac{1}{2}(\delta_{xx} - \delta_{yy}) \cos(2\alpha_z) + \delta_{xy} \sin(2\alpha_z) \quad (27)$$

Although each rotation pattern is fully determined by measuring the chemical shift at only three different angles, the usual practice is to obtain spectra at many angles by stepping the goniometer from 0° to 180° , and to extract the tensor elements using least-squares methods. This allows a more accurate determination of the tensor and is a necessity if the spectrum of the crystal contains many peaks, since the path of a single peak can be traced only when the crystal is rotated in small angular increments. In order to obtain all six elements of the chemical shift tensor for a particular set of magnetically equivalent nuclei, the path of the corresponding peak must not only be traced within each rotation but must also be traced between rotations. This is accomplished by matching up the rotation patterns at the orientations where they intersect. Figure 4 shows three rotation patterns from which the ^{13}C chemical shift tensors of naphthalene can be obtained.

The rotation method has been successfully applied to many medium-sized molecules;¹² however, it fails when the peaks in the spectra become numerous and crowded since it becomes impossible to trace the paths of individual peaks through the three rotation patterns. Another drawback of the rotation method is the necessity of accurately mounting the crystal three times along the three orthogonal sample axes, but this problem has been overcome using a two-axis goniometer and a unique rf coil as demonstrated by Hauser et al.¹³

Figure 4 Rotation patterns through 180° about the x , y , and z sample axis sufficient to measure the 10 chemical shift tensors in single crystal naphthalene

4 SINGLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The necessity of taking small angular increments in the rotation patterns can be eliminated using a 2D correlation method introduced by Carter et al.¹⁴ This technique obtains 2D spectra in which a peak from a single set of magnetically equivalent nuclei is located by its resonant frequencies at two different orientations of the single crystal. Such spectra are obtained with the modified 2D chemical exchange¹⁵ pulse sequence shown in Figure 5.

The preparation period of this sequence is identical to the usual cross-polarization experiment. During the evolution period, the spins precess at frequencies determined by their chemical shifts at the initial crystal orientation. The evolved magnetization is then stored along the z axis with the pulse labeled b and the crystal is reoriented during the mixing period. At the end of the mixing period, the stored magnetization is rotated back to the transverse plane with the pulse labeled a , and during the detection period the spins precess at frequencies determined by their chemical shifts at the final crystal orientation. An example of a 2D chemical shift tensor correlation spectrum is shown in Figure 6 where all 24 peaks in

Figure 5 Modified chemical exchange sequence for 2D chemical shift tensor correlation spectroscopy. See text for details. (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

Figure 6 Two-dimensional absorption mode spectrum obtained from sucrose corresponding to a reorientation of B_0 by 90° in the sample frame. The plotted spectral width is $5 \text{ kHz} \times 5 \text{ kHz}$ (approximately $100 \text{ ppm} \times 100 \text{ ppm}$). The spectrum diagonal runs from upper left (high frequency) to lower right (low frequency). (Adapted by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

single crystal sucrose are resolved despite the severe crowding that exists in the corresponding 1D spectra.

It has been shown that the information present in one rotation pattern can be obtained from four 2D spectra taken while stepping the sample from 0° to 45° , 45° to 90° , 90° to 135° , and 135° to 180° (equivalent to 0°).¹⁶ The redundancy in this information permits a powerful square construction which resolves the uncertainties due to peak overlap within each rotation. However, this single axis 2D technique does

not address the problem of joining the three rotation patterns together when there are many overlapping lines in the spectra at the orientations where the patterns intersect. Thus the application of the single axis 2D method is limited to samples where the connections can be made by conventional means. As in the traditional 1D method, it is necessary to mount the sample accurately three times for the single axis 2D measurements.

5 MULTIPLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The full power of the 2D technique can be realized by gathering data in such a way that all correlations between required crystal orientations are obtained with a single mounting of the crystal. This is accomplished with a multiple axis sample orienting mechanism which complements the 2D method to form an exceedingly powerful technique for measuring chemical shift tensors in complex single crystals.¹⁷

As mentioned above, the six independent elements of a chemical shift tensor, in principle, can be determined by measuring the chemical shift with the magnetic field oriented along six suitably chosen directions. Table 1 gives the orientations of six such directions in the sample frame.

Table 1 Six Magnetic Field Directions in the Sample Frame That can be Used to Measure a Chemical Shift Tensor

Magnetic field direction	$\cos(\gamma_X)$	$\cos(\gamma_Y)$	$\cos(\gamma_Z)$	Observed shift
X	1	0	0	F_X
XY	$1/\sqrt{2}$	$1/\sqrt{2}$	0	F_{XY}
Y	0	1	0	F_Y
YZ	0	$1/\sqrt{2}$	$1/\sqrt{2}$	F_{YZ}
Z	0	0	1	F_Z
ZX	$1/\sqrt{2}$	0	$1/\sqrt{2}$	F_{ZX}

These directions lie on the surface of a trigonal pyramid and will be referred to here as the pyramidal directions. The observed chemical shifts F_X , F_{XY} , F_Y , F_{YZ} , F_Z , and F_{ZX} are easily calculated from equation (15), yielding the relationships

$$F_X = \delta_{xx} \quad (28a)$$

$$F_{XY} = \delta_{xy} + \delta_{xx}/2 + \delta_{yy}/2 \quad (28b)$$

$$F_Y = \delta_{yy} \quad (28c)$$

$$F_{YZ} = \delta_{yz} + \delta_{yy}/2 + \delta_{zz}/2 \quad (28d)$$

$$F_Z = \delta_{zz} \quad (28e)$$

$$F_{ZX} = \delta_{zx} + \delta_{zz}/2 + \delta_{xx}/2 \quad (28f)$$

which trivially invert to

$$\delta_{xx} = F_X \quad (29a)$$

$$\delta_{xy} = F_{XY} - F_X/2 - F_Y/2 \quad (29b)$$

$$\delta_{yy} = F_Y \quad (29c)$$

$$\delta_{yz} = F_{YZ} - F_Y/2 - F_Z/2 \quad (29d)$$

$$\delta_{zz} = F_Z \quad (29e)$$

$$\delta_{zx} = F_{ZX} - F_Z/2 - F_X/2 \quad (29f)$$

By obtaining the six 2D spectra corresponding to reorientation between the $X-XY$, $XY-Y$, $Y-YZ$, $YZ-Z$, $Z-ZX$, and $ZX-X$ direction pairs, the correlation data are sufficient to determine the complete chemical shift tensors for all of the sets of magnetically equivalent nuclei in the sample. Starting first with the $X-XY$ 2D spectrum, the chemical shifts of the X and XY directions are measured and correlated. Then the observed chemical shifts in the XY direction from the $X-XY$ spectrum are matched with those from the $XY-Y$ spectrum to advance the correlation of the chemical shift to the Y direction, and so forth through YZ , Z , ZX , and back to X . After completion of the full cycle of reorientations, the chemical shift is known for each set of magnetically equivalent nuclei at all six orientations and the tensor elements can be calculated from equations (29a)–(29f). The correlation of chemical shifts around the full cycle forms the closed path depicted in Figure 7(a).

It may be noted that the sense of the reorientation is unimportant. The same frequency information is obtained by reorienting from the X to the XY direction as is obtained by reorienting from XY to X . The only consequence is to interchange the F_1 and F_2 axes of the spectrum.

A powerful criterion, analogous to the square construction described for the single axis 2D approach, allows the correlation of peaks which have identical frequencies at one or more of the six magnetic field directions. It employs reorientations between other pairs of the six measurement directions. The full matrix of 36 possible 2D correlation spectra is shown in Figure 7(b). The 2D spectra that lie along the diagonal of this matrix correspond to trivial correlations between two identical orientations, and are thus of no experimental value. The spectra related by the transpose of this matrix differ only by the sense of the reorientation, and contain the same correlation information. Therefore, only 15 of the 36 possible spectra are necessary to obtain all of the available correlation and frequency information. The spectra matrix construction allows the chemical shifts of a single set of magnetically equivalent nuclei to be traced through all 15 possible 2D correlation spectra simply by connecting the peaks with horizontal and vertical lines as shown in Figure 7(b).

A mechanism which accomplishes the 15 flips has been described in detail elsewhere.¹⁷ Briefly, it consists of an armature into which a glass tube containing the sample is

Figure 7 Matrix of 2D spectra. (a) Six 2D spectra corresponding to $XY-X$, $XY-Y$, $YZ-Y$, $YZ-Z$, $ZX-Z$, and $ZX-X$ reorientations. The relationship of the peaks in these spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. Dotted lines indicate the diagonals in the spectra. (b) All 36 possible 2D spectra. The relationship of the peaks in the spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. The six unshaded spectra with dotted diagonals correspond to those of Figure 7(a). The six darkly shaded spectra with solid diagonals are the trivial autocorrelation spectra with the peaks on the diagonals (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

mounted. The armature contains seven accurately drilled holes which define seven rotation axes in the sample frame. A stationary plate attached to the NMR probe contains five axle bearing holes which define five rotation axes in the laboratory frame. The mechanism is assembled by inserting an axle through one of the bearings in the stationary plate

and into one of the holes in the armature. By selecting the appropriate combination of bearing and armature hole, each of the 15 possible flips can be performed. The angle of rotation is limited by a precise system of stops. One advantage of this mechanism is that the axis of the tube containing the sample changes by only 19.5° over all assemblies of the mechanism, so that a reasonably good filling factor can be achieved in the rf solenoid.

Although the pyramidal set of directions was used in the original demonstration of multiple axis 2D chemical shift tensor correlation spectroscopy, it should be realized that any set of six directions would suffice if when substituted into equation (15) they yield a system of linearly independent equations for the six chemical shifts. This restriction eliminates any set of directions that completely lie either in a plane or on the surface of a cone.

An important question that arises is how sensitive is the determination of a tensor given a particular set of measurement directions. To address this question, a variance-like figure of merit was developed¹⁸ which quantifies the sensitivity of a given set of measurement directions. This figure of merit was evaluated for a variety of sets of measurement directions including the pyramidal set and the orthogonal rotation set. The most sensitive set of directions was found to be the six apolar directions defined by the vertices of an icosahedron. For this geometry, the figure of merit represents a significant decrease by a factor of 1.0/1.8 from that of the pyramidal directions. Therefore, it is worth considering the icosahedral direction set when designing future mechanisms. It should be noted that there is no further increase in sensitivity upon including more measurement directions than the six icosahedral directions. Another interesting result of this analysis is that the figure of merit for the orthogonal rotations set is only 1.2 times greater than that for the icosahedral directions set. This indicates that the sensitivity of the tensor measurements made using the traditional rotation method is nearly optimal.

The high symmetry of the icosahedron makes possible a very simple mechanism which rotates the crystal about a single laboratory axis inclined at an angle of 64.4° from the field. As can be seen in Figure 8, it will still be necessary to employ three rotation axes in the sample frame as specified by the three vertices labeled a, b, and c. Unfortunately the sample tube axis will reorient by 68.3° in this new mechanism, and a sacrifice in filling factor may be necessary when implementing this geometry.

Figure 8 Icosahedra showing the vertex directions which can be aligned along the magnetic field by rotating around the a vertex (a), the b vertex (b), and the c vertex (c) (Reproduced by permission of Academic Press from D. W. Alderman, M. H. Sherwood, and D. M. Grant, *J. Magn. Reson.*, 1990, **86**, 60)

6 ASSIGNMENT TECHNIQUES

Before chemical shift tensors can be rationalized in terms of molecular structure, they must first be assigned to their respective nuclei in the unit cell. This can be a challenging step in the interpretation of the results, since the number of possible assignment permutations increases rapidly for larger molecules. The problem is compounded by the fact that most organic crystals contain two or more magnetically nonequivalent molecules in the unit cell. In order fully to exploit the power of the techniques described above, systematic methods of assignment have been developed based on local symmetry and dipolar spectroscopy. These methods have been described in detail in the literature and therefore will only be described qualitatively here.

Nearly all of the chemical shift tensor assignments made to date are based on the assumption that the symmetry elements of the representation ellipsoid should closely coincide with the actual or approximate local symmetry of its assigned nuclear site. For example, it is well established that the δ_{33} principal values of the ^{13}C chemical shift tensors orient perpendicular to the molecular plane in polycyclic aromatic hydrocarbons.¹⁹ This fact is widely used to assign tensors to a particular molecule when there is more than one molecule in the unit cell. In more complicated molecules lacking any molecular symmetry, the approximate local symmetry established by the directly bonded atoms can be used to make assignments. For small molecules this procedure consists of manually comparing principal axis directions of the measured tensors with the approximate local symmetry elements determined from diffraction data until a reasonable match is found. As the number of measured tensors increases, it becomes more difficult to make all possible comparisons and their qualitative nature makes it difficult to distinguish between closely related assignments. In order to quantify such comparisons, the concept of a distance between two tensors was developed.¹⁰ This distance concept has been combined with linear modeling in order to make possible an automated assignment technique which can explore all possible assignments of a reasonably large set of measured tensors to a corresponding set of chemically similar but magnetically nonequivalent nuclear sites.^{10, 20}

The orientational dependence of dipolar interactions has also been exploited in order to assign chemical shift tensors to specific nuclei in single crystal samples. Assignments made in this way are quite reliable since dipolar couplings can be calculated with a high degree of accuracy from the positions of the nuclei alone without resorting to molecular electronic theory. In many organic molecular crystals, the positions of all of the carbon and hydrogen nuclei in the unit cell are known from neutron diffraction studies and thus ^{13}C – ^1H separated local field experiments^{21, 22} can be used in solving the assignment problem.

A simple extension of 2D chemical shift tensor correlation spectroscopy yields a 3D technique which allows detection of ^{13}C – ^1H dipolar couplings for each of the magnetically nonequivalent sets of carbons in the sample.²⁰ The response of each spin is separated according to its chemical shifts at two different magnetic field orientations and a dipolar spectrum is displayed in the third dimension. This is accomplished by inserting a dipolar evolution period between the end of the mixing time and the beginning of the detection period of the previously described 2D experiment.

1 INTRODUCTION

Observations of NMR signals, whose resonance positions in different compounds depend upon the chemical environment of the nucleus, were first made during 1949–50 for ^{14}N by Proctor and Yu,¹ for ^{19}F by Dickinson,² and for ^1H independently by Lindström³ and by Thomas.⁴ In 1951 Arnold, Dharmatti, and Packard⁵ first published a single spectrum in which three separate ^1H resonance peaks were observed in a single compound, ethanol, with its three chemically different protons. This series of papers, on a chemically dependent spectral feature, launched the field of NMR into the world of chemistry. Such chemically induced shifts in the resonance positions of chemically different nuclei provide unique experimental information on the electronic structure in molecules, and these data have become the basis for innumerable chemical studies for almost half of a century. Among physical measurements in the world of chemistry the chemical shift enjoys a special distinction, and every year brings even greater and varied applications for this chemically sensitive parameter.

Dominated by the local electronic structure in the immediate vicinity of a resonating nucleus, the shift becomes a characteristic chemical signature of the atom in question and its immediate atomic neighbors. Remote structural perturbations of the chemical shift are usually restricted either to molecules in which the electronic structure is readily polarized by long-range electrostatic fields or to molecules in which distant molecular moieties have folded back upon the resonating nucleus. In this latter case, a steric perturbation of the electronic structure of the impacted atom leads to predictable chemical shifts that specify the geometry of the steric interaction.

In liquid samples, rapid molecular motions have tumbling rates sufficiently high to average the various chemical environments and the diverse orientations found in liquids. These motions narrow the resonance lines and yield sharp peaks whose frequencies provide a very sensitive way to analyze the composition of low viscosity liquids. These line positions, expressed by the chemical shifts, are highly reproducible quantities that provide a powerful set of parametric values for

characterizing the molecular conformations and intermolecular interactions important in the liquid state.

Even though liquid chemical shifts may be expressed as scalar numbers, the associated shielding of a nuclear spin is a tensor quantity that depends upon the electronic environment, but also varies with the molecular orientation in the magnetic field. When the molecular orientation is locked into a solid powder sample, the nuclear resonance frequency also reflects the orientation of the sample's microcrystalline particles. The orientational diversity in a powder leads to broad resonance bands for each chemically unique nucleus. Although these tensor bands contain considerably more details on the electronic structure than found for tumbling liquid molecules, the extensive banding in powder samples with many different nuclei typically obscures the additional structural information that is available in isotropic liquid shifts.

In recent years the shift tensor's importance has increased significantly as line-narrowing methods and techniques have emerged for analyzing the overlapping spectral bands found in solids. Consequently, solid NMR shift data now rival liquid data in the study of the molecular and electronic structure of matter. For materials such as polymers, coals, and other insoluble substances, only solid state methods are available for NMR analysis. The field of solid state NMR has been treated extensively, and several excellent treatises^{6–12} provide additional information on chemical shift tensors and their importance in chemistry.

This article is organized into sections with Sections 2–6 providing the main body of the work. Section 2 provides mathematical definitions of an induced magnetization vector associated with nuclear shielding and magnetic susceptibility. These magnetizations modify the static magnetic field that governs NMR frequencies, and their relative importance is discussed. The chemical shift of a resonance frequency is referenced to a designated fiducial peak, and this practice avoids the dilemma of referring chemically dependent shifts to the immeasurable resonance of a bare nucleus. The mathematical form of the chemical shift tensor is introduced in Section 2, and these expressions reflect both the chemical environment and their orientational dependence.

The transformations needed to convert shift tensors between different coordinate frames are presented in Section 3, and their importance is briefly discussed. Tensor representations (i.e., the icosahedral and irreducible spherical tensors) are discussed along with the properties that make them attractive for deriving mathematical relationships and for statistically analyzing and comparing tensor data.

Section 4 analyzes the chemical shift information contained in powder samples where the random orientations of microcrystallites produce resonance bands. These spectral bands have characteristic shapes depending upon the magnitude of the tensor components and the overall symmetry of the shift tensor. The conformal mapping approach of Bloembergen and Rowland¹³ relates the intensities and frequencies found in a spectral pattern to the principal chemical shift values of the tensor expressed in its own principal axis frame (PAF).

Section 5 summarizes two single crystal methods used for obtaining complete chemical shift tensors, including both the principal shift values and the tensor's orientation in the crystal. Such crystal data provide the six parameters needed to describe a general asymmetric tensor, whereas powder patterns can provide only the three principal shift values. The

tensor's orientation, obscured in powder samples, is readily available from single crystal data. The traditional 1D single-axis goniometer method is discussed in Section 5 along with a newer 2D spatial correlation method. This 2D approach has the capacity of indexing close to an order of magnitude more peaks than the 1D single-axis goniometer method.

Section 6 briefly identifies symmetry and structural features that dominate the chemical shift tensor. Both diamagnetic and paramagnetic shielding currents are important in chemical shifts, and the magnitudes of a representative sampling of ^{13}C shifts are discussed to illustrate the governing principles. While first-order diamagnetic currents produce large shifts, arising from carbon electrons in the 1s inner shell and in the 2s, 2p valence shell, these diamagnetic currents vary less between different molecules than corresponding paramagnetic currents which arise from mixing intrinsic angular momentum components from p and d electrons into the molecule's electronic structure. Such paramagnetic shifts arise from a second-order perturbation between the nuclear magnetic moment and the static magnetic field. As these shielding currents represent very weak perturbations of the electronic structure they can vary by orders of magnitude without altering appreciably the overall electronic energy. Thus, highly variable paramagnetic currents depend upon a variety of structural factors to be discussed in Section 6.

2 THE CHEMICAL SHIFT

2.1 Chemical Shielding and Magnetic Susceptibility

Ignoring spin-spin interactions, rapidly tumbling molecules in nonviscous liquids exhibit narrow nuclear resonance lines with frequencies, f_i , given by,

$$\begin{aligned} f_i &= \frac{\gamma_s}{2\pi} \mathbf{I}(i) \cdot \mathbf{B}_i = \frac{\gamma_s}{2\pi} \mathbf{I}(i) \cdot (\mathbf{M}_i + \mathbf{H}_0) \mu_0 \\ &= \frac{\gamma_s}{2\pi} \mathbf{I}(i) \cdot (1 - \sigma_i - \chi_m) \mu_0 \mathbf{H}_0 \quad (1) \end{aligned}$$

The angular momentum of the i th spin and its corresponding gyromagnetic ratio are given, respectively, by $\mathbf{I}(i)$ and γ_s . The magnetic induction at the nucleus, $\mathbf{B}_i$, is equal to the vector sum of the static magnetic field, $\mathbf{H}_0$, and an induced magnetization vector, $\mathbf{M}_i$, arising from electronic currents that exist within the sample. This magnetization is given by $\mathbf{M}_i = -(\sigma_i + \chi_m)\mathbf{H}_0$ and is directly proportional to $\mathbf{H}_0$. The proportionality constant between $\mathbf{M}_i$ and $\mathbf{H}_0$, includes the chemical shielding, σ_i , and the magnetic susceptibility, χ_m , of the material surrounding the nuclear spin of interest. The magnetic permeability of free space, μ_0 , equals unity in Gaussian magnetic units and $4\pi \times 10^{-7}$ in SI units.¹⁴

The subdivision in equation (1) of the magnetization vector into chemical shielding and magnetic susceptibility is somewhat arbitrary, unfortunately, as they both arise from the same phenomena, circular electronic currents induced in the sample by $\mathbf{H}_0$. Typically, the variable shielding terms, σ_i , designate specific currents in the vicinity of the nucleus, and their variability reflects changes primarily in the electronic structure of the molecule of interest. The magnetic susceptibility term, χ_m , is usually reserved for

more remote electron currents that contribute to a uniform bulk magnetic property for the sample. It is presumed that χ_m is equal for all nuclei in a given molecule, leaving variations in the nuclear resonance frequencies within the same molecule to be attributed solely to chemical shielding. It is the assignment of electron currents at intermediate distances (e.g., in neighboring molecules) which creates the challenge for separating σ_i from χ_m . In liquids, the separation of the induced magnetization into intramolecular currents for chemical shielding and into intermolecular currents for magnetic susceptibility is partially justified as molecular diffusion, both rotation and translation, averages the effect of intermolecular currents between adjacent tumbling molecules into a fairly uniform induced magnetization vector.

In solids, the absence of rapid motional averaging makes a simple division of $\mathbf{M}_i$ into either chemical shielding or magnetic susceptibility more difficult. It is still straightforward to assign all intramolecular currents within the parent molecule to chemical shielding and distant electronic currents to magnetic susceptibility. However, proximate intermolecular currents no longer average to uniform values across a given molecule, but depend upon the nature of the surrounding molecules and upon the irregular shape of the crystalline cavity when the parent molecule is conceptually removed from consideration. When designation of sizable intermolecular currents from neighboring molecules to χ_m fails to meet the criterion that the susceptibility should be a homogeneous bulk property, these proximate intermolecular shielding currents should appropriately be included as a part of σ_i . The lack of a precise prescription for designating a term as either shielding or susceptibility is imposed on us in part by our inability to identify experimentally or to calculate reliably the theoretical contributions to the magnetization from currents beyond the immediate molecular domain. Fortunately, the susceptibility variations in the resonance frequencies for many molecules are often less than the solid linewidths and their contributions may be ignored. When the isotropic solid and liquid shifts are very similar, then strong evidence exists that the shielding is dominated by intramolecular electronic currents.

2.2 Chemical Shifts in Liquids

As the resonance frequency of a bare nucleus cannot be measured by ordinary means, chemical shifts are typically reported relative to a fiducial resonance peak of a specified nucleus. Reference compounds are selected for their stability and chemical inertness. For example, tetramethylsilane (TMS) has become the standard for chemical shift measurements of both the ^{13}C and ^1H nuclides because the TMS resonance lines are relatively insensitive to solvent interactions and, in addition, this compound is chemically stable. The chemical shifts of each nuclear species in the sample are measured from their reference frequencies in accordance with the following chemical shift expression:

$$\delta_i(\text{ppm}) = \frac{f_i - f_{\text{ref}}}{f_{\text{ref}}} \times 10^6 \quad (2)$$

The f_{ref} is the resonance frequency of the reference nucleus and f_i is the corresponding frequency of the i th nucleus. Variations in f_i from f_{ref} are usually small and according to

IUPAC conventions δ_i are reported in units of parts per million (ppm). For simplicity of notation, the 10^6 factor in equation (2) is only implied henceforth in this article. By substituting equation (1) into equation (2) and rearranging the expression, one obtains

$$\delta_i = \frac{\sigma_{\text{ref}} - \sigma_i}{1 - \sigma_{\text{ref}} - \chi_m} \simeq \sigma_{\text{ref}} - \sigma_i \quad (3)$$

The final expression for δ_i is obtained by neglecting the higher order infinitesimal, δ_i ($\sigma_{\text{ref}} + \chi_m$).

The difference in the sign of δ_i versus σ_i is a consequence of δ_i applying to frequency space and σ_i designating a fractional change in the magnetic field. In NMR spectroscopy the reciprocal relationship between the magnetic field and the resonance frequency provides one of the rich legacies of this special spectroscopy, in which a variety of spectral frequencies are made possible by altering the static magnetic field. The sign anomaly in equation (3) is a modest inconvenience considering the benefits of dealing flexibly with both field and frequency variables. Unfortunately, this dual convention for reporting the position of NMR peaks introduces some perplexities in their use, especially to those approaching the field for the first time.

By substituting equation (3) in equation (1), a convenient form of the resonance frequency is given by

$$f_i = (1 + \delta_i)f_{\text{ref}} = \frac{\gamma_s}{2\pi} I(i)(1 + \delta_i)B_{\text{ref}} \quad (4)$$

where the magnetic induction at the reference nucleus, B_{ref} , is given by

$$B_{\text{ref}} = (1 - \sigma_{\text{ref}} - \chi_m)\mu_0 H_0 \quad (5)$$

As discussed in Section 2.1, the value for χ_m is presumed to be the same for all nuclei in a given molecule and differences between f_i are ascribed solely to variations in δ_i . Magnetic susceptibility corrections need to be applied from time to time in the comparison of chemical shifts obtained either from different solutions or from the same material with different physical shapes. External referencing of chemical shifts in different solvents therefore should be approached with care.

Historically, NMR spectra were obtained at constant frequency while sweeping the magnetic field, and in the early days of the field it was the practice to report resonance shifts as differences in shielding constants. With the arrival of Fourier transform methods, it is now more common to record and process chemical shift data in frequency units. However, quantum mechanical calculations of nuclear shielding, by their nature, provide absolute shifts that are expressed relative to the resonance frequency of a bare nucleus. For this reason, and supported by the historical convention, most theoretical estimates of shifts are still reported as σ_i values. This can pose a problem when one wishes to compare δ_i directly to ($\sigma_{\text{ref}} - \sigma_i$), as only theoretical methods exist for estimating the magnitude of σ_{ref} for a given reference nucleus. Jameson has related the absolute chemical shift scales of different nuclei to each other and this topic is discussed elsewhere in this Encyclopedia, (see C. J. Jameson *Chemical Shift Scales on an Absolute Basis*).

2.3 Chemical Shifts in Solids

A variety of proton-decoupled ^{13}C spectra of methyl β -D-xylopyranoside are given in Figure 1 to illustrate the effect of immobilizing molecules in solids. The liquid spectrum is shown in Figure 1(a) with a single peak appearing for each of the six different carbons of methyl β -D-xylopyranoside. Figure 1(b) exhibits the corresponding solid spectrum using the popular cross polarization (see D. P. Burum *Cross Polarization in Solids*) and magic angle spinning (CP MAS) techniques (see E. A. Andrew *Magic Angle Spinning*) to suppress the orientational information. Such CP MAS spectra, obtained on powdered solids, have an appearance similar to liquid spectra. The CP MAS spectral lines are considerably broader than the very sharp liquid lines, but only relatively small chemical shifts exist between the two spectra given in Figures 1(a) and (b). These shifts reflect modest changes in the molecular conformations or intermolecular associations that exist between the liquid and solid states.

The final three spectra, given in Figures 1(c), (d), and (e), are from three mutually perpendicular orientations of a single crystal of methyl β -D-xylopyranoside. It is readily apparent in these three spectra that the shift data exhibit a high dependence on the orientation of the single crystal sample. The six lines in the liquid and CP MAS spectra are doubled to 12 lines due to the presence of two magnetically different molecules, designated as a and b, within the unit cell. Only the two C-6 peaks, 6a and 6b, are labeled in Figure 1 to illustrate the effect of magnetic nonequivalence in the unit cell, but these two lines represent the doubling found for all six carbons in methyl β -D-xylopyranoside. It should be noted that the average of the three peaks labeled 6a and the average of those labeled 6b each gives the same shift as found for the C-6 peak in the CP MAS spectrum, thereby indicating that the pair of resonances labeled 6a and 6b are chemically congruent.

The doubling of resonance lines in methyl β -D-xylopyranoside arises from two chemically equivalent but magnetically nonequivalent molecules in the crystal. The different resonance shifts between corresponding nuclei in the two molecules are due only to a difference in the orientation of the two molecules relative to the magnetic field. The chemically equivalent molecules are related by the symmetry elements in the unit cell, but in an arbitrarily oriented crystal the magnetic field usually does not comply with this symmetry. Molecules, symmetrically related but not identically oriented in the magnetic field, exhibit different resonance frequencies. Such congruent frequencies reflect the orientational dependence of the chemical shifts in solid samples and indicate the need for mathematical expressions that specify the orientational aspects of chemical shift tensors (see Section 2.4 below).

If a single crystal of methyl β -D-xylopyranoside is pulverized, broad powder patterns are observed in place of the discrete peaks found in Figures 1(c)–(e). But now these spectral bands are the same for the different a and b molecules that led to the line doubling in Figures 1(c)–(e). This loss of congruent shift information obscures the tensor's orientational information in powder samples. Excessive overlapping of powder bands also limits the chemical shift information that can be measured for multiple spins. Usually, only two, or at most three, overlapping spectral bands may be analyzed successfully from a simple 1D solid spectrum.

Figure 2 contains simulated band spectra for a variety of spectral powder patterns. Typical spectral bands for two axially

Figure 1 NMR spectra of methyl β -D-xylopyranoside obtained under various conditions: (a) typical liquid spectrum; (b) CP MAS solid spectrum; (c)–(e) single crystal spectra with magnetic field oriented along the X, Y, and Z axes, respectively. To avoid congestion in the labeling of lines, only the 6a and 6b conjugate resonance lines are illustrated. See Figure 13 for the remaining assignments. (Courtesy of Fang Liu)

Figure 2 Spectral powder patterns for the following tensor symmetries: (a) prolate; (b) oblate; (c) centrosymmetric; and (d) general asymmetric tensors. (Courtesy of Mark S. Solum)

symmetric tensors are shown in Figures 2(a) and (b). The definition of an axial pattern requires two principal shift values, i.e. $\delta_{||}$ associated with the magnetic field along the axially symmetric or unique principal axis and $\delta_{\perp}$ for the magnetic

field perpendicular to the unique principal axis. Depending upon the relative magnitudes of these two principal shift frequencies, the banded spectrum consists of either a prolate ($\delta_{||} > \delta_{\perp}$) or oblate ($\delta_{\perp} > \delta_{||}$) powder pattern. Three breakpoints are readily apparent in asymmetric powder patterns, as shown in the two remaining spectra given in Figures 2(c) and (d). These three positions correspond to the three principal values of the chemical shift tensor and may be associated with three mutually perpendicular directions in the molecule. The centrosymmetric tensor, illustrated in Figure 2(c), is defined by the relationship $\delta_{22} = \frac{1}{2}(\delta_{11} + \delta_{33})$, but no constraints are imposed on the values for δ_{11} , δ_{22} , and δ_{33} for the general asymmetric tensor shown in Figure 2(d).

2.4 The Quadratic Form of Chemical Shift Tensors and Their Orientational Dependence

The orientational dependence of resonance frequencies in solid samples is described by the following quadratic formulation of the chemical shift tensor:

$$f_i = \frac{\gamma_s}{2\pi} \mathbf{I}(i) \cdot \mathbf{B}_i = \frac{\gamma_s}{2\pi} \mathbf{I}(i) \cdot (\mathbf{1} + \boldsymbol{\delta}_i) \cdot \mathbf{B}_{\text{ref}} \quad (6)$$

Again, the angular momentum vector and the corresponding value for the magnetic induction vector at the nucleus i are

given by $I(i)$ and B_i , respectively. The quantity B_i is related to the magnetic induction at the reference peak, B_{ref} , through the unit dyadic and the chemical shift tensor given, respectively, as follows:

$$\mathbf{1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \delta_i = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & \delta_{zz} \end{bmatrix} \quad (7)$$

The unit dyadic, $\mathbf{1}$, along with γ_s characterize the effect of the nuclear Zeeman splitting and the second-rank chemical shift tensor is given by δ_i . For the sake of simplicity in notation, the nuclear index, i , has been suppressed from the individual matrix elements in equation (7).

To analyze the tensor's effect on the shift frequency, it is helpful to express the B_i found in equation (6) in matrix form using equation (7) to give

$$\begin{aligned} B_i &= \begin{bmatrix} B_{i,x} \\ B_{i,y} \\ B_{i,z} \end{bmatrix} = \begin{bmatrix} (1 + \delta_{xx}) & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & (1 + \delta_{yy}) & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & (1 + \delta_{zz}) \end{bmatrix} \\ &\times \begin{bmatrix} 0 \\ 0 \\ B_{\text{ref}} \end{bmatrix} = \begin{bmatrix} \delta_{xz} B_{\text{ref}} \\ \delta_{yz} B_{\text{ref}} \\ (1 + \delta_{zz}) B_{\text{ref}} \end{bmatrix} \end{aligned} \quad (8)$$

In equation (8), the laboratory coordinate frame is defined with the z axis oriented along the magnetic field vector, B_{ref} . The spatial relationships between the components of the magnetic induction, B_i , and the corresponding reference field, B_{ref} , may be visualized in Figure 3. Note that the contributions to B_i of the three tensor components are mutually perpendicular, but the perpendicular components fail to contribute to the measurable magnitude of B_i , which is given relative to B_{ref} by the Pythagorean theorem as follows:

$$\begin{aligned} B_i &= \sqrt{(\delta_{xz} B_{\text{ref}})^2 + (\delta_{yz} B_{\text{ref}})^2 + [(1 + \delta_{zz}) B_{\text{ref}}]^2} \\ &\simeq (1 + \delta_{zz}) B_{\text{ref}} \end{aligned} \quad (9)$$

Because $(1 + \delta_{zz}) B_{\text{ref}}$ is several orders of magnitude larger than either $\delta_{xz} B_{\text{ref}}$ or $\delta_{yz} B_{\text{ref}}$, a root-squared sum of these components makes all contributions negligible except the one along the z axis. The expanded insert in Figure 3 attempts to indicate schematically this feature, but one must realize that the shift components are infinitesimally small compared with the magnetic field vectors even though they have been drawn out of scale to exhibit their geometrical orientations. It is the orientation of this B_i vector along the z axis which quantizes the nuclear angular momentum and makes $I_x(i) = I_y(i) = 0$ in the equilibrium description of the resonance frequency. Consequently, when the i th nuclear spin quantizes along B_i , it is also quantized, within our present ability to make measurements, along B_{ref} . Hence, B_i and B_{ref} are drawn parallel in Figure 3. Substituting equation (9) for B_i and $I_z(i)$ for $I(i)$ into equation (6) yields the following expression for f_i in the laboratory frame of the magnet:

$$f_i = \frac{\gamma_s}{2\pi} I_z(i) (1 + \delta_{zz}) B_{\text{ref}} \quad (10)$$

Figure 3 Chemical shift tensor components contributing to B_i in the laboratory frame. The z axis is not scaled linearly to allow the geometrical features associated with the various shift components to be portrayed. The perpendicular components have no measurable effect on the magnitude or orientation of B_i as portrayed in the expanded insert

Equation (10) correctly characterizes the resonance frequency associated with the molecular orientation in the magnetic field, and defines a single shift value, δ_{zz} , for this one measurement. The simplicity of equation (10) may be misleading, however, as a single measurement fails to provide the diversity of resonance frequencies arising from various molecular orientations that are needed to characterize a chemical shift tensor. A shift tensor can only be prescribed when a sufficient number of resonance frequencies exist to define the principal values and their orientations in space. Thus, the tensor must be formulated with equations that express explicitly the orientation of the magnetic field relative to the tensor's orientation. In the tensor's principal axis frame (PAF) the orientation of the B_{ref} field may be designated with two polar angles, θ and ϕ , as shown in Figure 4, and these two polar angles are sufficient for analyzing powder spectra. Other features in Figure 4 will be discussed in more detail in Section 3.1.2.

Figure 4 Chemical shift tensor components contributing to B_i in the PAF. In this frame all of the principal δ_{xx} , δ_{yy} , and δ_{zz} components contribute to B_i , as indicated. Only their projections onto B_{ref} , shown in the expanded insert, make measurable contributions to the resonance frequency

The spatial orientation of the PAF relative to a molecular or a unit cell frame also must be specified whenever the full chemical shift tensor is to be described. The full six-parameter tensor for chemical shielding requires not only the three principal values but also three Euler angles to describe the orientation of the PAF in a microscopic molecular frame. Only single crystal measurements can provide both principal shift values and the tensor's orientation in a molecular frame. Section 5 provides the mathematical expressions which track the resonance frequencies using the full six-parameter chemical shift tensor.

3 THE CHEMICAL SHIFT TENSOR IN A VARIETY OF REFERENCE FRAMES AND REPRESENTATIONS

3.1 The Cartesian Chemical Shift Tensor

3.1.1 Separation of the Chemical Shift Tensor into Matrices of Different Rank

The chemical shift tensor in a general reference frame may be expressed as a typical 3×3 Cartesian matrix that can be separated, respectively, into three individual tensors of rank zero, one, and two as follows:

$$\begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & \delta_{zz} \end{bmatrix} = \delta_o \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + \begin{bmatrix} 0 & \delta_{xy}^{(a)} & \delta_{xz}^{(a)} \\ -\delta_{xy}^{(a)} & 0 & \delta_{yz}^{(a)} \\ -\delta_{xz}^{(a)} & -\delta_{yz}^{(a)} & 0 \end{bmatrix} + \begin{bmatrix} (\delta_{xx}^{(s)} - \delta_o) & \delta_{xy}^{(s)} & \delta_{xz}^{(s)} \\ \delta_{xy}^{(s)} & (\delta_{yy}^{(s)} - \delta_o) & \delta_{yz}^{(s)} \\ \delta_{xz}^{(s)} & \delta_{yz}^{(s)} & (\delta_{zz}^{(s)} - \delta_o) \end{bmatrix} \quad (11)$$

where the zero, first, and second rank components appearing on the right-hand side of equation (11) are due to the scalar isotropic chemical shift, $\delta_o = \frac{1}{3}(\delta_{xx} + \delta_{yy} + \delta_{zz})$, the antisymmetric chemical shifts, $\delta_{ij}^{(a)} = \frac{1}{2}(\delta_{ij} - \delta_{ji})$, and the symmetric chemical shifts, $\delta_{ij}^{(s)} = \frac{1}{2}(\delta_{ij} + \delta_{ji})$, respectively. Substitution of these defined quantities into equation (11) readily verifies the relationship given by this equation. In this separated form the symmetry properties of the three different ranks may be considered individually.

3.1.1.1 The Isotropic Chemical Shift, δ_o . The isotropic chemical shift, δ_o , is the trace of the Cartesian tensor and is invariant to any rotational transformation of the coordinate frame. Thus, under the rapid rotational tumbling encountered in liquid samples, the value of δ_o remains constant, but both the antisymmetric first-rank and the symmetric second-rank tensors vanish if the motion is isotropic. Unfortunately, this averaging process prevents access to anisotropic chemical shift information in isotropic liquids. Quite frequently, the trace of the chemical shift tensor in solids is similar to averaged shifts in isotropic liquids. The small shifts observed between solid and liquid spectra, such as shown in Figures 1(a) and (b), usually reflect minor conformational variations between solid and liquid samples. However, δ_o in solids may differ significantly from the liquid isotropic shift

whenever the solid state affects the intermolecular associations extensively, e.g., hydrogen bonding or some similar strong electrostatic intermolecular interaction. Simple van der Waals intermolecular interactions, found in many compounds, seldom change ($\delta_o - \delta_{liq}$) beyond the experimental errors in solid shift measurements.

3.1.1.2 The Antisymmetric Chemical Shifts. The absence of diagonal elements in the first-rank antisymmetric shifts, $\delta_{ij}^{(a)}$, has significant implications as it leaves only shielding fields oriented perpendicular to the $\mathbf{B}_{ref}$ as specified in Figure 3. Such shielding fields, as discussed in Section 2.4, are perpendicular to the strong static field, $\mathbf{B}_{ref}$, associated with the Zeeman splitting, and the quantization of the nuclear spin angular momentum along $\mathbf{B}_{ref}$ leaves these second-order infinitesimal shift frequencies immeasurable. While negligible in their effect on the resonance spectral frequencies, such antisymmetric shifts may provide a significant mechanism for spin relaxation with motional tumbling. Theoretical studies suggest, however, that these anomalous relaxation rates are significant only in fairly unusual molecular systems. Molecules in which the antisymmetric shifts appear to be important for spin relaxation include π -electron systems with distorted bond arrangements, such as found in cyclopropene or cyclopropenone.

3.1.1.3 The Symmetric Chemical Shifts and Shift Anisotropy. The second-rank symmetric matrix, $\delta_{ij}^{(s)}$, also develops shielding field components perpendicular to the applied magnetic field, $\mathbf{H}_0$, in a manner similar to antisymmetric shifts, but this second-rank tensor, while traceless, has diagonal elements that can provide first-order anisotropic shifts that add or subtract directly from the Zeeman frequencies. Even though small compared with the Zeeman splitting, the shifts associated with ($\delta_{zz} - \delta_o$) are directly measurable in the NMR spectra of solids (see Figure 3). Because the $\delta_{ij}^{(s)}$ matrix is symmetrical, any reorientation of the magnetic field in the molecular frame will still leave anisotropic shifts along the diagonal of the transformed second-rank symmetrical matrix. Unlike the antisymmetric components, the off-diagonal shifts in the symmetric portion of the chemical shift tensor will affect the principal values under the transformations associated with matrix diagonalization. These new diagonal or principal value components will then project along $\mathbf{B}_{ref}$ and shift the resonance frequency. Antisymmetric shifts under rotational transformations can never contribute to a diagonal element, because of symmetry considerations, and therefore are not measured in the NMR frequency.

3.1.2 Transformations Between Different Cartesian Frames

The transformation of the symmetric portion of the Cartesian tensor from one reference frame (e.g., xyz frame) to another (e.g., XYZ frame) requires the following similarity transformation:

$$\delta(XYZ) = \mathbf{T}\delta(xyz)\mathbf{T}^{-1} \quad (12)$$

where the rotation matrix, $\mathbf{T}$, effects a rotational transformation, $\mathcal{R}(\alpha, \beta, \gamma)$, of the tensor from the xyz coordinate frame into the corresponding XYZ frame. The matrix, $\mathbf{T}$, may be expressed with the nine directional cosines relating the two

frames or with an equivalent matrix using the Euler angles, α , β , and γ , as follows:^{15,16}

$$\mathbf{T} = \begin{bmatrix} c_{Xx} & c_{Xy} & c_{Xz} \\ c_{Yx} & c_{Yy} & c_{Yz} \\ c_{Zx} & c_{Zy} & c_{Zz} \end{bmatrix} = \begin{bmatrix} (c_\alpha c_\beta c_\gamma - s_\alpha s_\gamma) & (s_\alpha c_\beta c_\gamma + c_\alpha s_\gamma) & (-s_\beta c_\gamma) \\ (-c_\alpha c_\beta s_\gamma - s_\alpha c_\gamma) & (-s_\alpha c_\beta s_\gamma + c_\alpha c_\gamma) & (s_\beta s_\gamma) \\ (c_\alpha s_\beta) & (s_\alpha s_\beta) & (c_\beta) \end{bmatrix} \quad (13)$$

The directional cosines, c_{Qq} , relate the two sets of Cartesian axes found in the alternative frames. The shortened notation, $c = \cos$ and $s = \sin$, has been utilized to conserve space in equation (13) and is applied with the three Euler angles, α , β , and γ . As $\mathbf{T}$ is a real unitary matrix, its inverse matrix in equation (12) is given by the transpose (i.e., $\mathbf{T}^{-1} = \mathbf{T}^t$).

Typical chemical shift reference frames used in tensor studies are shown in Figure 5 and the rotational transformations, $\mathcal{R}(\alpha, \beta, \gamma)$, that link these various frames. Successive rotations may be represented by a single rotation given by $\mathcal{R}(\alpha, \beta, \gamma) = \mathcal{R}(\alpha_m, \beta_m, \gamma_m) \times \mathcal{R}(\alpha_l, \beta_l, \gamma_l)$. Successive rotations also may be represented by nested similarity transformations as follows:

$$\begin{aligned} \delta_{\text{PAF}}(x_o, y_o, z_o) &= \mathbf{T}(\alpha_m, \beta_m, \gamma_m) \delta_{\text{mol}}(x_m, y_m, z_m) \\ &\quad \times \mathbf{T}^{-1}(\alpha_m, \beta_m, \gamma_m) \\ &= \mathbf{T}(\alpha_m, \beta_m, \gamma_m) \mathbf{T}(\alpha_s, \beta_s, \gamma_s) \delta_{\text{samp}}(x, y, z) \\ &\quad \times \mathbf{T}^{-1}(\alpha_s, \beta_s, \gamma_s) \mathbf{T}^{-1}(\alpha_m, \beta_m, \gamma_m) \end{aligned} \quad (14)$$

Consequently, there will always be a matrix $\mathbf{T}(\alpha, \beta, \gamma) = \mathbf{T}(\alpha_m, \beta_m, \gamma_m) \mathbf{T}(\alpha_s, \beta_s, \gamma_s)$ that will relate the experimental shift tensor, $\delta_{\text{samp}}(x, y, z)$, in the sample frame to the tensor, $\delta_{\text{PAF}}(x_o, y_o, z_o)$, in its own PAF. The $\mathbf{T}(\alpha, \beta, \gamma)$ matrix may be readily obtained using standard diagonalization routines from tensors measured in any reference frame; this is illustrated as follows for the sample frame tensor

$$\delta_{\text{PAF}}(x_o, y_o, z_o) = \mathbf{T}(\alpha, \beta, \gamma) \delta_{\text{samp}}(x, y, z) \mathbf{T}^{-1}(\alpha, \beta, \gamma) \quad (15)$$

Using the transformation in equation (15) along with a general expression for equations (6) and (7) provides the resonance frequency in matrix form as follows:

$$\begin{aligned} f_i &= \frac{\gamma_i}{2\pi} [I_{o,x} \ I_{o,y} \ I_{o,z}] \\ &\quad \times \begin{bmatrix} (1 + \delta_{xx}^{\text{PAF}}) & 0 & 0 \\ 0 & (1 + \delta_{yy}^{\text{PAF}}) & 0 \\ 0 & 0 & (1 + \delta_{zz}^{\text{PAF}}) \end{bmatrix} \\ &\quad \times \begin{bmatrix} B_{\text{ref},x} \\ B_{\text{ref},y} \\ B_{\text{ref},z} \end{bmatrix} \end{aligned} \quad (16)$$

Equation (16) may be simplified using the geometry exhibited in Figure 4 where $B_{\text{ref},x} = lB_{\text{ref}}$, $B_{\text{ref},y} = mB_{\text{ref}}$, and $B_{\text{ref},z} = nB_{\text{ref}}$. The respective directional cosines (i.e., l , m , and n) of the magnetic induction vector, $\mathbf{B}_{\text{ref}}$, are defined in the PAF relative to the corresponding x_o , y_o , and z_o axes. Likewise, $I_{o,x} = lI_o$, $I_{o,y} = mI_o$ and $I_{o,z} = nI_o$ as

Figure 5 Representative coordinate frames for the sample, laboratory, principal axis, and molecular frames. Rotational functions with their Euler angles are given with arrows linking the various frames

the total angular momentum, given by $\mathbf{I}_o$, also quantizes along $\mathbf{B}_{\text{ref}}$. The consequence of equation (16) is visualized in Figure 4 where $\mathbf{B}_i$ lies along $\mathbf{B}_{\text{ref}}$. The contributions to $\mathbf{B}_i$ from components perpendicular to $\mathbf{B}_{\text{ref}}$ are immeasurable, and the directional cosine form of equation (16) eliminates these perpendicular components from consideration. The measurable changes in $\mathbf{B}_i$ arise only from the projections of the shielding components along $\mathbf{B}_{\text{ref}}$ as indicated in Figure 4. Using the directional cosines in the expansion of equation (16) renders the resonance frequency as follows:

$$f_i = \frac{\gamma_i}{2\pi} I_o B_{\text{ref}} (1 + l^2 \delta_{xx}^{\text{PAF}} + m^2 \delta_{yy}^{\text{PAF}} + n^2 \delta_{zz}^{\text{PAF}}) \quad (17)$$

Note, the expression $l^2 + m^2 + n^2 = 1$ retains the simplicity of the Zeeman contribution. The spectral breakpoints observed in all of the solid powder patterns in Figure 2 correspond to the principal shift values (i.e., δ_{xx}^{PAF} , δ_{yy}^{PAF} , and δ_{zz}^{PAF}) found in equations (16) and (17). These equations contain the functional dependence of the PAF orientation necessary for analysis of spectral patterns associated with solid powder samples. The details of the powder analysis are found in Section 4.

In single crystal work, the chemical shift is tracked for various orientations of the magnetic field in the sample frame. These data are then transformed into either the frame of the unit cell or one of the molecular frames to determine the tensor's orientation in the molecule. Diffraction data provide the necessary structural relationships between the unit cell and various molecular frames. Tensors in any of these microscopic frames may be diagonalized to obtain the shift tensor in the PAF. In the process the molecular orientation of the PAF tensor is obtained. Thus, a variety of Cartesian sample frames are used in the process of measuring a shift tensor in a single crystal. The importance of such spatially correlated data, obtained from single crystals, will be discussed in Section 5. Before dealing explicitly with either powder or single crystal experiments, two alternative representations, the irreducible spherical tensor and the icosahedral representations, prove beneficial for different mathematical treatments of chemical shift tensor

data, and these are considered respectively in Sections 3.2 and 3.3.

3.2 Irreducible Spherical Representation of Chemical Shifts

Standard treatments^{17,18} of the chemical shift tensor have shown that the chemical shift Hamiltonian may be expressed as an expansion of spin and spatial irreducible spherical tensors as follows:

$$\begin{aligned}\hat{\mathcal{H}} &= h\hat{f}_i = \hbar\gamma_s\hat{\mathbf{I}}_o(i) \cdot (\mathbf{1} + \delta_i) \cdot \mathbf{B}_{\text{ref}} \\ &= \hbar\gamma_s \left[\hat{\mathbf{I}}_o(i)B_{\text{ref}} + \sum_{l,m} (-1)^m \hat{F}_m^{(l)}(i, b) \delta_{-m}^{(l)}(i) \right] \quad (18)\end{aligned}$$

The composite irreducible spin-field tensor components are given by $\hat{F}_m^{(l)}(i, b)$ and the chemical shift tensor components are given by $\delta^{(l)}_m$.

3.2.1 Combined Spin-Field Irreducible Spherical Tensors

The second-rank irreducible spherical form of the combined spin-field tensor is formed by coupling^{17,19} the first-rank angular momentum operators for a single spin with the first-rank magnetic field vector. The resulting combined irreducible spherical tensors are given as

$$\left. \begin{aligned}\hat{F}_0^{(0)}(i, b) &= -\frac{1}{\sqrt{3}} \left[\hat{I}_z b_z + \frac{1}{2}(\hat{I}_+ b_- + \hat{I}_- b_+) \right] \\ \hat{F}_0^{(1)}(i, b) &= \frac{1}{\sqrt{8}} [\hat{I}_+ b_- - \hat{I}_- b_+] \\ \hat{F}_{\pm 1}^{(1)}(i, b) &= -\frac{1}{2} [\hat{I}_z b_{\pm} - \hat{I}_{\pm} b_z] \\ \hat{F}_0^{(2)}(i, b) &= \sqrt{\frac{2}{3}} \left[\hat{I}_z b_z - \frac{1}{4}(\hat{I}_+ b_- + \hat{I}_- b_+) \right] \\ \hat{F}_{\pm 1}^{(2)}(i, b) &= \mp \frac{1}{2} [\hat{I}_{\pm} b_z + \hat{I}_z b_{\pm}] \\ \hat{F}_{\pm 2}^{(2)}(i, b) &= \frac{1}{2} \hat{I}_{\pm} b_{\pm}\end{aligned} \right\} \quad (19)$$

where $b_{\pm} = (l \pm im)B_{\text{ref}}$, $b_z = nB_{\text{ref}}$, and l , m , and n are the directional cosines between the magnetic field and the x , y , and z axes, respectively. Likewise, $\hat{I}_{\pm} = (l \pm im)\hat{\mathbf{I}}_o$ and $\hat{I}_z = n\hat{\mathbf{I}}_o$.

In the laboratory frame, the z axis is defined by the static magnetic field, $\mathbf{B}_{\text{ref}}$; thus, $n = 1$ and $l = m = 0$. Using these values for the appropriate directional cosines leaves $\hat{\mathbf{I}}_o$ quantized along the z axis, and with the quantization approximation the following combined spin-field irreducible spherical tensor components in the laboratory frame then become

$$\left. \begin{aligned}\hat{F}_0^{(0)}(i, b) &= -\frac{1}{\sqrt{3}} \hat{I}_z B_{\text{ref}}, & \hat{F}_0^{(1)}(i, b) &= 0, \\ \hat{F}_{\pm 1}^{(1)}(i, b) &= 0 \\ \hat{F}_0^{(2)}(i, b) &= \sqrt{\frac{2}{3}} \hat{I}_z B_{\text{ref}}, & \hat{F}_{\pm 1}^{(2)}(i, b) &= 0, \\ \hat{F}_{\pm 2}^{(2)}(i, b) &= 0\end{aligned} \right\} \quad (20)$$

3.2.2 Chemical Shift Irreducible Spherical Tensors

The irreducible spherical tensor representation, $\delta_m^{(l)}(xyz)$, for the chemical shift components are given in a generalized reference frame¹⁷ as follows:

$$\left. \begin{aligned}\delta_0^{(0)} &= -\sqrt{3}\delta_o = -\frac{1}{\sqrt{3}}(\delta_{xx} + \delta_{yy} + \delta_{zz}) \\ \delta_0^{(1)} &= -i\sqrt{2}\delta_{xy}^{(a)} = \frac{-i}{\sqrt{2}}(\delta_{xy} - \delta_{yx}) \\ \delta_{\pm 1}^{(1)} &= [\delta_{xz}^{(a)} \pm i\delta_{yz}^{(a)}] = \frac{1}{2}[(\delta_{xz} - \delta_{zx}) \pm i(\delta_{yz} - \delta_{zy})] \\ \delta_0^{(2)} &= \sqrt{\frac{2}{3}}[\delta_{zz}^{(s)} - \frac{1}{2}(\delta_{xx}^{(s)} + \delta_{yy}^{(s)})] \\ &= \sqrt{\frac{2}{3}}\left[\delta_{zz} - \frac{1}{2}(\delta_{xx} + \delta_{yy})\right] \\ &= \sqrt{\frac{3}{2}}[\delta_{zz} - \delta_o] \\ \delta_{\pm 1}^{(2)} &= \mp[\delta_{xz}^{(s)} \pm i\delta_{yz}^{(s)}] = \mp\frac{1}{2}[(\delta_{xz} + \delta_{zx}) \pm i(\delta_{yz} + \delta_{zy})] \\ \delta_{\pm 2}^{(2)} &= \left[\frac{1}{2}(\delta_{xx}^{(s)} - \delta_{yy}^{(s)}) \pm i\delta_{xy}^{(s)}\right] \\ &= \frac{1}{2}[(\delta_{xx} - \delta_{yy}) \pm i(\delta_{xy} + \delta_{yx})]\end{aligned} \right\} \quad (21)$$

As the zero-rank irreducible term $\delta_0^{(0)} = \sqrt{3}\delta_o$ contains only the isotropic chemical shift, it also is invariant under molecular tumbling. The first-rank terms $\delta_0^{(1)}(i)$ and $\delta_{\pm 1}^{(1)}(i)$ include only antisymmetric chemical shifts that are immeasurable in the frequency spectrum; they are not considered further. The remaining irreducible terms $\delta_0^{(2)}$, $\delta_{\pm 1}^{(2)}$, and $\delta_{\pm 2}^{(2)}$ are all second-rank symmetrical chemical shifts that can contribute to the measurable components of the tensor.

Equation (21) is simplified considerably in the PAF where off-diagonal elements are zero. The three persisting diagonal components contribute to $\delta_n^{(l)}(\text{PAF})$ as follows:

$$\left. \begin{aligned}\delta_0^{(2)}(\text{PAF}) &= \sqrt{\frac{2}{3}} \left[\delta_{zz}^{\text{PAF}} - \frac{1}{2}(\delta_{xx}^{\text{PAF}} + \delta_{yy}^{\text{PAF}}) \right] \\ &= \sqrt{\frac{3}{2}} [\delta_{zz}^{\text{PAF}} - \delta_o] \\ \delta_{\pm 1}^{(2)}(\text{PAF}) &= 0 \\ \delta_{\pm 2}^{(2)}(\text{PAF}) &= \frac{1}{2} [\delta_{xx}^{\text{PAF}} - \delta_{yy}^{\text{PAF}}]\end{aligned} \right\} \quad (22)$$

3.2.3 Resonance Frequency Expressions in the Irreducible Representation

In the laboratory frame equation (18) may be used with the combined spin-field irreducible tensor given in equation (20) along with the general irreducible spherical form of the chemical shift tensor in equation (21) to obtain the following expression:

$$\begin{aligned}\hat{f}_i &= \frac{\gamma}{2\pi} [\hat{I}_z B_{\text{ref}} + \hat{F}_0^{(0)}(i, b)\delta_0^{(0)}(i) + \hat{F}_0^{(2)}(i, b)\delta_0^{(2)}(i)] \\ &= \frac{\gamma}{2\pi} (1 + \delta_{zz}) \hat{I}_z B_{\text{ref}}\end{aligned} \quad (23)$$

It is not surprising that equations (23) and (10) are equivalent for the resonance frequency expressed in the laboratory

frame, but this simple exercise illustrates the application of equation (18).

In the case of the PAF, equation (18) utilizes equation (19) for the general spin-field irreducible tensor along with equation (22) for the chemical shift tensor in the PAF to yield the following expression:

$$\begin{aligned} \hat{f}_i &= \frac{\gamma}{2\pi} [\hat{I}_0 B_{\text{ref}} + \hat{F}_0^{(0)}(i, b) \delta_0^{(0)}(\text{PAF}) \\ &\quad + \hat{F}_0^{(2)}(i, b) \delta_0^{(2)}(\text{PAF}) + (\hat{F}_{+2}^{(2)}(i, b) \\ &\quad + \hat{F}_{-2}^{(2)}(i, b)) \delta_{\pm 2}^{(2)}(\text{PAF})] \\ &= \frac{\gamma_i}{2\pi} \hat{I}_0 B_{\text{ref}} (1 + l^2 \delta_{xx}^{\text{PAF}} + m^2 \delta_{yy}^{\text{PAF}} + n^2 \delta_{zz}^{\text{PAF}}) \end{aligned} \quad (24)$$

Once again, equation (24) gives an equivalent expression to equation (17) for the resonance frequency in the PAF and this procedure provides a second illustration for the use of equation (18). One advantage of irreducible spherical tensors is discussed in the next section dealing with their transformation properties.

3.2.4 Transformation Properties of Irreducible Spherical Tensors

The rotations associated with coordinate frame transformations, such as indicated in Figure 5, may be implemented readily for any tensor expressed in the irreducible spherical tensor representation. Wigner rotation matrices, $\mathcal{D}_{n,m}^{(l)}(\alpha, \beta, \gamma)$, may be used to convert the irreducible shift components from one frame to another in accordance with the standard formulations²⁰ given by

$$\delta_m^{(l)}(XYZ) = \sum_n \mathcal{D}_{n,m}^{(l)}(\alpha, \beta, \gamma) \delta_n^{(l)}(xyz) \quad (25)$$

where an explicit expression for the Wigner rotation matrix is given by

$$\mathcal{D}_{n,m}^{(l)}(\alpha, \beta, \gamma) = e^{-in\alpha} d_{n,m}^{(l)}(\beta) e^{-im\gamma} \quad (26)$$

and

$$\begin{aligned} d_{n,m}^{(l)} &= \sum_v \frac{(-1)^v \sqrt{(l+m)!(l-m)!(l+n)!(l-n)!}}{(l-n-v)!(l+m-v)!(v+m-n)!v!} \\ &\quad \times \left(\cos \frac{\beta}{2} \right)^{2l+m-n-2v} \left(\sin \frac{\beta}{2} \right)^{n-m+2v} \end{aligned} \quad (27)$$

The index v sums over all terms for which the factorial arguments are nonvanishing. It is actually the linear feature of equation (25) that empowers the Wigner rotation matrices in problems of this type and makes the irreducible spherical tensors so useful in mathematical developments of chemical shift expressions. The α , β , and γ Euler angles associated with the similarity transformations are the same as used in equation (13). The process is illustrated by transforming the irreducible

spherical components from the PAF into irreducible spherical components in a generalized Cartesian frame as follows:

$$\left. \begin{aligned} \delta_0^{(2)} &= \mathcal{D}_{0,0}^{(2)}(\alpha, \beta, \gamma) \delta_0^{(2)}(\text{PAF}) \\ &\quad + [\mathcal{D}_{2,0}^{(2)}(\alpha, \beta, \gamma) + \mathcal{D}_{-2,0}^{(2)}(\alpha, \beta, \gamma)] \delta_2^{(2)}(\text{PAF}) \\ \delta_{\pm 1}^{(2)} &= \mathcal{D}_{0,\pm 1}^{(2)}(\alpha, \beta, \gamma) \delta_0^{(2)}(\text{PAF}) \\ &\quad + [\mathcal{D}_{2,\pm 1}^{(2)}(\alpha, \beta, \gamma) + \mathcal{D}_{-2,\pm 1}^{(2)}(\alpha, \beta, \gamma)] \delta_2^{(2)}(\text{PAF}) \\ \delta_{\pm 2}^{(2)} &= \mathcal{D}_{0,\pm 2}^{(2)}(\alpha, \beta, \gamma) \delta_0^{(2)}(\text{PAF}) \\ &\quad + [\mathcal{D}_{2,\pm 2}^{(2)}(\alpha, \beta, \gamma) + \mathcal{D}_{-2,\pm 2}^{(2)}(\alpha, \beta, \gamma)] \delta_2^{(2)}(\text{PAF}) \end{aligned} \right\} \quad (28)$$

3.3 Icosahedral Representation of the Chemical Shift Tensor

There arises a dilemma in comparing two tensors when they are described solely by their three principal shift values. The common practice of reporting chemical shift anisotropies using only the principal values while neglecting the three orientational Euler angles, α , β , γ , given in equation (13), prevents one from determining whether two tensors are identical or merely congruent. Two tensors are considered to be identical only if the three principal values and the spatial orientations of their three principal axes agree completely. Two tensors are congruent if they have the same set of principal values but the orientations of the principal shift axes differ, a situation commonly encountered for symmetry-related molecules in the unit cell of a single crystal. Therefore, the comparison of two sets of principal values may at most indicate whether two tensors are congruent, but the information is insufficient to indicate whether the tensors are identical.

Symmetrical Cartesian shift tensors with three diagonal and three off-diagonal components contain sufficient elements for the tensor to be described completely. Similarly, three principal values and three orientational Euler angles also provide six independent quantities for fully designating a chemical shift tensor. However, comparison of two different tensors described with such mixed parameters (e.g. shift values and orientational parameters) is complicated by the necessity of relating different types of parameters, and the statistical comparison of such tensors²¹ requires complex weighting metrics.

An icosahedral representation²² of the chemical shift tensor has been proposed that employs six parameters all of the same type and has a simple metric to specify the statistical weighting factors. This representation consists of six shift components that are obtained when the magnetic field is placed along the six unique directions associated with the 12 vertices (i.e., the six diagonal pairs) of an icosahedron. The geometrical construct in Figure 6 shows the relationships between a given Cartesian frame and the corresponding icosahedron oriented in this frame. The six icosahedral directions shown in Figure 6 are numbered with single Arabic numerals and the relationship of these values to the Cartesian tensor components is given by

$$\left. \begin{aligned} \delta_1 &= a^2 \delta_{xx} + b^2 \delta_{yy} - 2ab \delta_{xy}, \quad \delta_2 = a^2 \delta_{xx} + b^2 \delta_{yy} + 2ab \delta_{xy} \\ \delta_3 &= a^2 \delta_{yy} + b^2 \delta_{zz} - 2ab \delta_{yz}, \quad \delta_4 = a^2 \delta_{yy} + b^2 \delta_{zz} + 2ab \delta_{yz} \\ \delta_5 &= a^2 \delta_{zz} + b^2 \delta_{xx} - 2ab \delta_{zx}, \quad \delta_6 = a^2 \delta_{zz} + b^2 \delta_{xx} + 2ab \delta_{zx} \end{aligned} \right\} \quad (29)$$

The geometrical constants $a = \cos(\phi/2) = 0.8507$ and $b = \sin(\phi/2) = 0.5257$ relate the shift directions to the structure of the

Figure 6 (a) Geometrical relationships of the six icosahedral directions to the Cartesian frame. (b) The six directions are identified with the 12 icosahedral vertices

icosahedron. The icosahedral angle, ϕ ($= 63.44^\circ$), subtends the two vectors drawn from the center of the icosahedron to two adjacent icosahedral vertices.

The icosahedral representation enjoys the advantage that all six components have the same metric represented by a unit matrix, allowing a statistical comparison of two tensors to be undertaken on the same basis with equal weighting coefficients. Further, no scaling problems are encountered as the coordinate system is transformed between various chemical shift reference frames (e.g., sample, laboratory, unit cell, molecular, or principal axes frames), and the rather complicated phase factors and normalization constants found in the irreducible spherical tensors are avoided. Finally, the individual shifts in the icosahedral representation are orthogonal and linear regression methods execute optimally in this representation.

As any one vertex is equidistant from the remaining five unique icosahedral directions in this geometry, the six directions are arrayed with a maximum angular separation from each other. Consequently, the icosahedral representation optimizes the sensitivity with which a tensor can be specified with six numbers. It is anticipated that future single crystal probes will be constructed with orientational mechanisms that exploit this optimal sensitivity associated with the icosahedral symmetry. A relative figure of merit for assessing sensitivity has been reported for a variety of measurement devices,²² and the icosahedral device has the highest sensitivity for cataloging minor deviations in shift tensor data.

3.4 Conventions for Reporting Chemical Shift Tensors

The relatively large number of coordinate frames and representations used for measuring chemical shift tensors has resulted in several chemical shift conventions for describing these tensors. This diversity of conventions, and some inconsistencies in their use, have led at times to ambiguity in reporting chemical shift tensors. Such complexities, however, may always be avoided if a full, six-parameter tensor in any representation is reported along with a molecular drawing that clearly designates the orientation of the x , y , and z reference frame. Most assignment ambiguities have been created whenever principal shift values obtained from powder spectra are reported without orientational details and without properly designated sign conventions. Three accepted conventions for reporting principal shift values are discussed

below. The first involves a frequency ordered set of principal values, rank ordered from high to low frequencies, and the remaining two focus more on specific aspects of the tensor's symmetry and are cast in forms related to irreducible spherical tensor components.

3.4.1 Frequency Ordered Principal Shift Values, δ_{11} , δ_{22} , and δ_{33}

The simplest convention, and one that avoids confusion in discussing the three principal shifts, employs frequency ordered shifts. This convention prescribes that the principal shifts be designated as $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with the frequency ordering from high to low shifts specified with Arabic numerals as indicated. These symbols were used for the two asymmetric spectra depicted in Figures 2(c) and (d). The principal values lie along three perpendicular directions in space, but no attempt is made to identify the three shifts with specific x , y , and z directions in the PAF. Only if the tensor's orientation is specifically required in a molecular reference frame is there any need for more information than contained in this set of frequency ordered values.

The motivation for using conventions more complicated than the frequency ordered set of shifts is related to the symmetry of shift tensors and to the common practice of reporting isotropic shifts, similar to those found in liquids. The isotropic shift, contained in the zero-rank component of equation (11) requires two additional second-rank components to characterize the three principal elements on the diagonal of a shift tensor. These symmetrized conventions are strongly influenced by the form of the irreducible spherical tensors.

3.4.2 The Anisotropy, ζ , and Asymmetry, η , Parameters

In the PAF, the chemical shift anisotropy, ζ , and the chemical shift asymmetry, η , parameters along with the isotropic shift, δ_o , are defined for the chemical shift tensor as follows:

$$\left. \begin{aligned} \delta_o &= \frac{1}{3}(\delta_{xx} + \delta_{yy} + \delta_{zz}) \\ \zeta &= \delta_{zz} - \frac{1}{2}(\delta_{xx} + \delta_{yy}) = \frac{3}{2}(\delta_{zz} - \delta_o) \\ \eta &= \frac{(\delta_{xx} - \delta_{yy})}{(\delta_{zz} - \delta_o)} = \frac{3(\delta_{xx} - \delta_{yy})}{2\zeta} \end{aligned} \right\} \quad (30)$$

These parameters relate to the irreducible spherical representations given in equation (22). The z axis in the irreducible spherical basis is designated as the $m = 0$ projection, and this convention prescribes that the unique principal frequency in an axial tensor be assigned to the z axis in order to capitalize on the cylindrical symmetry found in the $\delta_0^{(2)}$ component of an irreducible spherical tensor. Thus, the ζ and η convention places the z direction along the unique tensor axis (i.e., $\delta_{zz} = \delta_{||}$) in the axial tensors shown in Figures 2(a) and (b), with $\delta_{zz} = \delta_{11}$ for the prolate axial tensors and $\delta_{zz} = \delta_{33}$ for the oblate case, respectively. The remaining degenerate axial components are given by $\delta_{\perp} = \delta_{xx} = \delta_{yy}$ in both cases. For the axial case, the anisotropy is given by $\zeta = \delta_{||} - \delta_{\perp}$ and $\eta = 0$, with ζ positive for a prolate axial tensor and negative for an oblate axial tensor.

In asymmetric shift tensors, the assignment of the x , y , and z axes to the three principal values uses the convention^{23,24} that the x component is assigned to δ_{22} and the shift furthest

removed from δ_{22} is designated as δ_{zz} in a manner consistent with the axially symmetric case. This leaves δ_{yy} assigned to the component at the other extreme. For Figure 2(d) where $(\delta_{11} - \delta_{22}) > (\delta_{22} - \delta_{33})$, δ_{zz} is assigned to the δ_{11} shift; $\delta_{yy} = \delta_{33}$ and $\delta_{xx} = \delta_{22}$. Thus, the tensor's anisotropy, ζ , is a positive quantity for the pattern in Figure 2(d) using the definitions in equation (30). The asymmetry parameter, η , as defined in equation (30) is also a positive quantity because of the frequency order associated with the δ_{xx} and δ_{yy} labels. Conversely, if $(\delta_{11} - \delta_{22}) < (\delta_{22} - \delta_{33})$ then δ_{zz} is assigned to δ_{33} , $\delta_{yy} = \delta_{11}$ and $\delta_{xx} = \delta_{22}$. The value for ζ is now negative but η still retains its positive sign because the reversal in the order of the δ_{xx} and δ_{yy} designations compensates for the negative ζ value. As δ_{22} moves from one side of the pattern's midpoint to the opposite side, the sign of ζ changes in this convention.

Probably no better example exists to illustrate one of the awkward features confronting the ζ and η convention than the case of the centrosymmetric tensor given in Figure 2(c). Here, the selection of either $\delta_{zz} = \delta_{11}$ or $\delta_{zz} = \delta_{33}$ both comply with the convention as δ_{22} is equidistant from both δ_{11} and δ_{33} , but the sign of ζ changes with the two alternative choices even though the magnitudes of ζ and η are not altered. The centrosymmetric tensor is recognized in this convention when $\eta = 1$. This convention also suffers by not providing a readily recognized value for the overall spectral width, i.e., $(\delta_{11} - \delta_{33})$.

The indiscriminate use of anisotropy and asymmetry parameters with both nuclear shieldings, σ_i , and the chemical shift, δ_i , along with the change of signs in equation (3) has also seriously aggravated the usage of ζ and η . Some literature reports fail to indicate clearly whether the data are given in shift or shielding values, and this uncertainty leaves the sign of the anisotropy ambiguous. As most experimental shift data are now reported in frequency units, only shift parameters should be used in the definition of ζ and η unless otherwise clearly stated.

3.4.3 The Span, Ω , and Skew, κ , Chemical Shift Parameters

A recent convention²⁵ for principal shifts has been proposed that uses the following relationships:

$$\begin{aligned}\delta_o &= \frac{1}{3}(\delta_{11} + \delta_{22} + \delta_{33}), \quad \Omega = \delta_{11} - \delta_{33}, \\ \kappa &= \frac{2\delta_{22} - (\delta_{11} + \delta_{33})}{(\delta_{11} - \delta_{33})}\end{aligned}\quad (31)$$

The isotropic shift is the same, the chemical shift span, Ω , measures the powder pattern's width and the chemical shift skew, κ , measures the tensor's deviation from centrosymmetry. The skew is bounded by -1 for a prolate axial tensor, i.e., $\delta_{22} = \delta_{33}$ and by $+1$ for an oblate axial tensor, i.e., $\delta_{22} = \delta_{11}$. The simplicity of this convention is derived from use of frequency ordered principal shift values rather than Cartesian labels that vary when δ_{22} is either greater or less than δ_o . This convention leaves one free to select the spatial labels, i.e., xyz , to serve other purposes in the mathematical manipulation or spatial visualization of shift tensors. The centrosymmetric case, which posed a dilemma for the previous convention, is characterized by $\kappa = 0$, and the change of κ is continuous and smooth as δ_{22} moves from above to below δ_o . This span and

skew convention avoids switching the label of δ_{zz} between δ_{11} and δ_{33} and claims to be both simpler and easy to remember.

The form of equations (22) and (31) suggests the use of $\delta_{xx} = \delta_{11}$, $\delta_{yy} = \delta_{33}$, and $\delta_{zz} = \delta_{22}$ for forming irreducible spherical tensor quantities, thereby making $\Omega = (\delta_{11} - \delta_{33}) = 2\delta_{\pm 2}^{(2)}$ and $\Omega\kappa = \delta_{22} - \frac{1}{2}(\delta_{11} + \delta_{33}) = \sqrt{\frac{2}{3}}\delta_0^{(2)}$. This somewhat nontraditional use for $\delta_{\pm 2}^{(2)}$ and $\delta_0^{(2)}$ still leaves in place the full benefits of the irreducible spherical tensor machinery.

4 TENSOR POWDER PATTERNS IN SOLIDS

4.1 Conformal Mapping of Principal Tensor Shifts onto Frequency Patterns

The extraction of tensor principal values from powder patterns was first discussed by Bloembergen and Rowland.¹³ Using their approach, expressions describing spectral powder patterns may be obtained by conformal mapping of the chemical shift tensor, given in its own PAF, onto the frequency coordinate of a powder spectrum. Rearranging equation (17) yields the following expression in frequency space:

$$f_i = f_{xx} \sin^2 \theta \cos^2 \phi + f_{yy} \sin^2 \theta \sin^2 \phi + f_{zz} \cos^2 \theta \quad (32)$$

where the directional cosines in polar angles are $l = \sin \theta \cos \phi$, $m = \sin \theta \sin \phi$, and $n = \cos \theta$. The three principal frequency values, $f_{qq} = (\gamma_i/2\pi) I_o B_{\text{ref}}(1 + \delta_{qq})$, for $q = x, y, z$ characterize the chemical shift tensor in its PAF.

Using conformal mapping procedures, the relationship between the integrated NMR signal, S , in the Cartesian space of the PAF and in the frequency space of the spectrum is given by

$$S = \int I(f_i) df_i \int_0^1 dg = 8 \int_0^{\pi/2} \int_0^{\pi/2} P(\theta, \phi) \sin \theta d\theta d\phi \quad (33)$$

where $I(f_i)$ is the intensity of the spectral band at the frequency f_i , and $P(\theta, \phi)$ is the probability that the magnetic field lies along the (θ, ϕ) direction in the PAF of the chemical shift tensor. The completion integral in dg , with a value of unity, is required to make the dimensionality of the frequency space correspond to the dimensionality of the tensor expressions in polar angles. This integral over g maps onto a line integral in the tensor space corresponding to a constant spectral frequency. The factor of 8 on the right-hand side of equation (33) converts the PAF octant integral to a complete spherical integral. The term $P(\theta, \phi)$ is a constant for all directions in a randomly oriented powder sample; its normalized value is given by

$$S = 8 \int_0^{\pi/2} \int_0^{\pi/2} P(\theta, \phi) \sin \theta d\theta d\phi = 1 \quad (34)$$

and therefore

$$P(\theta, \phi) = \frac{1}{8 \int_0^{\pi/2} \int_0^{\pi/2} \sin \theta d\theta d\phi} = \frac{1}{4\pi} \quad (35)$$

A Jacobian, $J\{f_i, g | \theta, \phi\}$, is now used to convert the differentials on the right-hand side of equation (33) into frequency space as follows:

$$d\theta d\phi = \frac{df_i dg}{J\{f_i, g | \theta, \phi\}} \quad (36)$$

where

$$J\{f_i, g | \theta, \phi\} = \begin{vmatrix} \frac{\partial f_i}{\partial \theta} & \frac{\partial f_i}{\partial \phi} \\ \frac{\partial g}{\partial \theta} & \frac{\partial g}{\partial \phi} \end{vmatrix} = \left(\frac{\partial f_i}{\partial \theta} \right) \left(\frac{\partial g}{\partial \phi} \right) - \left(\frac{\partial f_i}{\partial \phi} \right) \left(\frac{\partial g}{\partial \theta} \right) \quad (37)$$

Substituting equations (35) and (36) into equation (33) yields

$$\int I(f_i) df_i \int_0^1 dg = \frac{2}{\pi} \int_{g_1}^{g_2} \frac{\sin \theta dg df_i}{J\{f_i, g | \theta, \phi\}} \quad (38)$$

and extraction of $I(f_i)$ from the integral over f_i gives

$$I(f_i) = \frac{2}{\pi} \int_{g_1}^{g_2} \frac{\sin \theta dg}{J\{f_i, g | \theta, \phi\}} \quad (39)$$

The derivation of an expression for $I(f_i)$ has thus been reduced to finding a function, g , which defines the line integral of constant resonance frequency in tensor space. It also involves solving for $\sin \theta$ and the Jacobian $J\{f_i, g | \theta, \phi\}$ in terms of f_i and g , and finally scaling the expression for g such that the limits for g_1 and g_2 are 0 and 1, respectively. The details of this procedure differ for axially symmetric and asymmetric tensors and the two cases are now treated separately.

4.2 Analytical Expressions for Powder Patterns

4.2.1 Axially Symmetric Tensors

Equation (32) in the axially symmetric limit becomes

$$f_i = f_{\perp} \sin^2 \theta + f_{\parallel} \cos^2 \theta = f_{\perp} - (f_{\perp} - f_{\parallel}) \cos^2 \theta \quad (40)$$

where $f_{\perp} = f_{xx} = f_{yy}$ and $f_{\parallel} = f_{zz}$. Differentiating, equation (40) yields

$$\frac{\partial f_i}{\partial \theta} = 2(f_{\perp} - f_{\parallel}) \cos \theta \sin \theta, \quad \frac{\partial f_i}{\partial \phi} = 0 \quad (41)$$

As f_i is dependent only upon the polar angle θ and not ϕ , it may be shown by inspection that the constant frequency condition required for g , properly scaled to give the correct integral limits, yields the following expression for g :

$$g = \frac{2}{\pi} \phi \quad (42)$$

and

$$\frac{\partial g_i}{\partial \theta} = 0, \quad \frac{\partial g_i}{\partial \phi} = \frac{2}{\pi} \quad (43)$$

Figure 7 The ellipsoidal representation of an axial tensor in its PAF has the principal or parallel axis along the z axis and the two perpendicular principal components in the xy plane. The constant frequency path in this portrayal is indicated by f_a

Equation (42) defines the line integral in tensor space required by equation (39) for the intensity at the frequency f_i . This line integral's relationship to the tensor's orientation is illustrated graphically in Figure 7 for a prolate axially symmetric tensor. Note, the limits of 0 and $\pi/2$ for ϕ yield the values of 0 and 1 for g_1 and g_2 , respectively. Using equations (37), (41), and (43), the Jacobian is evaluated as

$$J\{f_i, g | \theta, \phi\} = \begin{vmatrix} 2(f_{\perp} - f_{\parallel}) \sin \theta \cos \theta & 0 \\ 0 & 2/\pi \end{vmatrix} = \frac{4}{\pi} (f_{\perp} - f_{\parallel}) \sin \theta \cos \theta \quad (44)$$

Rearranging equation (40) yields

$$\cos \theta = \sqrt{\frac{f_{\perp} - f_i}{f_{\perp} - f_{\parallel}}} \quad (45)$$

Substituting equations (44) and (45) into equation (39) for $I(f_i)$ gives the following:

$$I(f_i) = \frac{1}{2(f_{\perp} - f_{\parallel})} \sqrt{\frac{f_{\perp} - f_{\parallel}}{f_{\perp} - f_i}} \int_0^1 dg = \frac{1}{2\sqrt{(f_{\perp} - f_{\parallel})(f_{\perp} - f_i)}} \quad (46)$$

This equation applies to the range between $f_{\parallel}$ and $f_{\perp}$ but excludes the singular point at $f_i = f_{\perp}$. Outside the range from $f_{\parallel}$ to $f_{\perp}$ the spectral intensity is zero. When properly convoluted with a line-broadening function, equation (46) describes the axially symmetric patterns shown in Figures 2(a) and (b). The unique or parallel tensor value in axially symmetric tensor bands is at the lower intensity

Figure 8 The ellipsoidal representation of a general asymmetric tensor has the f_{11} , f_{22} , and f_{33} principal components placed along the x , z , and y axes, respectively. The constant frequency paths in region a ($f_{11} > f_a > f_{22}$) and region b ($f_{22} > f_b > f_{33}$) are indicated, respectively, by f_a and f_b . The constant f_{22} frequency path at the singular point is at $\phi = \alpha$

breakpoint, while the degenerate perpendicular values are at the breakpoint of higher intensity.

4.2.2 Asymmetric Tensors

Equation (32) provides an expression for f_i in terms of the asymmetric tensor's principal shift values as follows:

$$f_i = f_{11} \sin^2 \theta \cos^2 \phi + f_{33} \sin^2 \theta \sin^2 \phi + f_{22} \cos^2 \theta \quad (47)$$

where f_{11} and f_{33} correspond, respectively, to the f_{xx} and f_{yy} principal shift values given in equation (32), and f_{22} is identified with f_{zz} as indicated in Figure 8. Note, the constant frequency path for $f_i = f_{22}$ is given by $\phi = \alpha$. The derivatives required in the Jacobian for f_i relative to θ and ϕ are

$$\left. \begin{aligned} \frac{\partial f_i}{\partial \theta} &= 2(f_{11} \cos^2 \phi + f_{33} \sin^2 \phi - f_{22}) \cos \theta \sin \theta \\ \frac{\partial f_i}{\partial \phi} &= -2 \sin^2 \theta \cos \phi \sin \phi (f_{11} - f_{33}) \end{aligned} \right\} \quad (48)$$

An appropriate function for g , required in the conformal mapping of the shifts in tensor and frequency space, may be expressed as

$$g_a = \frac{\cos \theta}{\cos \theta_a}, \quad g_b = \frac{\cos \theta}{\cos \theta_b} \quad (49)$$

These two line integrals may be visualized in Figure 8 for the two constant frequency functions, f_a and f_b . Spectral region a spans the frequencies between f_{11} and f_{22} and region b between f_{22} and f_{33} . The expressions for $\cos \theta_a$ and $\cos \theta_b$

in equation (49) are obtained from equation (47) using the boundary conditions exhibited in Figure 8 for the constant frequency values f_a and f_b as follows:

$$\left. \begin{aligned} f_a &= f_i(\theta_a, 0) = f_{11} \sin^2 \theta_a + f_{22} \cos^2 \theta_a \\ &= f_{11} - (f_{11} - f_{22}) \cos^2 \theta_a \\ f_b &= f_i(\theta_b, \pi/2) = f_{33} \sin^2 \theta_b + f_{22} \cos^2 \theta_b \\ &= f_{33} + (f_{22} - f_{33}) \cos^2 \theta_b \end{aligned} \right\} \quad (50)$$

Solving for $\cos \theta_a$ and $\cos \theta_b$ in equation (50) yields

$$\cos \theta_a = \sqrt{\frac{f_{11} - f_a}{f_{11} - f_{22}}}, \quad \cos \theta_b = \sqrt{\frac{f_b - f_{33}}{f_{22} - f_{33}}} \quad (51)$$

Thus

$$g_a = \cos \theta \sqrt{\frac{f_{11} - f_{22}}{f_{11} - f_a}}, \quad g_b = \cos \theta \sqrt{\frac{f_{22} - f_{33}}{f_b - f_{33}}} \quad (52)$$

The angular derivatives of g needed in the Jacobian now become

$$\left. \begin{aligned} \frac{\partial g_a}{\partial \theta} &= -\sin \theta \sqrt{\frac{f_{11} - f_{22}}{f_{11} - f_a}} \\ \frac{\partial g_b}{\partial \theta} &= -\sin \theta \sqrt{\frac{f_{22} - f_{33}}{f_b - f_{33}}} \\ \frac{\partial g_a}{\partial \phi} &= \frac{\partial g_b}{\partial \phi} = 0 \end{aligned} \right\} \quad (53)$$

Substituting equations (48) and (53) into equation (37) provides the asymmetric tensor expression for the Jacobians in the two spectral regions as follows:

$$\left. \begin{aligned} J\{f_a, g_a | \theta, \phi\} &= -2 \sin^3 \theta \sin \phi \cos \phi (f_{11} - f_{33}) \sqrt{\frac{f_{11} - f_{22}}{f_{11} - f_a}} \\ J\{f_b, g_b | \theta, \phi\} &= -2 \sin^3 \theta \sin \phi \cos \phi (f_{11} - f_{33}) \sqrt{\frac{f_{22} - f_{33}}{f_b - f_{33}}} \end{aligned} \right\} \quad (54)$$

Substitution of equation (54) into equation (39) yields the following expressions for the band intensity for regions a and b, respectively:

$$\left. \begin{aligned} I(f_a) &= -\frac{2}{\pi} \int_{g_1}^{g_2} \frac{\sin \theta dg}{2 \sin^3 \theta \sin \phi \cos \phi (f_{11} - f_{33}) \sqrt{\frac{f_{11} - f_{22}}{f_{11} - f_a}}} \\ I(f_b) &= -\frac{2}{\pi} \int_{g_1}^{g_2} \frac{\sin \theta dg}{2 \sin^3 \theta \sin \phi \cos \phi (f_{11} - f_{33}) \sqrt{\frac{f_{22} - f_{33}}{f_b - f_{33}}}} \end{aligned} \right\} \quad (55)$$

The dependence of the band intensity upon polar angles must now be converted into the frequency functions, f_i and g_i . This is done by rearranging equation (47) and using standard trigonometric identities to give

$$\left. \begin{aligned} \sin^2 \theta \cos^2 \phi (f_{11} - f_{33}) &= (f_i - f_{33}) - (f_{22} - f_{33}) \cos^2 \theta \\ \sin^2 \theta \sin^2 \phi (f_{11} - f_{33}) &= (f_{11} - f_i) - (f_{11} - f_{22}) \cos^2 \theta \end{aligned} \right\} \quad (56)$$

The square root of the product of the two expressions in equation (56) yields the following:

$$\frac{\sin^2 \theta \cos \phi \sin \phi (f_{11} - f_{33})}{\sqrt{[(f_i - f_{33}) - (f_{22} - f_{33}) \cos^2 \theta][(f_{11} - f_i) - (f_{11} - f_{22}) \cos^2 \theta]}} \quad (57)$$

To complete the derivation of the band intensity for the asymmetric tensor, the limits of the integrals are evaluated using the boundary conditions indicated in Figure 8. With equation (49) these limits for both regions a and b are the same, i.e., $g_1 = 1$ and $g_2 = 0$. The minus sign in equation (55) may be removed, with further benefit, by reversing the integration limits. Substituting equation (57) into equation (55) and introducing the appropriate a and b labels for the i th label in equation (57) yield the following expressions:

$$\left. \begin{aligned} I(f_a) &= \frac{1}{\pi} \int_0^1 \frac{dg_a}{\sqrt{(f_{11} - f_{22})(f_a - f_{33}) \left[1 - \frac{(f_{22} - f_{33})}{(f_a - f_{33})} \cos^2 \theta\right] \left[1 - \frac{(f_{11} - f_{22})}{(f_{11} - f_a)} \cos^2 \theta\right]}} \\ I(f_b) &= \frac{1}{\pi} \int_0^1 \frac{dg_b}{\sqrt{(f_{11} - f_b)(f_{22} - f_{33}) \left[1 - \frac{(f_{22} - f_{33})}{(f_b - f_{33})} \cos^2 \theta\right] \left[1 - \frac{(f_{11} - f_{22})}{(f_{11} - f_b)} \cos^2 \theta\right]}} \end{aligned} \right\} \quad (58)$$

Using equation (52) to simplify equation (58) one obtains

$$\left. \begin{aligned} I(f_a) &= \frac{1}{\pi \sqrt{(f_{11} - f_{22})(f_a - f_{33})}} \\ &\times \int_0^1 \frac{dg_a}{\sqrt{(1 - m_a g_a^2)(1 - g_a^2)}} \\ I(f_b) &= \frac{1}{\pi \sqrt{(f_{11} - f_b)(f_{22} - f_{33})}} \\ &\times \int_0^1 \frac{dg_b}{\sqrt{(1 - g_b^2)(1 - m_b g_b^2)}} \end{aligned} \right\} \quad (59)$$

where the values for m_a and m_b are given as

$$\begin{aligned} m_a &= \frac{(f_{11} - f_a)(f_{22} - f_{33})}{(f_a - f_{33})(f_{11} - f_{22})} \text{ and} \\ m_b &= \frac{(f_{11} - f_{22})(f_b - f_{33})}{(f_{11} - f_b)(f_{22} - f_{33})} \end{aligned} \quad (60)$$

The integrals found in equation (59) are complete elliptic integrals of the first kind and have a solution that is readily calculated on a computer with the following power series in m_a or m_b :

$$\begin{aligned} &\int_0^1 \frac{dg_i}{\sqrt{(1 - m_i g_i^2)(1 - g_i^2)}} \\ &= \frac{\pi}{2} \left[1 + \left(\frac{1}{2}\right)^2 m_i^2 + \left(\frac{3}{2 \times 4}\right)^2 m_i^4 \right. \\ &\quad \left. + \left(\frac{3 \times 5}{2 \times 4 \times 6}\right)^2 m_i^6 + \dots \right] \end{aligned} \quad (61)$$

4.3 Line Broadening in Spectral Powder Patterns

The calculated powder pattern described by equation (59) must be convoluted with a line-broadening function, either of

a Lorentzian or Gaussian variety, to provide for the effect of transverse relaxation. Powder patterns of the type shown in Figures 2(c) and (d) include Lorentzian broadening. In the author's laboratory an equivalent numerical method, referred to as POWDER,²⁶ has been found to be numerically efficient for simulating such powder patterns and is especially useful in SIMPLEX fitting of multiple tensor powder patterns. In 1D powder patterns, one may seldom extract the tensor information from more than two or three overlapping ^{13}C bands if they cover wide spectral ranges. Thus, chemical shift tensors, with their highly unique spatial information, have eluded study in solid powders except for simple compounds where overlapping powder patterns can be isolated and analyzed for their principal shift values.

4.4 Resolution of Tensor Powder Patterns using 2D Spectral Methods

In recent years several 2D spectral methods have been proposed to portray powder spectra such that the principal shift values may be acquired for compounds on more than the two or three different nuclei achieved in 1D powder spectra. These include a 2D magic angle hopping experiment²⁷ and several modifications of the 2D magic angle slow turning experiment^{28,29} (see J. Z. Hu et al. *Magic Angle Turning and Hopping*) that slowly rotates the sample about the magic angle to obtain the isotropic shift in the evolution dimension. Also, a variety of 2D powder correlation experiments involving a mechanical flipping mechanism have been used to measure chemical shift tensors, especially in polymers.^{30,31} These 2D powder methods reorient the sample during the mixing period between the evolution and detection periods. By spreading the spectral data into 2D, improved resolution is achieved for analyzing overlapping bands.

All powder spectral methods provide only shift values in the tensor's PAF, and information on the orientation of the tensor within the molecular or unit cell frames remains unavailable. Principal shift data obtained from powder samples contain up to three times more information than that found in isotropic liquid shifts, but these data are still deficient without information on the tensor's orientation in the molecular frame. A powder approach for determining ^{13}C tensor orientations involves the coupling of a dipole-dipole interaction with the shift tensor to provide the tensor's orientation.^{32,33} This approach involves the analysis of composite dipolar-shift spectral patterns that arise from both the Pake dipolar splittings and the chemical shift tensor to give the orientation of the dipole-dipole vector within the PAF.

5 CHEMICAL SHIFT TENSORS FROM SINGLE CRYSTALS

5.1 Expressions for Chemical Shift Tensors in the Sample Frame

Chemical shift studies of single crystals provide both the principal tensor values and the orientations of their PAF in the sample frame. This complete tensor description involves six parameters which normally contain at least twice the information obtained from a powder pattern and up to six times the information found in the isotropic shift of a single liquid peak. The chemical shift expressions given in equations (9) and (32), and the experiments to which they relate, fail to provide for the orientation of the shift tensor in the sample frame and, therefore, have no way for delineating the orientation of tensors in their molecular frames. Thus, to describe a full chemical shift tensor, mathematical expressions are needed that correlate the resonance frequency with the orientation of the single crystal. Spatially correlated information in the sample frame allows the tensor's orientation to be projected onto one of the crystal's microscopic frames, such as the unit cell frame or the various frames at the molecular level. Because unit cells with two or more congruent molecules contain redundant shift information, the symmetry elements that take congruent tensors into one another usually identify the transformations that will convert the sample frame NMR data into the frame of the crystal's unit cell. Diffraction data may then be used to establish the structural relationships that exist between coordinates in the unit cell and the molecular frames.

The orientation of the magnetic field in a crystal's sample frame may be described by the directional cosines, l_S , m_S and n_S . In this sample frame, equations (6) and (7) become

$$f_i = \frac{\gamma_i}{2\pi} I_0 B_{\text{ref}} [l_S \ m_S \ n_S] \times \begin{bmatrix} (1 + \delta_{xx}) & \delta_{xy} & \delta_{xz} \\ \delta_{xy} & (1 + \delta_{yy}) & \delta_{yz} \\ \delta_{xz} & \delta_{yz} & (1 + \delta_{zz}) \end{bmatrix} \begin{bmatrix} l_S \\ m_S \\ n_S \end{bmatrix} \quad (62)$$

Equation (62) is of the same form as equation (17), deviating only in the use of a full matrix representation for the shift tensor in a non-PAF. Expansion of the matrix in equation (62) yields the following general expression:

$$f_i = f_{\text{ref}}(1 + l_S^2 \delta_{xx} + m_S^2 \delta_{yy} + n_S^2 \delta_{zz} + 2l_S m_S \delta_{xy} + 2m_S n_S \delta_{yz} + 2l_S n_S \delta_{zx}) \quad (63)$$

where $f_{\text{ref}} = (\gamma_i/2\pi) I_0 B_{\text{ref}}$. In the formulation of equation (63), use is made of the identity $(l_S^2 + m_S^2 + n_S^2) = 1$. Thus, it is the off-diagonal tensor values in equations (62) and (63) that may be used to specify the relationship between the sample frame and the tensor's PAF.

5.1.1 Single Axis Goniometer Methods

For single axis goniometer measurements, it is common to construct the data sets so they will fall in the three cardinal planes (i.e., $x = 0$, $y = 0$, and $z = 0$) of the sample frame. For example, if the data are collected for a crystal mounted with

the rotation axis of the goniometer successively on the x , y , and z axis of the sample coordinate system (see Section 5.2), then the rotational dependence of these three rotation data sets in f_i become

$$\left. \begin{aligned} f_i(\xi_z) &= f_{\text{ref}}(1 + \delta_{xx} \cos^2 \xi_z + \delta_{yy} \sin^2 \xi_z) \\ &\quad + 2\delta_{xy} \cos \xi_z \sin \xi_z) \\ f_i(\xi_y) &= f_{\text{ref}}(1 + \delta_{zz} \cos^2 \xi_y + \delta_{xx} \sin^2 \xi_y) \\ &\quad + 2\delta_{zx} \cos \xi_y \sin \xi_y) \\ f_i(\xi_x) &= f_{\text{ref}}(1 + \delta_{yy} \cos^2 \xi_x + \delta_{zz} \sin^2 \xi_x) \\ &\quad + 2\delta_{yz} \cos \xi_x \sin \xi_x) \end{aligned} \right\} \quad (64)$$

The angular displacements about the three different rotational axes are given by ξ_z , ξ_y , and ξ_x . The connections between the angular displacements given in equation (64) and the directional cosines found in equations (62) and (63) are given by $\cos \xi_z = \sin \xi_y = l$, $\cos \xi_x = \sin \xi_z = m$, and $\cos \xi_y = \sin \xi_x = n$. This traditional method for studying single crystals provides high-quality data except for samples with too many magnetically unique atoms per unit cell. Overlapping signals prevent the indexing of lines in spectra with more than about 15–18 peaks.

5.1.2 Two-Dimensional Single Crystal Spatial Correlation Methods

The time requirements of the single axis goniometer method and its rather restricted limits on the number of atoms in the unit cell led to the development of a more powerful 2D spatial correlation method for obtaining single crystal spectra. The greater resolution of 2D methods allows roughly an order of magnitude increase in the number of single crystal NMR peaks that may be indexed, and only six 2D spectra are required to determine the tensor. Figure 9 schematically depicts the pulse and mechanical flipping features of this 2D spatial correlation method. The ^{13}C signals of the single crystal are first cross polarized, placed in the transverse plane, and allowed to evolve in the first time dimension. During the mixing period the evolving magnetization is returned and stored along the magnetic field axis while the crystal is mechanically reoriented to a new position. In Figure 9 the sample is reoriented by 45° during the mixing period. Upon completing the mechanical reorientation, the stored magnetization is then returned to the transverse plane where the FID acquisition period constitutes the second time dimension.

Each peak in this 2D experiment exhibits the two resonance frequencies corresponding to the two directions in space. For example, a sample may be placed in the X direction during the evolution period and observed along the XY diagonal direction (i.e., $\cos \xi_z = 45^\circ$) during the FID acquisition time. A discussion of the mechanical devices used to reorient the sample is beyond the scope of this article and may be obtained from the literature.³⁴ All possible pairs of cardinal (X , Y , Z) and diagonal (XY , YZ , ZX) directions may be used to compose the 2D spectrum. Such spatially correlated data, of course, are the essence of the information required to

Figure 9 Mechanical and pulse relationships for the 2D spatial correlation method

characterize a chemical shift tensor. The six different sample-frame frequencies for cardinal and diagonal directions in this 2D spatial correlation experiment are given by

$$\left. \begin{aligned} f_X &= f_{\text{ref}}(1 + \delta_{xx}), & f_{XY} &= f_{\text{ref}}\left(1 + \frac{1}{2}\delta_{xx} + \frac{1}{2}\delta_{yy} + \delta_{xy}\right) \\ f_Y &= f_{\text{ref}}(1 + \delta_{yy}), & f_{YZ} &= f_{\text{ref}}\left(1 + \frac{1}{2}\delta_{yy} + \frac{1}{2}\delta_{zz} + \delta_{yz}\right) \\ f_Z &= f_{\text{ref}}(1 + \delta_{zz}), & f_{ZX} &= f_{\text{ref}}\left(1 + \frac{1}{2}\delta_{xx} + \frac{1}{2}\delta_{zz} + \delta_{zx}\right) \end{aligned} \right\} \quad (65)$$

From the six frequencies given in equation (65), the corresponding six shift parameters are obtained by inverting this set of equations.

5.2 Data from the Single Axis Goniometer

Method—Naphthalene ^{13}C Tensors

The single crystal of naphthalene belongs to the $P2_1/a$ space group and has two molecules per unit cell, each chemically equivalent but oriented differently. This unit cell, first described by Bragg³⁵ and more recently the subject of a neutron diffraction study,³⁶ indicates that the inversion symmetry center of the crystal is at the center of the naphthalene molecule. The inversion symmetry makes the atoms of one naphthalene ring equivalent to those of the second ring (e.g., C-1 is equivalent to C-5, C-2 to C-6, etc.). Thus, in a single crystal of naphthalene five NMR resonance signals (four unique ring carbons and one bridgehead carbon) exist for each of the two structurally different molecules.³⁷ These 10 peaks constitute the single crystal spectrum of naphthalene, and a representative 1D ^{13}C spectrum is given in Figure 10. The two groupings of five peaks observed in this spectrum correspond to the two congruent naphthalene molecules in the unit cell. A twofold symmetry axis transforms the congruent molecules into each other. Pairs of tensors from corresponding atoms in the two congruent molecules have the same principal values. However, these tensors differ in their

Figure 10 Single crystal spectrum of naphthalene with two groupings of five peaks from the two congruent molecules in naphthalene. (This figure is taken from Sherwood et al.³⁷)

relative orientations within the unit cell. The spectral patterns for a naphthalene powder sample also exhibit five different tensor bands, as congruent shifts each give the same powder patterns. Unfortunately, the five naphthalene powder bands are so similar that it is impossible to extract the very similar but slightly different principal values from the five magnetically unique atoms in naphthalene.

A single axis goniometer is used to rotate a naphthalene crystal around the x , y , and z sample axes with small angular displacements. Nineteen crystal spectra of the type shown in Figure 10 were accumulated for successive 10° angular displacements from 0° through 180° . These measurements create a dataset of 570 (i.e., $19 \times 10 \times 3$) chemical shifts as shown in Figure 11. The sinusoidal character of the data in successive spectra, see equation (64), is apparent in this figure where each of the 19 successive spectra are plotted versus the angular rotational displacements in the goniometer. Typical data-fitting techniques allow the shift parameters of the several tensors to be extracted from the data in Figure 11 using equation (64). The full tensors for each of the 10 resonance peaks are described by six values (i.e., 60 total tensor shift parameters for the 10 peaks) in the sample frame. Thus, the acquired dataset is almost 10 times larger than the derived shift parameter set, and this redundancy improves the accuracy of the chemical shift measurements. The error in shift values, estimated from the marginal standard deviations between principal axis values in congruent tensors, is about ± 0.5 ppm.

The NMR data on congruent tensors must conform to the symmetry and structural features that obtain in the unit cell. The direction of the δ_{33} principal axis for the five tensors in one of the naphthalene molecules were all found to lie, within experimental error, along the normal to the aromatic plane. Thus, NMR provides an independent measure for the angles (i.e., 63.59° for the NMR data and 63.53° for the diffraction data) between the two normal vectors of the congruent molecules and the twofold axis of the unit cell. This excellent agreement between the NMR and the diffraction data identifies the twofold symmetry axis and places the diffraction and NMR single crystal structures into direct correspondence. Using such symmetry considerations, the shift tensor is easily transformed into the unit cell frame, and consequently into the molecular frames of both congruent molecules.

Figure 11 Three single axis goniometer patterns for naphthalene with the goniometer axis placed along the X, Y, and Z axis of the single crystal. Each rotation pattern was obtained from 19 spectra with an angular displacement of 10° . The spectral slice at each angular setting portrays up to 10 peaks as seen in Figure 10 which is taken from the Y rotational pattern with the angle in the vicinity of 120° . (Courtesy of Mark H. Sherwood)

The naphthalene shift tensor components obtained from Figure 11 are reported in Table 1. These tensor data in the molecular frame may be readily converted into the PAF using standard matrix diagonalization methods, and Table 1 also contains the naphthalene principal shift tensors. The orientations of the principal axes in the molecular frame are provided in Figure 12 which also contains theoretical bond orders obtained from quantum mechanical methods. The significance of the bond orders will be apparent in Section 6 when the relationship between tensor orientation and electronic structure is briefly discussed. The orientation of the in-plane δ_{22} component is perpendicular to the δ_{11} component and to the δ_{33} component which is oriented perpendicular to the molecular plane.

Figure 12 Orientation of the δ_{11} tensor components in naphthalene is given along with the bond orders obtained from quantum mechanical calculations. As the bridgehead tensor is nearly axially symmetric (see Table 1) its orientational error is considerably larger than the remaining directions

5.3 Data from the Single Crystal Spatial Correlation

Method

The single crystal method, using a goniometer and successive small angular displacements, may be used whenever the unit cell contains about a dozen or less different nuclear resonances. The exact number depends upon the extent of spectral

Table 1 ^{13}C Chemical Shift Tensors for Naphthalene

Shift component	C-1	C-2	C-3	C-4	C-4a
δ_{xx}	143.2	196.8	195.9	148.1	208.3
δ_{yy}	221.8	170.0	169.9	221.3	202.4
δ_{zz}	22.8	11.1	10.4	20.4	-5.9
δ_{xy}	15.5	42.0	-42.8	-13.8	1.1
δ_{yz}	-0.6	0.8	-0.1	0.5	0
δ_{zx}	-0.4	0.8	1.2	-0.8	-0.9
δ_{11}	224.7	227.6	227.6	223.9	208.5
δ_{22}	140.3	139.3	138.2	145.6	202.2
δ_{33}	22.8	11.1	10.4	20.4	-5.9
δ_{iso}	129.3	126.0	125.4	129.9	134.9

dispersion, linewidths, and other factors affecting spectral resolution. In Figure 11 the large chemical shift ranges associated with aromatic carbon atoms contribute significantly to the ease of indexing the 10 naphthalene peaks. Sometimes, spectra of even less nuclei cannot be spatially correlated between successive angular displacements using a single axis goniometer probe if the spectral peaks are unusually close to each other. Compacted single crystal spectra encounter assignment ambiguities whenever overlapping lines prevent the indexing of unresolved spectral lines and the preparation of the required sinusoidal spectral traces from which tensor components are extracted. Furthermore, the spectral data in Figure 11 required 19 independent experiments for each of three different crystal mountings in the single axis goniometer. These 57 different experiments represent such an extensive body of work that it is easy to understand why single crystal NMR studies have been relatively rare.

The 1D single crystal spectra in Figure 1 for methyl β -D-xylopyranoside exhibited extensive overlapping of spectral lines, and even with only 12 lines in this simple sugar

Figure 13 The 2D spatial correlation spectra of methyl β -D-xylopyranoside for the XZ versus X and XZ versus Z experiments. These 2D spectra are portrayed along with their 1D projections in the X and Z directions. Spatial correlation of shifts is given by the position of each 2D peak in these spectra. (Courtesy of Fang Liu)

it would be difficult to index the peaks using the 1D single-axis goniometer method. Figure 13 contains two 2D spectra in which the XZ orientation is given along one frequency dimension for both spectra and the second frequency dimension corresponds in the two spectra to the magnetic field along the X and Z directions, respectively. The respective spectral traces above each 2D spectrum are the same as those in Figures 1(c) and (e), and correspond to the X and Z projections of the corresponding 2D spectra. Note in Figure 13 how the position of the overlapping 1D spectral lines may be clearly established from the well-resolved peaks in the 2D spectra. These 2D spectra also illustrate how information is obtained from 2D spatially correlated spectra. Each individual spectrum provides correlated data between, respectively, the XZ and X directions and between the XZ and Z directions in the sample frame. Taken together, the pair of 2D spectra ultimately provide the correlated information between the X and Z projections. A set of six properly selected 2D spectra allow the spatial correlation to be determined for all frequencies between the three cardinal (i.e., X, Y, Z) and three diagonal (i.e., XY, YZ, ZX) directions. Such data, when used with equation (65), provide six tensor parameters for every unique spectral peak.

Figure 14 exhibits the 2D spatial correlation spectrum for 40 distinct peaks in a single crystal of perylene. This molecule exhibits the same $P2_1/a$ space group found in naphthalene, except in perylene the inversion center lies in between the four molecules per unit cell. Thus the inversion symmetry reduces the number of NMR unique molecules in the unit cell

from four to two but, unlike the naphthalene case, inversion leaves all 20 atoms from each congruent molecule in unique chemical environments. The two sets of 20 peaks produce 40 distinguishable peaks in Figure 14. Only a limited number of spectral degeneracies or near-degeneracies are observed in this case, but these pose no problem to the data analysis due to the redundancy arising from the two congruent tensors. The white space remaining in the 2D spectrum of perylene suggests that single crystals of more than 100 unique carbon resonances may in certain cases be studied using the 2D spatial correlation method.

The extensive procedures required to analyze the six 2D spectra from a single crystal of a molecule as complicated as perylene (i.e., $6 \times 40 = 240$ peaks) pose assignment difficulties requiring strategies whose discussion is beyond the scope of this article. It is sufficient to indicate, however, that the perpendicular δ_{33} components for all nuclei in planar molecules are parallel to each other and provide a method of allocating sets of tensors to congruent molecules. This molecular grouping of tensors by the δ_{33} orientation causes the two sets of 20 peaks to cluster in Figure 14. The YZ direction is nearly perpendicular to the molecule with peaks designated by primes; hence the YZ shifts for this molecule lie between 0–40 ppm from TMS. Conversely, the YZ direction is nearly in the plane of the other congruent molecule and exhibits typical in-plane shifts of 130–200 ppm. Assignments of peaks within each set of 20 peaks depend in part on the orientation of the δ_{11} components and in part upon what appears to be a small

Figure 14 The 2D spatial correlation spectra of perylene appears in two spectral regions, and the 20 peak groupings in each region correspond to one of the two congruent molecules. The spectral assignments for the two molecules are compatible and transform into one another using the spatial symmetry of the unit cell of this crystal. (Courtesy of Robbie Iuliucci)

deformation from planarity along the C-3a and D-9a axis of the molecule. The assignments are also assisted by quantum mechanical calculations of the ^{13}C shifts. Predicted shift values are able in some cases to distinguish between similar tensors. The peaks from the two congruent sets of 20 tensors transform into each other under the symmetry elements in the unit cell, and this feature becomes a critical aspect of the assignment procedure.

6 MOLECULAR ORIGINS OF THE CHEMICAL SHIFT TENSOR

6.1 Effect of Molecular Symmetry and Electronic Structure on Shift Tensors

As indicated in Section 2, the chemical shift parameter has its origin in the shielding currents induced by the magnetic field in the molecular electrons. Because the magnitude of these shielding fields depends upon the inverse cubic distance of the circular current from the nucleus, it is primarily the electronic structure in the immediate vicinity of a nucleus that has the most effect on the shielding parameters. The schematic in Figure 15 summarizes the magnitudes and directions of shielding fields. Typical ranges in shift values are included for a few structural moieties to illustrate the variety of values encountered in chemical shift tensors.

Figure 15 Carbon-13 shielding and shift scales are compared. The magnitudes of various diamagnetic and paramagnetic shift components are indicated for the 1s, 2s, and 2p electrons. Typical shift values are presented for representative molecules and classes of compounds

The shielding phenomenon arises both from diamagnetic and paramagnetic induced currents. All electrons exhibit diamagnetic currents which flow in such a manner so as to oppose the static magnetic field, H_0 , and thereby reduce the resonance frequency or chemical shift of the spectral line. The diamagnetic shifts result from first-order currents that depend on the density of electrons and the inverse cubic distance of the electron from the nucleus. Paramagnetic currents, also induced by the magnetic field, arise from p and d electrons that possess electron orbital angular momentum. The magnetic field induces very small admixtures of angular momentum components into the wavefunctions and these produce paramagnetic shielding currents. Intrinsic angular momentum has an associated magnetic field that enhances H_0 ; hence, the paramagnetic fields increase the resonance frequency or chemical shift of a nucleus. These paramagnetic shifts may vary greatly between molecules and are very sensitive to electronic symmetry and molecular structural features that control the orbital mixing.

In Figure 15 it is observed that the 1s electrons in the carbon's K shell are accompanied by a very large diamagnetic shift (~ 200 ppm), but the K shell is deeply embedded within the electronic structure of organic molecules and therefore is essentially insensitive to chemical variations. Thus, the 1s contribution to the chemical shift is essentially constant for all carbon atoms in different types of molecular environments and therefore will not explain the diversity of carbon-13 chemical shifts. The L shell associated with the four valence electrons of carbon (i.e., 2s and 2p electrons) also exhibits a reasonably large diamagnetic shift, ca. 80 ppm for the four valence electrons (i.e., ~ 20 ppm per valence electron). Since 1s and 2s electrons in carbon possess zero orbital angular momentum, they contribute to the chemical shift only through diamagnetic

currents. While these diamagnetic shifts in ^{13}C are comparable in magnitude to the corresponding paramagnetic shifts they do not vary greatly from one molecular position to another, nor do they affect the anisotropy as much as paramagnetic currents. Thus, diamagnetic components contribute significantly to overall ^{13}C chemical shifts, but their variations and anisotropy are measured in units of 10 ppm. The low anisotropy in diamagnetic shifts supports the intuitive conclusion that the electronic structure of the carbon atom is nearly spherical in character because this diamagnetic term is proportional to the radius squared of the atom in the plane perpendicular to the magnetic field.

The large variability in the chemical shift range and the sizable chemical shift anisotropy reported for ^{13}C nuclei are due primarily to paramagnetic shielding currents, which are especially sensitive to both the symmetry and electronic structure of 2p valence electrons. For example, linear molecules with C_∞ symmetry about their long axes quench³⁸ the paramagnetic currents that lie in the plane perpendicular to this long axis. Conversely, the shift in the perpendicular directions is not quenched and may be sizable, leading to a large shift anisotropy for linear molecules such as acetylene. The presence of mirror symmetry in planar molecules likewise forces the δ_{33} principal shift component to lie perpendicular to the molecular plane, and this feature dominates the tensor orientation in alkenes and aromatic molecules.

The intrinsic orbital momentum of 2p electrons may contribute extensively to the paramagnetic shielding currents in organic molecules providing such orbital mixing is not symmetry-forbidden. The reason that paramagnetic components vary by several hundred ppm, more than the uniform diamagnetic currents, is explained by their second-order character. The admixture of very small angular momentum components into molecular wavefunctions can vary by several orders of magnitude for different chemical environments, and this variability has a corresponding impact on the shielding. These paramagnetic shifts are especially enhanced when multiple π -bond orbitals are present in the molecule. As π electrons are usually associated with lower promotion energies, orbital angular momentum components mix more readily into the quantum mechanical description of unsaturated molecules when placed in strong magnetic fields. The highly anisotropic nature of these paramagnetic currents reflects the π -bond structural anisotropy. Large shift ranges and anisotropies are found in acetylene and ethylene and related aromatic hydrocarbons, as shown in Figure 15. Conversely, typical aliphatic hydrocarbons exhibit chemical shift tensors that lie well within a 50 ppm range.

Sugar molecules of various types offer an important study in chemical shielding because of the high electronic polarization of the oxygen atoms in these compounds. Furthermore, hydrogen bonding strongly influences the molecular conformations in sugars. Both of these effects stamp their signature upon the sugar shift tensors. Tensor shifts for sugar molecules typically spread over a range of ca. 100 ppm, larger than aliphatic shifts but somewhat reduced from the spread in aromatic chemical shifts.

Table 2 Axial Chemical Shift Tensors in Linear or Near-Linear Molecules (Values in ppm from TMS)

Compound	$\delta_{\parallel}$	$\delta_{\perp}$	δ_{iso}	δ_{liq}
$\text{C}\equiv\text{O}$	-48	305	187	182.2
$\text{O}=\text{C}^*=\text{O}$	-90	245	133	132.2

6.2 Axial Chemical Shift Tensors in Linear and C_3 Symmetry Related Molecules

As the symmetry of a linear molecule quenches the paramagnetic currents about the long axis of the molecule, only diamagnetic shielding currents may affect the ^{13}C chemical shift. The C_∞ symmetry element present in a completely linear molecule also requires an axial chemical shift tensor. The theoretical considerations used to construct Figure 15 indicate that diamagnetic shifts, in the absence of any paramagnetic contributions, leave the ^{13}C resonance at around -90 ppm from TMS. A collection³⁹ of chemical shifts for selected linear or near-linear molecules is given in Table 2 to illustrate this effect of orbital angular momentum quenching upon paramagnetic currents. Note, the $\delta_{\parallel}$ components for all linear molecules are close to -90 ppm, except for carbon monoxide, CO, and for those linear alkyne carbons directly attached to the methyl group in methylacetylene and dimethylacetylene.

Carbon monoxide appears to be the exception that clearly breaks the -90 ppm rule. However, theoretical calculations indicate that the paramagnetic contribution to $\delta_{\parallel}$ is indeed quenched. The diamagnetic currents in carbon monoxide have been altered sufficiently by a charge polarization from the electronegative oxygen to account for the increased $\delta_{\parallel}$ shift. The C_{3v} symmetry of the methyl group, whilst also guaranteeing an axial tensor for the methyl carbon and for the directly attached carbon, is insufficient to symmetry-quench the paramagnetic currents along the parallel axis of these molecules. The terminal alkyne carbon in methylacetylene is apparently sufficiently removed from the methyl group to allow it also to reflect the same $\delta_{\parallel}$ shift value as acetylene. The pattern of $\delta_{\perp}$ values for the compounds listed in Table 2 may be explained by charge effects arising from the electronegativity of adjacent atoms attached to the linear carbon atoms.

The very narrow range in the chemical shift tensors for the methyl carbons in Table 2 are quite typical of methyl tensors in general. All of the electrons in the immediate vicinity of a methyl carbon are contained in σ bonds. Since these C-C and C-H bonds are comparable in energy, the contribution of both diamagnetic and paramagnetic currents along various directions from tetrahedral carbon atoms are quite similar, reducing the anisotropy between components. This equivalence does not imply a quenching of

the paramagnetic currents, merely a lack of anisotropy in the various directional components.

6.3 Asymmetric Chemical Shift Tensors in Molecules with Mirror Symmetry

Planar molecules with mirror symmetry elements require that at least one principal axis of the shift tensor has its orientation perpendicular to the molecular plane. This rule even holds for molecules in single crystals, where intermolecular shielding terms or modest planar deformations seldom distort the δ_{33} principal axis by more than a few degrees from the normal to the molecular plane. Such data support the hypothesis that intermolecular interactions produce only small indirect shifts in molecules when only van der Waals forces are involved. Furthermore, the negligible twist in the δ_{33} orientations also supports the conclusion that remote intermolecular shielding currents are also modest. Planar systems encountered in organic systems invariably involve sp^2 carbon atoms, and the π -electron systems oriented perpendicular to the molecular plane contribute large in-plane paramagnetic shifts. Table 3 contains the chemical shift tensors for a small representative number of planar molecules with sp^2 carbons. Ethylene and benzene are model compounds that provide illustrations of the importance of π electrons in the chemical shift anisotropy arising from the unique three-dimensional characteristics associated with π bonds. Figure 16 schematically illustrates the spatial orientation of electron orbitals that dominate the paramagnetic shifts in these two molecules.

In Figure 16 the δ_{33} tensor shift components, lying along the normal to the molecular plane, arise in both ethylene and benzene from circular shielding currents that lie in the molecular plane and involve only σ -bonding electrons. Such σ bonds are energetically stable and these tightly held electrons are less easily promoted into paramagnetic shielding currents. Thus, δ_{33} sp^2 values (i.e., -10 ppm to $+25$ ppm) are reduced accordingly and fall in the aliphatic hydrocarbon region of the ^{13}C spectrum. Observe also the corresponding δ_{33} values for naphthalene in Table 1.

The two in-plane components in sp^2 molecules (i.e., δ_{11} and δ_{22}) are oriented in a direction perpendicular to the $2p$ π electrons in both ethylene and benzene, as may be visualized in Figure 16. The δ_{22} in-plane component is parallel to the C–C π bond in ethylene and arises from paramagnetic currents that mix the π electrons with the σ electrons involved in the two C–H bonds. The δ_{22} shift in benzene is the component that arises from a paramagnetic current involving the π electrons and primarily the σ electrons of the C–H bond. This δ_{22} shift in benzene also involves to a lesser extent the σ electrons of the two adjacent C–C bonds.

The δ_{11} in-plane component in benzene lies along the C–H bond and mixes the π electrons with the σ electrons of the two

Figure 16 Electron orbitals contributing to shielding currents present in benzene and ethylene. The molecular orientations, the circular electron currents, and their associated principal shift components are represented for δ_{11} , δ_{22} , and δ_{33}

adjacent C–C bonds. Similarly, the δ_{11} component in ethylene lies perpendicular to the C=C bond and involves paramagnetic currents that mix the π electrons primarily with the σ electrons in the C=C bond, while in ethylene the σ electrons in the C–H bonds also participate to a lesser extent in this paramagnetic component. Figure 16 illustrates graphically which electrons participate primarily in the circular currents that affect the various principal shift components.

The principal chemical shifts for the α and β positions in naphthalene are listed in Table 1. Whereas the perpendicular mirror planes in benzene provide a symmetry basis for assigning the δ_{11} and δ_{22} chemical shift directions as indicated in Figure 16, no such perpendicular mirror planes exist for the carbons in naphthalene except at the bridgehead positions. Consequently, the δ_{11} directions for C-1 through C-4 in naphthalene deviate slightly from the C–H bond vectors. The orientation of the δ_{11} principal axis has been drawn in Figure 12 and the direction of this principal axis rotates slightly from the C–H bond direction in the molecular plane towards the C–C bond with the highest π -bond order. This is consistent with the concept that the largest paramagnetic currents are associated with a mixture of the π electrons into the carbon σ electrons of the C=C double bond. Thus, the δ_{11} component lies in the molecular plane but attempts to orient perpendicular to π bonds present in the molecule. When two or more π bonds are connected to a carbon atom, the δ_{11} direction will tend to orient perpendicular to the C–C bond of highest π -bond order (see Figure 12).

Table 3 Asymmetric Chemical Shift Tensors in Representative Planar Molecules (ppm from TMS)

Compound	δ_{11}	δ_{22}	δ_{33}	δ_{iso}	δ_{liq}
$\text{CH}_2=\text{CH}_2$	234	120	24	126	123.3
C_6H_6	234	146	9	130	128.7
C_5H_5^-	182	114	21	106	103.0
C_7H_7^+	280	168	22	157	156.3

6.4 Bond Energy Considerations and Chemical Shift Values

Three types of bonds appear in the sp^2 model compounds used in Figure 16 to illustrate the structural basis of the chemical shift tensor: they are the $\sigma_{\text{C-H}}$, $\sigma_{\text{C-C}}$, and $\pi_{\text{C-C}}$. The relative stability of these three bonds is given by $E(\sigma_{\text{C-H}}) > E(\sigma_{\text{C-C}}) > E(\pi_{\text{C-C}})$. As the admixture of angular momentum

components is inversely proportional to the bond energy of the affected electrons, other factors being equal it follows that the chemical shift tensor components will be related to the energy and the orientation of the bonding electrons. Thus, in benzene, the δ_{11} shift components employ electrons from the π_{C-C} and two σ_{C-C} bonds; the δ_{22} shift involve π_{C-C} , σ_{C-H} , and to a lesser extent the σ_{C-C} electrons; and finally δ_{33} involves the two σ_{C-C} and the σ_{C-H} bonds. The largest δ_{11} shift is therefore associated with the weakest set of bonds and the smallest δ_{33} shift with the strongest bonds. Note, the distinction between $E(\pi_{C-C})$ and $E(\sigma_{C-C})$ made here should not be confused with the total energy of a double bond consisting of the sum of these two energies. Similarly, for ethylene, the tensor component shifts and the contributing bonds are δ_{11} (π_{C-C} , σ_{C-C} , and to a lesser extent σ_{C-H}), δ_{22} (π_{C-C} and σ_{C-H}) and δ_{33} (σ_{C-C} and σ_{C-H}). These somewhat simplistic energy arguments need to be applied with some care as mixing of angular momentum components into the ground-state wavefunctions are dominated also by electron polarization and symmetry considerations which can override the somewhat simpler energy arguments presented here.

6.5 Aromatic Bond Orders in Fused Aromatic Bridgehead Carbons

Table 1 indicates that the chemical shift tensor of the bridgehead carbons for naphthalene are nearly axially symmetric. For example, the value for $\delta_{11} - \delta_{22}$ in bridgehead carbons is only 6.3 ppm, while $\delta_{11} - \delta_{22}$ for benzene is 88 ppm. The nonbridgehead carbon tensors in naphthalene are essentially like those indicated for benzene, with $\delta_{11} - \delta_{22}$ values in the vicinity of 80–90 ppm. Both of the in-plane bridgehead tensor components mix the π_{C-C} bond electrons with only σ_{C-C} bond electrons, and the tensor would be axial if the three π bonds to the three adjacent carbon atoms were to be equivalent. The diversity of π bonds varies greatly in fused aromatic hydrocarbons as may be observed in Figure 17 where the principal shift components of representative bridgehead carbons are plotted for a set of naphthalene-related molecules. The relevant bond orders are also indicated in Figure 17. Note, $\delta_{11} - \delta_{22}$ is smaller when all three bonds have comparable bond orders. When one of the three adjacent carbon atoms in a bridgehead fails to exhibit a significant π -electron population, the carbon shift tensor reverts to a more typical asymmetric pattern. The bond order between C-6a and C-6b moieties in perylene is very small (i.e., 1.07) and reflects only the presence of a σ_{C-C} bond. Hence, the value of $\delta_{11} - \delta_{22} = 59$ ppm for perylene is similar to the corresponding 70 ppm anisotropy observed for the α -carbons of 1,4,5,8-tetramethylnaphthalene.⁴⁰ However, the $\delta_{11} - \delta_{22}$ values for C-3a and C-12c are both ca. 2 ppm and still retain their near-axial character similar to the corresponding bridgehead shifts in naphthalene. This brief discussion of bridgehead shift tensors in naphthalene-related molecules illustrates the potential power of chemical shift tensor data in characterizing the electronic structural details in molecules.

6.6 The Effect of Charge Polarization in Sugar Chemical Shift Tensors

In tetrahedral carbon atoms, the simple energy arguments that are used to account for the large anisotropic shifts in

Figure 17 Bridgehead and substituted shift tensor components for naphthalene and related compounds. Small in-plane anisotropy in δ_{11} and δ_{22} is noted whenever all three adjacent carbons have sizable bond orders, indicating comparable π -electron populations. The C-6a bridgehead in perylene has similar bond orders to those at the substituted carbons in 1,4,5,8-tetramethylnaphthalene. Consequently, the large in-plane anisotropy in δ_{11} and δ_{22} results from the C-6a to C-6b bond exhibiting typical single σ -bond character

sp^2 aromatic carbons are less important because only σ -bonds are involved in such molecules, and these bonds tend to be much more similar to each other than corresponding bonds involving sp^2 carbons. Thus, other effects such as charge polarization and distortions in bond angles and internuclear distances are relatively more important in sugars. Bond angle distortions usually arise with steric perturbations of the molecular structure. Further, the absence of dominating symmetry features (e.g., mirror planes) in sugars leaves all of the principal values relatively free to orient in space such that simple recognizable patterns are not available to assist the systematization of the data. Even so, sugar shifts must also continue to reflect the three-dimensional structure of the molecular electrons, and the tensor shifts in the sp^3 sugar carbons are just as sensitive to electronic features as are the sp linear and sp^2 planar molecules discussed above.

Extensive data^{41–43} have been accumulated on a number of important sugar systems to delineate the effect of oxygen charge polarization and the rich conformational features found in various sugar molecules. Systematic trends are observed in these data, but when simple rules such as used to discuss aromatic and linear molecules are unavailable to systematize the data only a complete quantum mechanical treatment is

available to sort out the important structural factors in the shift tensors. Quantum simulations of chemical shifts give proper weight to a variety of factors, viz. symmetry, electronic energy, charge polarization and possible steric effects, etc. Fortunately, such theoretical methods are now approaching the point where their reliability provides sufficient independent information to resolve ambiguities in the assignment of very similar tensors not distinguished clearly by either the crystal symmetry or diffraction structural information.

6.7 Quantum Mechanical Calculations of Chemical Shift Tensors

Space in this article is insufficient to discuss every subtle nuance and structural detail found in chemical shift tensors, but a short discussion of the theoretical prediction of these shifts is valuable. The quantum chemical results have been effective in correlating a large body of experimental data and provide a means of comparing NMR tensor data with structural parameters obtained from diffraction studies. Using interatomic distances and bond angles obtained from either X-ray or neutron diffraction results, it is possible to calculate molecular wavefunctions that reflect even minor structural variations. These quantum mechanical wavefunctions are then used to predict chemical shift tensors, and it is found that very modest changes in interatomic bond distances and bond angles can lead to variations in predicted chemical shifts of several ppm. As the experimental NMR accuracy of crystal measurements is about ± 0.3 to ± 0.5 ppm, errors in structural data often cause scatter in the predicted shifts that are nearly an order of magnitude larger than limitations in the NMR data.

Figure 18 contains two plots of the theoretical versus experimental chemical shift tensor components for eight related sugar molecules. In Figure 18(a) the theoretical results depend solely on the diffraction structures in the literature. Where possible the neutron diffraction results have been used as they establish the positions of the protons in molecules much better. In one sugar, methyl β -D-glucopyranoside, a neutron structure was not available and the X-ray data had to be used. The neutron diffraction data provide wavefunctions that predict the chemical shift tensors with less scatter than the X-ray data, primarily because the C–H distances are better determined. A closer study of the neutron data, however, indicates very large Debye–Waller factors for methyl protons in these methylated sugars due to extensive librational motion. Thus, the neutron data provide quality proton positions for ring protons but still experience larger uncertainties in the methyl proton positions.

The plot in Figure 18(b) was obtained first by quantum mechanically optimizing all C–H bond distances in the eight sugar molecules. These refinements in the nuclear positions were then used to obtain wavefunctions for simulating chemical shift tensors. This process considerably improves both the slope and the scatter found in the correlation plot given in Figure 18(a). The improvement in Figure 18(b) presumably may be attributed to better proton positions. The improved wavefunctions predict sugar chemical shifts ranging over 100 ppm with only a scatter of ± 2.4 ppm. These results portend high promise for chemical shift tensors in the area of structural chemistry.

A similar theoretical study⁴⁴ of the shift tensors in naphthalene indicates that the errors in the diffraction parameters are

Figure 18 (a) GIAO calculations with X-ray and neutron diffraction structures versus experimental shift tensor components. (b) GIAO calculations with quantum mechanically optimized CH bond lengths versus experimental shift tensor components. (Courtesy of Fang Liu)

sufficient to account for variations of ± 4.9 ppm scatter found between the theoretical predictions and the experimental chemical shifts. This study used the neutron diffraction structure of Pawley and Yates³⁶ to obtain the naphthalene wavefunctions. Uncertainties of $0.01 \text{ \AA}$ in bond distances may lead to changes in the wavefunctions that can alter the predicted shifts by up to 2 ppm. Such uncertainties are common in diffraction studies and thus the present scatter in theoretical predictions of shifts can only be reduced by improvements in the structural parameters. A combination of quantum calculations and tensor shift data therefore provides a verifiable means of refining diffraction data. These results portend a bright future for chemical shift studies of single crystals as NMR solid measurements, with errors of less than ± 0.5 ppm, offer a considerable improvement in the relative accuracy of the measured quantity. This is especially important when neutron diffraction structures are not available or if the diffraction structure is on a very large molecule where diffraction uncertainties can be much larger.

7 CONCLUSIONS

From its first discovery in 1950, the chemical shift has made NMR spectroscopy an ubiquitous analytical method in chemistry. The applications are legend and every year literally thousands of research papers make significant chemical conclusions based on chemical shift results. Even though liquid chemical shifts have been extremely important, they reflect only part of the power of the full chemical shift tensor. Chemical shift tensors contain considerably more information on subtle changes in the electronic and chemical structures of all materials. Furthermore, important information on the three-dimensional structure of molecular systems may be obtained from chemical shift tensors. As many of the shift tensor developments have been realized in recent years, one can only conclude that chemical shift studies should be promising for many years to come.

1 INTRODUCTION

The purpose of this article is to outline briefly recent progress in understanding chemical shifts in biochemical systems—proteins, nucleic acids, carbohydrates, and lipids. The chemical shift is probably the most sensitive spectroscopic probe of local structure and environment, but until quite recently it has been quite refractory to detailed analysis, at least in macromolecules. In small molecules, this sensitivity manifests itself in isotope shifts, temperature dependence, gas-to-liquid shifts, and solvent shifts. In macromolecules, sensitivity is manifested as chemical shift nonequivalencies. The NMR chemical shift in biological systems contains a wealth of encoded structural information, and in order to decode this information it is first necessary to be able to predict chemical shifts from known structures.

From a theoretical standpoint, insights gained in studying chemical shifts in biological systems should also greatly help in testing, modifying, and improving present theories of the chemical shift. For example, proteins provide a unique test case for investigating the dependencies of the chemical shift on factors such as torsion angles, hydrogen bonding, and electrostatics. In sharp contrast, gas phase studies of small molecules would not be capable of yielding the torsional dependencies of the chemical shift. This is because variable-temperature measurements, in which the torsional effects would be visible, also include significant contributions from centrifugal distortion, and, in addition, a change in one torsion angle may significantly change the overall shape of a small molecule, and consequently the way it interacts with its environment. Proteins, on the other hand, do not require variable-temperature studies, since sites which differ only in torsion angles are already present. Hence, the ability to interpret and reproduce chemical shift nonequivalencies in biological systems should not only be useful for structure elucidation, but is also of fundamental importance for the evaluation, development, and design of methods for chemical shift computation in general.

Chemical shift nonequivalencies due to folding have been known in proteins for more than two decades. McDonald and Phillips¹ first observed that several residues in hen egg white lysozyme could be resolved in ¹H NMR, and this was then followed by Allerhand et al. who observed a ~6 ppm range for the ¹³C chemical shift of C- γ of the six tryptophan residues in hen egg white lysozyme.² Although such chemical shift inequivalencies have made multidimensional NMR studies of proteins possible,^{3,4} understanding of the origins of such chemical shift nonequivalencies remained a very major challenge until recently, when a first-principles reproduction of the NMR spectra of the heavier nuclei (¹³C, ¹⁵N, and ¹⁹F) in proteins was demonstrated to be feasible.⁵ Here, we trace the development of NMR chemical shift interpretations in biological systems, starting from the discovery of empirical correlations between shift and structure in proteins, up to the present ab initio interpretation of protein, nucleic acid, and carbohydrate chemical shifts, and the derivation of structure from shielding.

2 EMPIRICAL SHIFT–STRUCTURE CORRELATIONS IN PROTEINS

The earliest attempts at unraveling the relationship between secondary structure and chemical shifts were focused on H- α .^{6–8} Due to the small chemical shift range and the sensitivity of ¹H shielding to not only electrostatic effects but also magnetic factors, such as ring currents and the anisotropy of the diamagnetic susceptibility of peptide groups, only general trends were found between structure and shielding.^{9,10} In contrast to ¹H NMR, the heavier nuclei exhibit a much wider chemical shift range, rendering such magnetic effects of minor importance. Hence, ¹³C and ¹⁵N nuclei offer more promise, and considerable efforts were made in interpreting these shifts as soon as they became available.

In early work, Kricheldorf et al.¹¹ and Saito et al.¹² showed that ¹³C chemical shifts in peptides were mainly influenced by the torsion angles ϕ and ψ . Theoretical attempts involving a semiempirical finite perturbation—incomplete neglect of differential overlap (FPT–INDO) method aimed at reproducing these observations were somewhat successful in demonstrating the nonequivalency between helical and sheet residues,¹³ but the calculated differences were much smaller than the range observed experimentally. With an increasing number of assigned C- α and C- β resonances in various proteins—bovine pancreatic trypsin inhibitor (BPTI), calmodulin, interleukin-1 β and staphylococcal nuclease—Spera and Bax introduced the first empirical ϕ , ψ chemical shift surface for C- α and C- β using known X-ray data,¹⁴ shown in Figures 1(a) and (b). Figure 1(c) shows histograms of the secondary shift distribution in α -helical and β -sheet residues. From the presently available database of ¹³C chemical shifts it is clear that C- α resonances of helical sites are deshielded compared with those residues which occur in sheet regions. The opposite trend is evident for C- β , where helical sites are more shielded.¹⁴ Such empirical observations have found use in the chemical shift index,¹⁵ which permits prediction of helical and sheet structure, based on C- α C- β , C $^{\circ}$, and H- α shifts.

Considerable attention was also given early on to ¹⁵N shifts in proteins.^{16,17} However, the problem of whether or

Figure 1 Secondary chemical shift surfaces $\Delta\delta(\phi, \psi)$ and secondary chemical shift histograms for C- α and C- β sites in proteins. not ^{15}N chemical shifts can provide information regarding local structure remained unanswered. Glushka et al. then noticed a correlation between ^{15}N chemical shifts and the torsion angle ψ_{i-1} for residues in sheet regions in BPTI and apamin, but no other structural or ‘interaction’ features were found.¹⁸ More recently, using a much larger database (consisting of 14 proteins and 1477 ^{15}N chemical shifts), Le and Oldfield¹⁹ found a better empirical correlation between the peptide ^{15}N chemical shift and the torsion angles ϕ_i and ψ_{i-1} , indicating that there is indeed a significant relationship between ^{15}N chemical shifts and secondary structure. The larger number of points permitted study of individual amino acid shift surfaces. Figures 2(a)–(c) show the agreement obtained between experimentally obtained ^{15}N chemical shifts and those derived from the empirically fitted shift surfaces, for aspartic acid, lysine, and valine. The presence of an intrinsic relationship between ^{15}N chemical shifts and secondary structure becomes evident from these studies. However, it can also be inferred that there are other factors, such as electrostatic interactions, side-chain conformation, and hydrogen bonding, which all potentially influence ^{15}N shielding. The side chain of valine, for example, introduces an additional angle χ^1 , which can modify the ^{15}N chemical shift behavior, since the presence of a substituent at the β -carbon site introduces a γ -gauche effect, as noted earlier by Tonelli.²⁰ In order to take this into account, a much larger database would be needed in order to create separate shift surfaces for each of the three common χ^1 conformers. Empirical database approaches are thus useful in indicating trends, but it would clearly be desirable to be able to predict shifts accurately using first principles or ab initio approaches. For example, the ^{15}N -valine χ^1 -torsional problem is one which can easily be solved if the torsional dependencies can be derived from first principles. As demonstrated recently, this is now possible.¹⁵ In addition, sensitivity to side-chain conformation is not exclusive to ^{15}N , since ^{13}C shifts for C- α and C- β sites are also expected to exhibit a χ^1 dependence. This, however, would be difficult to see with only a small database of assigned ^{13}C shifts. Ab initio methods therefore clearly have an advantage over empirical approaches since chemical shift surfaces for individual amino acids, as well as for various χ^1 conformers, can in principle be evaluated.

With the rapidly growing database of ^1H chemical shifts,²¹ there has been renewed interest in using ^1H NMR in protein structure studies.^{22–27} These studies have taken advantage of the availability of large numbers of ^1H chemical shifts to relate chemical shifts to structure. In addition to the correlation found between secondary structure and the chemical shifts of H- α and H-N, the large amount of spectroscopic information available has also permitted a breakdown of ^1H shielding into electrostatic and peptide magnetic anisotropy effects. Thus, the coefficients needed in order to evaluate electrostatic contributions from nearby polar groups, as well as the anisotropy effects arising from peptide bonds, have been derived empirically. The complexity and number of factors that affect ^1H chemical shifts, however, make a direct chemical shift to structure route very difficult, although structure refinement using H- α shifts has promise.³⁰

Figure 2 Correlation between experimental secondary ^{15}N chemical shifts and those computed from empirically fitted individual secondary chemical shift surfaces. 3 THE AB INITIO APPROACH TO PROTEIN SHIELDING

Although empirical and semiempirical approaches for ^1H NMR are useful for analyzing secondary structures, these approaches are more limited for the heavier nuclei. The reason for this is that long range magnetic anisotropy effects will be very small for ^{13}C and ^{15}N , due to the large ^{13}C and ^{15}N shift ranges ($\sim 8\text{--}30\text{ ppm}$). Moreover, $\text{C-}\alpha$ and $\text{C-}\beta$, being both sp^3 -hybridized carbons, are not expected to have their chemical shift greatly influenced by electrostatic factors. Thus, in order successfully to predict and interpret the chemical shift of heavy nuclei in proteins, it is desirable to apply ab initio methods. These, in general, successfully predict shielding for such heavy elements—at least for ^{13}C , ^{15}N , and ^{19}F . The system, however, consists of so many atoms that a computation which includes the whole protein would be prohibitive, even with supercomputers. Fortunately, however, since the chemical shift is inherently a localized property, it is wrong to suppose that the effects of all atoms in a protein need to be incorporated into the computation. One approach is to separate the total shielding, σ_{t} , into three parts³¹

$$\sigma_{\text{t}} = \sigma_{\text{s}} + \sigma_1 + \sigma_0 \quad (1)$$

where σ_{s} refers to the short-range contribution, σ_1 corresponds to long range electrostatic effects, and σ_0 contains the magnetic effects. Although orthogonality may not be achieved, such a partitioning of the various chemical shift contributions helps develop computational strategies for solving each contribution.

The short range contribution can be further divided into several categories: local structure, repulsive interactions, and strong hydrogen bonding. Local structure includes the dependencies of the chemical shift on bond lengths, bond angles, and torsion angles. For the long range electrostatic contributions, several methods can now be used. One can either incorporate the charge field at the self-consistent field

(SCF) level,³² or use the multipole shielding polarizability (MSP) approach.³³ Lastly, σ_0 can be calculated by a variety of classical methods, basically as discussed above for ^1H NMR. This contribution is, however, still within the error limits of present ab initio methods for calculating σ_{s} and σ_1 , although it can still be expected to help somewhat with shift predictions. For further discussions on intra- and intermolecular factors which influence shielding, several recent reviews are available.^{34,35}

Hence, for a protein, atoms belonging to the residue which contains the nucleus of interest can be regarded as contributing to σ_{s} , while the rest of the protein contributes to σ_1 . This partitioning greatly reduces the size of the fragment on which full ab initio calculations need to be performed. When combined with recent improvements in hardware (such as powerful workstations) and a method which avoids gauge errors in calculating the shielding property [the gauge-including atomic orbital (GIAO) method],³⁶ together with the application of new algorithms to improve code efficiency,³⁷ the ab initio reproduction of chemical shifts in proteins is now at hand.

In recent work,⁵ it was shown that a small molecular fragment, *N*-formyl-L-alanine amide, interacting with formamide molecules (used to represent hydrogen bond partners) and point charges (representing the rest of the protein) successfully reproduced the experimentally observed ^{13}C chemical shifts for the 12 alanine $\text{C-}\alpha$ and $\text{C-}\beta$ sites in the protein staphylococcal nuclease, as shown in Figure 3. The ability to predict the chemical shift opens up a new avenue for protein structure elucidation, especially if the factors which lead to such nonequivalencies can be identified. The partitioning of the shielding as described above greatly facilitated this quest.^{5,38} As expected, $\text{C-}\alpha$ and $\text{C-}\beta$ chemical shift nonequivalencies were found to be dominated by the local structure, or short-range factors, σ_{s} .³⁶ In addition, based upon an examination of the dependencies of $\text{C-}\alpha$ and $\text{C-}\beta$ shielding on bond lengths, bond angles, and torsion angles, it was established that torsion angles clearly dominate the experimentally observed trends. In particular, it was also noted that the chemical shifts at these

Figure 3 Comparison between calculated ^{13}C NMR shieldings and experimental chemical shifts for alanine residues in staphylococcal nuclease. (a) C- α , (b) C- β . (Reproduced by permission of the American Association for the Advancement of Science from A. C. de Dios, J. G. Pearson, and E. Oldfield, *Science*, 1993, **260**, 1491)

sites were extremely sensitive to bond lengths. In fact, the variations in bond lengths of the same type of residue seen in a single-crystal X-ray structure were shown to lead to a chemical shift range as large as the experimentally measured range, but the predicted shifts were wholly uncorrelated with experiment.³⁹ Residues of the same type in a protein therefore have bond lengths that are much more similar to each

other than X-ray structures would suggest. Nevertheless, from these same studies, ϕ - and ψ -angles were found to be highly correlated with C- α and C- β shifts. Shielding surfaces have therefore been constructed using a model fragment, *N*-formyl-L-alanine amide, in order to map out the effects of ϕ and ψ on C- α and C- β shieldings.³⁸ With this surface serving as a look-up table, and knowledge of ϕ and ψ , ^{13}C shieldings (or chemical shifts) for any alanine site in a protein can readily be obtained—at least in the absence of large-amplitude motions.

Nitrogen-15 shieldings are expected to be more difficult to predict, since well-defined ϕ and ψ correlations have not been observed, and hydrogen bonding and electrostatic effects could also be important. Recent work,⁵ however, has shown that ^{15}N chemical shifts in proteins can now be predicted using the GIAO method, with explicit hydrogen bond partners, and point charges representing the rest of the protein. Figure 4 shows results for valine residues in staphylococcal nuclease.⁵ The results in Figure 4(a) were obtained by using a molecular fragment; formyl-L-alanyl-L-valine amide. In Figure 4(b), hydrogen bond partners were explicitly included (as formamide molecules), while Figure 4(c) includes the rest of the protein, represented as point charges. Although the dominance of torsion angles found in ^{13}C chemical shifts is less dramatic with ^{15}N , the generally good accord between calculated and observed values when long range factors are included indicates that ^{15}N NMR is a potentially powerful technique for structure validation. Its sensitivity to long range interactions extends the structural information that can be obtained beyond the local torsion angles, thus complementing ^{13}C NMR.

Although not naturally occurring in most proteins, ^{19}F is a particularly sensitive probe of electrostatic field effects in proteins. Its incorporation, for example, into tryptophan residues of *Escherichia coli* galactose-binding protein (GBP)⁴⁰ and hen egg white lysozyme⁴¹ has generated information on how long range factors, such as van der Waals and electrostatic interactions, influence the chemical shift. Using point charges, GIAO has been shown⁵ to reproduce satisfactorily the observed ^{19}F NMR spectrum of 5-F-Trp-labeled GBP, except for solvent-exposed sites. With prior knowledge of how shielding is affected by a uniform electric field, field gradient, and field hypergradient (the MSP approach), dynamic averaging becomes tractable,⁵ and even shielding at sites that are highly mobile and solvent exposed can be satisfactorily reproduced.³⁹

Overall, ^{13}C chemical shifts show great promise in structure elucidation, as noted above for alanine. Successful prediction of ^{13}C chemical shifts has also been shown for glycine and valine residues.³⁹ Here, the dominance of ϕ and ψ is similarly evident. The correlation between calculated and experimental shieldings for glycine sites is less satisfactory than with alanine and valine, possibly due to glycine mobility. On the other hand, the presence of the side chain in valine introduces an additional angle that can influence both C- α and C- β shieldings. Taking advantage of this additional dependency, crystal-to-solution structural differences became apparent upon close examination of the C- α and C- β shifts of valine residues in calmodulin.⁴² Corroborated by coupling constant information, this work demonstrated that five out of the seven valine residues assume a side-chain conformation different from that seen by X-ray crystallography.

Figure 4 Calculated ^{15}N chemical shieldings versus experimental shifts for the valine sites in staphylococcal nuclease. (a) Using isolated valine fragments; (b) as in part (a) but with inclusion of a hydrogen bond partner; (c) as in part (b) but with incorporation of point charges to represent the rest of the protein. Finally, we briefly consider shielding as a tensor quantity. Here, all elements and their directions need to be evaluated—six parameters versus one isotropic shift, representing a serious challenge for theory. For amino acid crystals, the charge field perturbation gauge including atomic orbital (CFP-GIAO) method gives excellent agreement with

experiment.⁴³ Figure 5 shows a comparison between calculated and experimental shielding components for the ^{13}C nuclei in L-threonine⁴³ in the icosahedral representation⁴⁴ of the shielding tensor. The results shown here clearly illustrate the adequacy of present theoretical methods of predicting chemical shieldings, even in complex (zwitterionic, polar amino acid) systems.

4 NUCLEIC ACIDS

The usefulness of chemical shifts in studying biological systems is naturally not restricted to proteins. Chemical shifts of nucleic acids should similarly encode a wealth of information regarding structure, protonation sites, hydrogen bonding, and electrostatic field effects. The shielding caused by magnetic anisotropy effects on ^1H NMR spectra has already been studied using semiempirical methods,⁴⁵ and more recently ab initio methods have been used to study the pyrimidine base cytosine.⁴⁶ However, these early results were obtained using only a split valence set, insufficiently saturated with basis functions. A more recent study using a larger basis was performed by Schindler⁴⁷ using the individual gauge for localized molecular orbitals (IGLO) method.⁴⁸ The shielding tensors, as well as the magnetic susceptibilities, were calculated for cytosine, thymine, and uracil, as well as adenine and guanine. The calculated values compared favorably with experiment, but in general the computation of shielding tensors in nucleic acid bases is difficult because definite molecular structures that correspond to the systems on which the NMR measurements were taken are usually not available. In particular, the relative amounts of tautomers depend strongly on the solvent and pH, and the ^{15}N chemical shifts were found to be very sensitive to such environmental effects. Nevertheless, using ab initio optimized structures, it was shown that the calculated ^{15}N shielding trends caused by

protonation could indicate which species dominate in solution. However, the lack of a supportive trend from ^{13}C shieldings did not permit a more precise determination of the dominant tautomer.

5 CARBOHYDRATES

With the importance of carbohydrates in lipid and (glyco)protein structure, as well as in, for example, substrate/inhibitor binding (e.g. in lysozyme), and the occurrence of carbohydrates in metabolism, cell surface antigens, etc., it is surprising that so little work has been reported on ^{13}C and ^{17}O NMR shielding, at the ab initio level. An exception to this is the pioneering work of Grant et al.⁴⁹ on ^{13}C shieldings in methyl α -D-glycopyranoside and sucrose. Grant et al. showed that a root mean square deviation (rmsd) of ~ 3 ppm between theory and experiment (the rmsd from the straight line connecting shift and shielding) with $R^2 \sim 0.97$ and a slope of -0.99 (methyl glucoside), could be obtained at the 6-31G level, permitting a convincing reassignment of some earlier chemical shift assignments.

6 STRUCTURE FROM SHIELDING: PREDICTION, REFINEMENT, AND VALIDATION

The ability to predict the NMR spectra of biologically important molecules via ab initio methods heralds a new era in the use of the easiest NMR parameter to measure, the isotropic chemical shift. For proteins, the intimate relationship found between the torsion angles ϕ and ψ and the ^{13}C chemical shifts of C- α and C- β sites strongly suggests that it should be possible to derive structural information from chemical shifts in ways not founded on empirical relationships, size of database, or on X-ray structures. One such method of extracting torsion angles from spectroscopic parameters has recently been proposed.⁴⁸ Referred to simply as the 'Z-surface method', it begins with the assumption that a given spectroscopic parameter, P , can be represented as a function of a torsion angle α

$$P = f(\alpha) \quad (2)$$

and the probability that a given value P_i corresponds to a value of α can be cast as in

$$Z_i = \exp[-(P_i - f(\alpha))^2 / W] \quad (3)$$

W is a search width of typically about 1 ppm, and takes into account uncertainties in theoretical and experimental results, e.g. basis deficiencies, referencing errors, etc. Equation (3), of course, assumes a knowledge of $f(\alpha)$, which can be obtained via ab initio methods or from experiment. A plot of Z_i over possible values of α constitutes a probability surface for the angle α . Since the chemical shifts of C- α and C- β are both functions of torsion angles ϕ and ψ , a map of the whole Ramachandran space that shows which pair of ϕ - and ψ -angles closely agree with the observed chemical shifts can be easily constructed. For alanine residues in a variety of proteins, using this approach and the theoretical shielding surfaces for C- α and

C- β , plus an experimental surface for H- α , yields values for ϕ and ψ that have only $\sim 10^\circ$ rmsd values from the X-ray values.⁵⁰

Although ^{15}N chemical shifts are more susceptible to environmental effects, and ^{19}F shift inequivalencies are largely due to electrostatic interactions, this sensitivity of the ^{19}F and ^{15}N shieldings to electrostatic interactions can be utilized in testing present force fields, molecular dynamics programs, and electrostatic field calculations.⁵¹ Moreover, ^{15}N being sensitive to factors other than local structure, it can complement ^{13}C NMR in validating the overall structure of a protein.

7 CONCLUSIONS

Chemical shifts have been reported in biochemical systems for about 30 years. However, only very recently has it been possible to solve the chemical shift problem, and successfully predict chemical shifts in macromolecules, such as proteins.⁵ Since chemical shifts can now be intimately related to structure, and vice versa, it seems likely that many new applications to structure prediction, refinement, and validation will stem from these developments. Until recently, it was thought by many to be impossible to predict protein chemical shifts. However, the continuing revolution in computer/disk price/performance ratios now enables study of much larger fragments than heretofore possible. In the future, we believe that many such applications of 'biochemical shifts' and quantum chemistry will contribute greatly to our studies of lipid, protein, nucleic acid, and carbohydrate structure.

1 BRIEF HISTORICAL INTRODUCTION

The idea that electric fields could alter chemical shifts was first proposed by Schneider, Bernstein and Pople¹ to account for the ‘association shifts’ in hydrogen-bonded systems observed by proton magnetic resonance. To help confirm this notion a calculation of the electric field dependence of the nuclear shielding in the hydrogen atom was carried out by Marshall and Pople.² A more formal treatment of intermolecular interactions on chemical shifts which included the effects of electric fields was presented by Stephen.³ A general formulation of the effect of a uniform electric field upon nuclear shielding was then given by Buckingham.⁴ His treatment takes the shielding to second order in the electric field. Thus for the $\alpha\beta$ component of a nuclear shielding tensor σ :

$$\sigma_{\alpha\beta} = \sigma_{\alpha\beta}^{(0)} + \sigma_{\alpha\beta\gamma}^{(1)} E_{\gamma} + \frac{1}{2} \sigma_{\alpha\beta\gamma\delta}^{(2)} E_{\gamma} E_{\delta} \quad (1)$$

where $\sigma_{\alpha\beta}^{(0)}$ is a component of $\sigma^{(0)}$, the shielding tensor in the absence of the field $\mathbf{E}$, and $\sigma_{\alpha\beta\gamma}^{(1)}$ and $\sigma_{\alpha\beta\gamma\delta}^{(2)}$ are field-independent components of tensors $\sigma^{(1)}$ and $\sigma^{(2)}$. The Einstein summation convention is used in equation (1): the appearance of a suffix twice in a term denotes summation over all axes. Buckingham considered the effect of an electric field produced by a polar group within a molecule acting on a proton in another part of the same molecule and so contributing to the shielding change at that proton brought about by the introduction of the polar group. Upon averaging over all orientations of the molecule in the external magnetic field of the NMR spectrometer, but with the electric field held fixed relative to the molecule, the change in mean shielding was found to be:

$$\Delta\sigma = -AE_z - BE^2 \quad (2)$$

The parameters A and B were characteristic of the X–H bond involving the proton of interest, and the negative signs were included explicitly in equation (2) to render A and B positive quantities since it was expected that an electric field along the

z axis (from X to H) would lead to a reduction in shielding, as would the effect of the field at second order. In equation (2) the X–H bond is treated as cylindrically symmetric at first order and the electron distribution about the proton is treated as spherically symmetric at second order. Equation (2) frequently appears in textbooks and is referred to as ‘the Buckingham equation’. Musher⁵ offered some early calculations of the value of A for C–H bonds.

Electric fields were soon invoked to account in part for observed solvent effects on chemical shifts in liquids⁶ and for the density dependence of nuclear shielding in gases.⁷ To help explain the density dependence of the proton shielding in polar gases a statistical mechanical treatment using equation (2) was developed and this was supplemented by formulating the van der Waals contribution to the shielding as a mean electric field squared contribution $\bar{E}^2$ with a coefficient B identical with that in equation (2).⁷ This appeared very successful for proton shielding in gases^{7–10} and it was soon extended to ¹⁹F shielding.^{11,12}

Experimental results from NMR studies of both gases and solutions combined with the results of a number of semiempirical calculations meant that by 1972 it was possible to draw up a table of A and B values for protons and other nuclei in various bonding situations.¹³ In the 1970s, attention switched to ¹³C chemical shifts upon which electric field effects are more difficult to describe, partly because of the much greater lack of uniformity of the bonding situation at a carbon atom than at a hydrogen or fluorine atom, and partly because of the greater likelihood of the presence of through-bond effects which are intrinsically more difficult to formulate in mathematical terms. The only major theoretical attempt to study electric field effects on ¹³C shielding was the semiempirical study by Seidman and Maciel.¹⁴ There were, however, several good ab initio studies of electric field effects on the nuclear shielding in the small molecules H₂¹⁵ and HF¹⁶ during this period, together with some general studies by Aminova and Gubaidullina¹⁷ and Mukhomorov¹⁸ on C–H bonds.

In the 1980s, little was done on the subject apart from the important work of Volodicheva and Rebane,¹⁹ but since 1990 the situation has been transformed. This is largely because good ab initio calculations of the electric field coefficients are now possible on small and medium-sized molecules. In addition, work on the changes in chemical shifts for different conformations of proteins has also stimulated interest. It seems likely that within a few years coefficients for the effects of uniform electric fields on nuclear shielding [i.e. the coefficients defined in equation (1)] will be available which even take account of electron correlation. The effects of electric field gradients may also be well understood.

2 THEORETICAL BACKGROUND

In the presence of a uniform magnetic field $\mathbf{B}_0$ there is an interaction between a nuclear magnetic moment μ^N in a molecule and the magnetic field. The energy of this interaction W is given by:

$$W = -\mu_{\alpha}^N (\delta_{\alpha\beta} - \sigma_{\alpha\beta}) B_{0\beta} \quad (3)$$

where $\sigma_{\alpha\beta}$ is, as above, an element of the shielding tensor (see *Chemical Shift Tensors*). In the most general case

when the environment of the nucleus possesses no symmetry, nine independent coefficients are required to specify the nuclear shielding, since $\sigma_{\alpha\beta}$ is clearly not symmetric in α and β . Thus, for example, for the molecule CHFClBr nine independent coefficients are required to specify the magnetic field experienced by any one of the nuclei when the molecule is placed in an external field $\mathbf{B}_0$. For more symmetrical molecules fewer coefficients are required. The symmetry involved here is the so-called ‘site symmetry’ which may be the same or lower than the point group symmetry of the molecule. Table 1 gives some examples of site symmetry for the nuclei in several simple molecules. Table 2 shows the numbers of nonvanishing and of independent tensor components for all possible nuclear site symmetries.²⁰

Table 1 Some Examples of Site Symmetry for Nuclei in Selected Compounds

	C	H	O	F
CH ₄	T_d	C_{3v}	—	—
CO ₂	$D_{\infty h}$	—	$C_{\infty v}$	—
HCCH	$C_{\infty v}$	$C_{\infty v}$	—	—
CH ₃ F	C_{3v}	C_s	—	C_{3v}
H ₂ CO	C_{2v}	C_s	C_{2v}	—
CH ₂ CCH ₂	C-1, C_{2v} C-2, D_{2d}	C_s	—	—

When a uniform electric field is present, $\sigma_{\alpha\beta}$ is given by equation (1). The first requirement is to establish which of the components of the tensors $\sigma^{(1)}$ and $\sigma^{(2)}$ are nonzero for a particular nucleus. This also depends on the site symmetry at that nucleus. The answers can be obtained by using group theoretical techniques.²¹

For $\sigma^{(1)}$ there are 27 nonvanishing, independent coefficients in the case of no site symmetry. Fewer exist when some site symmetry is present. This is made clear in Table 3, which lists all the nonvanishing components for all the main nuclear site symmetries. A more complete list is given elsewhere.²² The axis systems used in obtaining the nonvanishing coefficients given in Table 3 are as follows: for the site symmetries C_{2v} , C_{3v} , and $C_{\infty v}$ the single axis of symmetry is chosen as the z axis; for the symmetries C_s , D_{2d} , and D_{3h} the plane or principal plane of symmetry is the xz plane. (This last choice differs from that used elsewhere.²²) For T_d site symmetry any axis system can be chosen.

For $\sigma^{(2)}$ there are 54 not 81, nonvanishing, independent coefficients in the general case since there is an intrinsic symmetry in the last two suffixes, i.e. $\sigma_{\alpha\beta\gamma\delta}^{(2)} = \sigma_{\alpha\beta\delta\gamma}^{(2)}$, even in the absence of any site symmetry. Table 4 lists the nonvanishing components of $\sigma^{(2)}$ for some site symmetries. For components that are equal due to intrinsic symmetry only one is listed in the table. A more complete list is given elsewhere.²²

In practice, as stated earlier, one needs to calculate the electric field dependence of the mean shielding σ_E , i.e. the dependence of the shielding averaged over all directions of the magnetic field but with the electric field kept fixed with respect to the molecule. One then has:

$$\sigma_E = -A_\gamma F_\gamma - B_{\gamma\delta} F_\gamma F_\delta \quad (4)$$

where

$$A_\gamma = -\frac{1}{3}\sigma_{\alpha\alpha\gamma}^{(1)} \quad (5)$$

and

$$B_{\gamma\delta} = -\frac{1}{6}\sigma_{\alpha\alpha\gamma\delta}^{(2)} \quad (6)$$

The number of independent A and B parameters depends on the site symmetry as shown in Table 5 for some selected site symmetries. A more complete list is given elsewhere.²² (It is to be noted that Table 4 in Raynes and Ratcliffe²² omits a third quadratic coefficient B_{zz} for C_s symmetry.) Thus for C_s symmetry:

$$\begin{aligned} \sigma_E = & -A_x E_x - A_z E_z - B_{xx} E_x^2 - B_{yy} E_y^2 \\ & - B_{zz} E_z^2 - B_{xz} E_x E_z \end{aligned} \quad (7)$$

whilst for C_{3v} and $C_{\infty v}$ symmetry

$$\sigma_E = -A_z E_z - B_{xx} F_x^2 - B_{zz} F_z^2 \quad (8)$$

3 CALCULATION OF ELECTRIC FIELD COEFFICIENTS

The computation of the components of $\sigma^{(1)}$ and $\sigma^{(2)}$ for nuclei in specific molecules by quantum mechanical methods has only been systematically carried out since 1990. Before that, as stated above, only the nuclei in the hydrogen atom² and in the H₂ and HF molecules^{15,16} had been studied at the ab initio level.

It is usual to recognize two stages in the ab initio calculation of molecular properties (see *Shielding Calculations: Perturbation Methods, Shielding: Overview of Theoretical Methods* and *Shielding in Small Molecules*). At the Hartree–Fock level—in practice the self-consistent field (SCF) level—the motion of each electron in the field of the atomic nuclei and a smoothed out field of all the other electrons is considered. It is at this level that most of the calculations of the electric field coefficients are carried out. The second stage involves taking into account ‘electron correlation’, the additional contributions arising from the interactions between individual electrons which are not included at the SCF level. A few calculations on small molecules in uniform electric fields in which some electron correlation was included have been performed.^{23,24} They show that electron correlation does make a significant contribution to the coefficients, especially those at the quadratic level. At any level of calculation it is essential to use large basis set wavefunctions.

Results at the SCF level for the tensor component of $\sigma^{(1)}$ and $\sigma^{(2)}$ for nuclei in a wide variety of molecules have been calculated with large basis set wavefunctions by Grayson and Raynes.^{25–28} Table 6 presents just a few of these results for carbon shielding possessing $C_{\infty v}$ and C_{3v} site symmetries in some simple molecules.²⁶ In all these cases the z axis is directed from the carbon nucleus of interest along the axis of symmetry towards the proton attached to that carbon (for C₂H₂ and HCN) or towards the plane containing the three protons (for CH₃CN and CH₃F). For C_{3v} symmetry the xz

plane contains a C–H bond. It can be seen that for both $\sigma^{(1)}$ and $\sigma^{(2)}$ components vary widely between molecules (e.g. $\sigma_{xxyy}^{(2)}$ for the five carbon nuclei in Table 6).

Table 7 gives all results for the A and B coefficients of proton shielding so far obtained by calculation at the SCF level, except for some of the earlier results for H_2 , HF, and CH_3F ²⁹ which have now been superseded by those given. For all unreferenced results in Table 7 with $C_{\infty v}$ and C_{3v} site symmetries the proton of interest lies on the z axis and has the most positive z coordinate of all nuclei present; for C_s site symmetries (i.e. when A_x and B_{xz} differ from zero) the z axis is directed along the X–H bond towards the proton and the positive x axis points towards the other proton (or protons) present. Except where indicated, all the results in Table 7 are taken from two papers by Raynes and Grayson.^{27,28} Augspurger, Dykstra and co-workers^{30,31} chose the z axis (referred to by them as the x axis) always to lie along molecule symmetry axes. In all their calculations the electric field was directed along this axis.

Table 8 gives ab initio SCF results so far obtained for the shielding of carbon and several other nuclei. Earlier results for HF¹⁶ and CH_3F ²⁹ have now been superseded by those given in Table 8. For $C_{\infty v}$ and C_{3v} site symmetries the z axes of the molecules in Table 8 are taken along the principal symmetry axis, with the molecule arranged so that protons lie on the positive z axis or that the nearest protons to the nucleus of interest lie on the positive z axis. For C_{2v} site symmetry the z axis is along the two-fold axis towards the proton with the xz plane being that of the molecule. Except where indicated, all results in Table 8 are taken from two papers by Grayson and Raynes.^{25,26}

All the results in Table 6, 7 and 8 are given in units of ppm a.u.; these units are commonly used by workers who calculate the coefficients ab initio. For applications one must convert first to SI units. The appropriate conversion factors are 1 ppm a.u. = $1.94469 \times 10^{-18} \text{ m V}^{-1}$ for the linear coefficients and 1 ppm a.u. = $3.78182 \times 10^{-30} \text{ m}^2 \text{ V}^{-2}$ for the

quadratic coefficients. Two other useful conversion factors are those from c.g.s. units (i.e. e.s.u.) to SI units which involve multiplying A values by 0.33357×10^{-4} and B values by 0.1113×10^{-8} , and those from c.g.s. units (or e.s.u.) to ppm a.u. which require linear coefficients to be multiplied by 17.153×10^{12} and quadratic coefficients by 2.943×10^{20} .

As mentioned earlier, electron correlation, which is not very important for the shielding constants, makes substantial contributions to the electric field coefficients, especially at second order. This has been established by the work of Bishop and Cybulski²⁴ who used second order Møller–Plesset (MP2) theory to include the effects of correlation. Some of their results are presented in Table 9, where a comparison with SCF results obtained from the same basis set is made. The signs of A are positive for all nuclei in Table 9, indicating that the nucleus of interest lies on the z axis with the other nucleus having a less positive z coordinate.

4 ELECTRIC FIELD GRADIENTS

The electric fields encountered at the molecular level are highly nonuniform, and therefore it is necessary to study the effects of electric field gradients on nuclear shielding. This was first done by Buckingham and Lawley³² for a hydrogen atom in a uniform field gradient. They found that the contribution due to the field gradient should normally be negligible compared with the quadratic electric field effect.

Later, Batchelor^{33,34} invoked the importance of electric field gradients to explain ^{13}C shielding changes brought about by the protonation of amino acids and peptides. Although an improved agreement between theory and experiment was achieved by the introduction of field gradients, an insufficient number of cases was studied to establish with certainty that field gradients cannot be ignored. Augspurger and Dykstra³⁰ calculated the coefficients of magnetic shielding for a range of nuclei in a number of simple axially symmetric molecules with the field gradient along the axis of symmetry. As with the A and B coefficients, the field gradient coefficients C are very sensitive to the bonding for a particular nuclear species.

5 APPLICATIONS

So far our concern has been with the general theory of the electric field dependence of shielding and with the coefficients which multiply the various components of the electric field. We now turn to the electric fields themselves. This introduces the problems to which the theory can be applied. It is convenient to divide these applications into several areas in which the treatments are of, perhaps, decreasing order of sophistication. These are, first, the area of intermolecular interactions in gases where the interaction between a pair of molecules is involved. The second one is that of solvent effects in liquids where dielectric theories are used to introduce the idea of a ‘reaction field’. However, models based upon interactions between individual pairs of molecules—the so-called ‘cage-models’—are also used for liquids. A third area is that of intramolecular electric fields due to the introduction of a polar group in a molecule. Difficulties arise here because of the problems of other shielding contributions such as magnetic anisotropy effects or through-bond effects. Another area is that of electric fields in solids. We first consider gases.

^a The origin of the vector potential was taken at the nucleus of interest.

5.1 Binary Interactions in Gases

The nuclear shielding in a gas varies with the density (see also *Gases at High Pressure* and *Gas Phase Studies of Chemical Exchange Processes*). In most cases there is a linear dependence, so that one may write formally:³⁵

$$\sigma = \sigma_0 + \sigma_1/V_m \quad (9)$$

where σ_0 is the shielding at very low density and V_m is the molar volume. For a gas mixture of two components labeled 1, which contains the nucleus of interest, and 2, one has:

$$\sigma_1 = x\sigma_1^{(11)} + (1-x)\sigma_1^{(12)} \quad (10)$$

where x is the mole fraction of species 1. The term $\sigma_1^{(11)}$ allows for the interactions of molecule 1 with a like molecule and $\sigma_1^{(12)}$ that with a molecules of species 2. We shall proceed to work with $\sigma_1^{(12)}$, since $\sigma_1^{(11)}$ is just a special case of it. $\sigma_1^{(12)}$ is made up of four contributions:

$$\sigma_1^{(12)} = (\sigma_1)_b + (\sigma_1)_a + (\sigma_1)_E + (\sigma_1)_w \quad (11)$$

where $(\sigma_1)_b$ and $(\sigma_1)_a$ are the bulk susceptibility and magnetic anisotropy contributions which do not involve electric fields; these can be accurately calculated,^{6,7} if the magnetic susceptibility and the magnetic susceptibility anisotropy of molecule 2 are known. $(\sigma_1)_E$ is the ‘polar effect’ due to the electric fields arising from the permanent electric dipole and quadrupole moments in 2. $(\sigma_1)_w$ is the van der Waals contribution and is usually described by an electric field squared, which involves the B parameters previously considered.

We first examine $(\sigma_1)_E$. Let us consider both molecules 1 and 2 to be axially symmetric and to be arranged as shown in Figure 1. For the particular orientation shown, the change in shielding of a nucleus in molecule 1 (assumed to lie on the molecular axis) due to the permanent and induced electric

**Figure 1** Orientation of axially symmetric molecules 1 and 2

dipole and the permanent quadrupole moments of 2, using equation (2), is

$$(\sigma_{\text{pair}})_E = -AE_z - BE^2 \quad (12)$$

where E_z is the electric field along the molecular axis of 1 and E^2 is the square of the electric field at 1. In equation (12) we assume that the electric field due to 2 is uniform at molecule 1 so that the coefficients A and B can be used. We also assume that the distinction between $B_{\parallel}$ and $B_{\perp}$ can be ignored. Then⁷

$$\begin{aligned} E_z = & -\mu_2 r^{-3} (2 \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2 \cos \phi) + \mu_1 \alpha_2 r^{-6} \\ & \times (3 \cos^2 \theta_1 + 1) - \frac{3}{2} \Theta_2 r^{-4} \\ & \times [\cos \theta_1 (3 \cos^2 \theta_2 - 1) + 2 \sin \theta_1 \sin \theta_2 \cos \theta_2 \cos \phi] \end{aligned} \quad (13)$$

where μ_1 and μ_2 are the permanent dipole moments of 1 and 2, respectively, and α_2 and Θ_2 are the mean polarizability and electric quadrupole moment, respectively, of 2. We assume that the molecular polarizability is isotropic. The square of the total field at molecule 1 is:

$$\begin{aligned} E^2 = & \mu_2^2 r^{-6} (3 \cos^2 \theta_2 + 1) - 2\mu_1 \mu_2 \alpha_2 r^{-9} \\ & \times (8 \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2 \cos \phi) + \frac{9}{4} \Theta_2^2 r^{-8} \\ & \times (1 - 2 \cos^2 \theta_2 + 5 \cos^4 \theta_2) \end{aligned} \quad (14)$$

$(\sigma_1)_E$ and $(\sigma_{\text{pair}})_E$ are related^{7,35} through the expression:

$$(\sigma_1)_E = \frac{1}{2} N \int (\sigma_{\text{pair}})_E \exp(-u/kT) d\tau \quad (15)$$

where u is the intermolecular potential and N is the Avogadro constant; u is usually represented by the Stockmayer potential which is the sum of a Lennard–Jones (6–12) potential and the interaction energy of two dipoles, viz.:

$$\begin{aligned} u = & 4\epsilon_0 \left[\left(\frac{r_0}{r} \right)^{12} - \left(\frac{r_0}{r} \right)^6 \right] + \mu_1 \mu_2 r^{-3} \\ & \times (2 \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2 \cos \phi) \end{aligned} \quad (16)$$

where

$$\tau = \mu_1 \mu_2 / \epsilon_0 r_0^3 \quad (17)$$

and

$$y = 2(\epsilon_0/kT)^{\frac{1}{2}} \quad (18)$$

The integration in equation (15) is taken over all mutual orientations and distances of separation. It can be carried out analytically and leads to the functions³⁶

$$H_n(y) = y^{\frac{27-n}{6}} \sum_{k=0}^{\infty} \Gamma\left(\frac{6k+n-3}{12}\right) \frac{y^k}{k!} \quad (19)$$

The final result is

$$\begin{aligned} (\sigma_1)_E = & -(\pi NA/6y^2)\{\mu_2[(\tau/3)H_6(y) + (y^4\tau^3/200)H_{12}(y) + \dots] \\ & + (4\mu_1\alpha_2/r_0^3y^2)[H_6(y) + (\tau^2y^4/40)H_{12}(y) + \dots] \\ & + (2\mu_1\Theta_2^2/y^2kTr_0^5)[H_8(y) + \dots]\} \\ & - (\pi NB/3y^4)\{(\mu_2^2/r_0^3)[H_6(y) + (\tau^2y^4/40)H_{12}(y) + \dots] \\ & + (\mu_1\mu_2\alpha_2/r_0^6)[y^2\tau H_{12}(y) + (y^6\tau^3/60)H_{18}(y) + \dots] \\ & + 3(\Theta_2^2/r_0^5)[H_8(y) + \dots] + \dots\} \end{aligned} \quad (20)$$

Equation (20) is the expression that has been used for the polar effect. As stated above it involves assuming that (a) the polarizability of molecule 2 is isotropic, (b) that $B_{\parallel} = B_{\perp}$, and (c) that u can be described by the Stockmayer potential. At the time of writing these assumptions are being relaxed and the author expects to obtain improved expressions in the near future. Even after this improvement the uniform field approximation [equation (8)] is still required. It has been difficult to establish the validity of equation (20) since, until recently, good values of A and B were not available and it is even more difficult (as discussed below) to formulate the van der Waals contribution which is always present.

$(\sigma_1)_w$ is regarded as being due to the fluctuating electric fields of instantaneous electric dipoles in 2 which average to zero but the mean square of which does not average to zero. Thus⁷

$$(\sigma_{\text{pair}})_w = -B\overline{E^2} \quad (21)$$

where B is identified with B in equation (20). For $\overline{E^2}$ the expression

$$\overline{E^2} = 3\alpha_2 I_2 / r^6 \quad (22)$$

has been widely used, where I_2 is the ionization potential of 2. Substitution of equation (22) into equation (21) and replacement of $(\sigma_{\text{pair}})_E$ by $(\sigma_{\text{pair}})_w$ in equation (15) leads to

$$\begin{aligned} (\sigma_1)_w = & -(\pi NB/y^4r_0^3)\alpha_2 I_2\{H_6(y) \\ & + (\tau^2/48)y^4H_{12}(y) + \dots\} \end{aligned} \quad (23)$$

All early values of A and B obtained from experiment were found by fitting equation (11) to the experimental data for which the only unknowns were A and B . Although, as stated above, it is difficult to test equation (20) because of the ubiquitous van der Waals forces, it is possible to test equation

(23) since one can study systems for which permanent dipole and quadrupole moments are absent, leaving only $(\sigma_1)_w$, and hence B , to be determined.

This has been done using methane as the test molecule. The density dependences of both the ^1H and ^{13}C shielding must involve only $(\sigma_1)_w$ after correction for $(\sigma_1)_b$. Values of $(\sigma_1)_w$ have been measured for both resonances over a very wide temperature range.^{37,38} It is found that the temperature dependences of $(\sigma_1)_w$ for both resonances are substantially greater than predicted by the factor $H_6(y)/y^4$ in equation (23) and that the magnitudes of $(\sigma_1)_w$, especially for the ^{13}C shielding, are many times greater than predicted using calculated B values (see Raynes³⁹ Table 3). It would appear that a mean square field model is unable to account for the observed results.

5.2 Interactions in Liquids

In the liquid phase we again have shielding changes due to the fields of permanent electric moments and those associated with van der Waals forces. In the former case it is usual to separate the situation when the solute molecule, which contains the nucleus of interest, has a permanent electric moment and the surrounding solvent molecules do not, from that in which the solvent molecules themselves also possess permanent electric dipole (or perhaps quadrupole) moments. When the solvent and solute molecules both possess permanent moments one is approaching the area of complex formation, including hydrogen bonding. This is usually treated not in terms of electric fields but in terms of chemical equilibrium theory.

For polar solutes in nonpolar solvents 'reaction field' theory is usually applied. This originates from the Onsager model.⁴⁰ The application to chemical shifts was first made by Buckingham et al.⁶ They treated the solute molecule as a point dipole at the center of a spherical polarizable cavity surrounded by the solvent which is taken to be a dielectric continuum of dielectric constant ϵ . The point dipole polarizes the neighboring solvent medium and this leads to a uniform 'reaction field' E_R across the cavity parallel to the point dipole μ . This gives

$$E_R = \frac{2(\epsilon - 1)(n^2 - 1)}{3(2\epsilon + n^2)} \frac{\mu}{\alpha} \quad (24)$$

where n is the solvent refractive index and α is the polarizability of the solvent molecule.

Diehl and Freeman⁴¹ improved the model by considering the cavity to be nonspherical. They obtained

$$E_R = \frac{\mu}{abc} 3\xi_a [1 + (n^2 - 1)\xi_a] \frac{\epsilon - 1}{\epsilon + (n^2\xi_a/1 - \xi_a)} \quad (25)$$

where

$$\xi_a = \frac{1}{2} abc \int_0^\infty \frac{d\lambda}{(a^2 + \lambda)^{\frac{3}{2}} (b^2 + \lambda)^{\frac{1}{2}} (c^2 + \lambda)^{\frac{1}{2}}} \quad (26)$$

and a , b and c are the axes of the cavity ellipsoid. Diehl and Freeman chose the proton shielding in acetonitrile and paraldehyde to test equation (25). They found that widely

different values of the parameter A for the C–H bonds in these molecules had to be used before equation (24) would agree with the experimental results. However, with equation (25) they found that very similar values of A (viz. $A = 3.0$ and 3.4 c.g.s. units) gave good agreement. They concluded that equation (25) was to be preferred. What they could not know was that their A values are in good agreement with the modern calculated values of A in ‘normal’ C–H bonds. Their mean value of A , viz. 3.2 c.g.s. units, is equivalent to 55 ppm a.u., which is only some 10% or so smaller than the A_z values for the C–H proton in CH_3F , CH_3Cl , and C_2H_4 given in Table 7. (It should be noted that reaction fields are sufficiently small that the contribution which is quadratic in the field is negligible.)

Following the work of Diehl and Freeman, another test of the reaction field model was undertaken by Laszlo and Musher.⁴² They concluded that no existing reaction field model was adequate to explain the observed results and that the reaction field must have very different values at different points in the solute molecule. No subsequent work appears to have been carried out to develop the theory further. However, with the A parameters now obtained independently from ab initio calculation, it should be possible to do this.

Contributions to the reaction fields of molecules with electric quadrupole moments have been studied by Biemond and co-workers.^{43,44} Their conclusion is that the electric quadrupole field contribution is not negligible in comparison with the van der Waals contribution. This is extended to include the octopole moment in the case of methane.⁴⁵ Another refinement is to allow for the fact that molecular vibrations produce an oscillating electric dipole moment which modifies the reaction field.⁴⁶

The dielectric theory is meant to be applicable when solvent dielectric constants are small. As stated above, for high dielectric constant solvents (i.e. highly polar solvents) chemical equilibrium theory is generally used. Exceptions to this are the work by Schmidt et al.^{47a} and by Akitt^{47b} who successfully used electric field models in such cases.

In attempting to deal with the contribution of intermolecular van der Waals interactions to nuclear shielding in liquids most authors start from a simpler form of equation (21):

$$\sigma_w = -B\overline{E^2} \quad (27)$$

where $\overline{E^2}$ is now the mean square electric field experienced by the solute molecule from the surrounding solvent molecules and B is an empirical constant. Two distinct approaches are used to obtain an expression for $\overline{E^2}$. One is to use an expression [usually equation (22)] for the interaction between the solute molecule and one solvent molecule and then to multiply it by the number of solvent molecules in the immediate vicinity of the solute. This is the ‘cage model’ or ‘gas model’ and was first used by Rummens et al.⁴⁸ The second approach, which uses the reaction field model and hence treats the solvent as a continuous dielectric, was introduced by Howard, Linder and Emerson.^{49,50} A detailed treatment of these two approaches is given by Rummens.⁵¹ Homer⁵² has also given an early review of the field. In later years much work was done by Homer and co-workers. Their approach was described most fully in 1984.⁵³ It separates σ_w into two parts—one which can be described in terms of a reaction field model, and one involving a short-range ‘buffeting’ interaction. Both interactions involve the coefficient B .

Table 10 Comparison of Ab Initio⁵⁵ and Empirically Determined Values of B (in 1×10^{-18} e.s.u., 1×10^{-18} cm² Statvolt⁻²) Using Various Models for Noble Gases Dissolved in Liquids⁵³

	Ab initio ⁵⁵	Linder	Empirical ⁵³		
			Rummens	RBB	BR
He	0.13	0.25	0.75	1.2	0.7
Ne	1.06	11	27	52	35
Kr	12.03	200	220	350	350
Xe	14.96	580	630	750	820

Further confirmation of the inadequacy of the simple mean square field approach to calculating σ_w values comes from a comparison of theoretical and experimental determinations of B values. Seydoux et al.⁵⁴ studied the shifts of He, Ne, Kr, and Xe dissolved in a variety of solvents. Using various models they obtained the B values given in Table 10. The true B values have now been calculated by Bishop and Cybulski.⁵⁵ It is clear that the empirical approaches grossly overestimate B , showing that the mean square field model with the uniform field B is inadequate. This point has also been made by de Dios and Jameson.⁵⁶

5.3 Intramolecular Electric Fields

It was realized very early that the small changes in nuclear shielding upon passing along a homologous series or upon substitution of a polar group in a molecule could not be understood by calculations using the Ramsey equation, and so the suggestion that the total shielding of a nucleus could be broken down approximately into a number of contributions was made.⁵⁷ It was in this context that Buckingham⁴ introduced that idea that, as well as contributing to intermolecular effects, electric fields arising from polar substituents could explain shielding differences between the substituted and the unsubstituted compound. The notion was first applied to proton shielding and then extended to the shielding of ^{19}F , ^{13}C , and other nuclei.

The central idea is to regard the shielding change at a given nucleus upon the substitution of a polar group at some distance away (usually greater than 0.3 nm) in a molecule as being due to the electric field emanating from a point electric dipole situated in the polar group. In carrying out calculations the following features arise: (i) it is assumed, for distances greater than 0.3 nm, that the electric field of the point dipole is sufficiently uniform for the coefficients A and B , as defined previously, to be used; (ii) allowance must be made for any other mechanism which could affect the shielding; and (iii) as the magnetic anisotropy of the polar groups is important here, it is assumed, for distances greater than 0.3 nm, that all inductive and mesomeric effects, which act through bonds rather than through space, can be neglected—the seat of the point dipole in the polar groups is determined so as to give the best overall agreement with experiment.

The first systematic study of intramolecular electric field effects was that by Zürcher.⁵⁸ He studied the effects of a number of polar groups upon proton shielding in conformationally rigid steroid molecules. He took magnetic anisotropy and other effects into account. For A he obtained a value of 4.2×10^{-12} e.s.u. (72 ppm a.u.). At the time this was higher than the A value generally accepted ($\sim 3 \times 10^{-12}$ e.s.u.) but, as shown in Table 7, somewhat lower than the true, typical A value

for a C–H bond. He took an optimistic view that in time it would 'be possible eventually to find the refined physical models with which to ascertain quantitatively the chemical shift changes due to some reactions field and specific group interactions'. This has, unfortunately, not proved possible, although the recent availability of reliable values of the A and B parameters could very well stimulate renewed activity towards this goal.

Following Zürcher, a detailed study of electric field effects was made by Hamer, Peat and Reynolds^{59–61} who studied 4-substituted styrenes using both ^1H and ^{13}C shielding. Their work confirmed the existence of intramolecular electric fields. For proton shielding they obtained values for A of 3.11×10^{-12} e.s.u. (53.3 ppm a.u.) when the field of the dipole was calculated at the C–H bond midpoint, and 4.77×10^{-12} e.s.u. (81.8 ppm a.u.) when the field was calculated at the proton.⁵⁹ Later they obtained values of $4.6\text{--}6.5 \times 10^{-12}$ e.s.u. (79–111 ppm a.u.) for protons in C–H bonds in aromatic compounds.⁶¹ Green and Martin⁶² obtained 56 ppm a.u. for the A value of the proton in CHCl_3 . A value for A of -3.0×10^{-11} e.s.u. (–51 ppm a.u.) was later obtained for ^{19}F shielding in C–F bonds.⁶³ This agreed with other experimental data, but disagrees with the ab initio value of –505.5 ppm a.u. for CH_3F in Table 8.

Considerable attention has been devoted to studying electric field effects on ^{13}C chemical shifts. Some of this work^{14,64–68} invokes the idea of an electric field but involves semiempirical calculations, and the effect is formulated in terms of ^{13}C electron densities or total shielding changes rather than in terms of A and B parameters. Other papers have explicitly involved the electric field coefficients,^{69–71} but have also involved highly empirical methods to estimate A . Values in the range $2\text{--}12 \times 10^{-11}$ e.s.u. (300–1800 ppm a.u.) have been obtained. This range is partly coincident with that of the new ab initio values given in Table 8.

In recent years there has been an upsurge in activity due to greatly increased interest in the chemical shifts brought about by changes in protein conformation^{72–77} (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). This has led to the calculations already referred to.^{30,31} There have also been semiempirical studies of electric field effects of substituents on nuclear shielding.⁷⁸

Intramolecular van der Waals effects on shielding can be treated by a mean square field approach, as was done by Tribble et al.⁷⁹ for ^1H shielding in hydrocarbons. From this work they obtained $B = 0.27 \times 10^{-18}$ e.s.u. (79 ppm a.u.), which is in fact in fairly good agreement with the B values for C–H protons given in Table 7. Earlier, Schaefer et al.⁸⁰ had pointed out the significance of intramolecular dispersion effects for ^1H on ^{13}C chemical shifts, and Yonemoto⁸¹ studied the van der Waals deshielding caused by halogen atoms.

5.4 Solid State Studies

Measurement of electric fields in solids by the determination of chemical shift changes has also been made. Muha and Yates⁸² started this topic with a proton resonance study of ethylene absorbed on a zeolite. A more recent study is that by Clayden⁸³ who studied ^{13}C shifts on aryl ether compounds. Applications to solid polymers are also possible (see *Solid Polymers: Shielding and Electronic States*).

6 CONCLUSIONS

The recent availability of ab initio calculated A and B values together with both new values and improvements to the old values yet to come should act as a spur not only to studies of chemical shifts in proteins but to the whole area of electric fields on chemical shifts. The A values obtained by calculation appear to be somewhat larger than those obtained from experiment. This may indicate the importance of electric field gradient effects. However, this can only be determined after there have been developments in the formal theory of field gradient effects combined with more ab initio calculations of the field gradient coefficients.

Other topics which stand to gain from the existence of good A and B values are associated with pair interactions in gases and reaction fields in liquids. An improved theory for van der Waals effects on shielding is required but it is not clear whether this can be expressed in terms of a mean square field model.

1 INTRODUCTION

Where an isotopic label is introduced into a molecule, every neighboring resonant nucleus experiences a slight chemical shift. If the labeling is less than 100%, the resonant nuclei in both the labeled and the unlabeled molecules are observed, with intensities according to statistical distribution. The magnitude of the shift depends on the fractional mass change at the isotope substitution site, on the remoteness of the resonant nucleus from the substitution site, and on the sensitivity of the shielding of the resonant nucleus. Every resonant nucleus in the isotopically labeled molecule experiences this chemical shift due to isotopic substitution, but the shift is only observable under favorable conditions, such as when the shift is larger than the halfwidth of the peaks. Isotope shifts as small as a few ppb have been observed, from zero bonds (the isotopic label itself is the resonant nucleus) to 12 bonds away from the substitution site.¹⁻³ When the isotopic label itself is the resonant nucleus, the isotope shift is called a primary isotope shift. Such primary isotope shifts can only be observed indirectly, when two in different molecules are compared. There are also attendant effects on the spin-spin coupling constants in the molecule.⁴ Here, the primary and secondary effects have to be deduced from the proper combination of observed couplings, and it is more appropriate to do this in the reduced coupling constant from which the gyromagnetic ratios have been removed altogether.

Isotope effects on chemical shifts and coupling constants are very important in two distinct ways. First, they have a multitude of practical applications, such as in the determination of molecular structure and the verification of mechanisms of reactions. This is just one more powerful tool in which a very selective tag carries with it the same wealth of information as the chemical shift itself. Second, isotope shifts provide a more stringent test of *ab initio* calculations of chemical shifts in specific molecules, being directly related to the slopes on the shielding surface (a mathematical surface), and, in a more general sense, the trends in the thousands of isotope shifts that have been accumulated¹⁻³ provide insight into the general

nature of these shielding surfaces, in terms of the dependence of the details of the surface on the nature of the chemical bond, the net charge of the molecule, bond orders, presence of lone pairs, etc.^{5,6} Isotope effects on coupling constants lack practical applications, but are invaluable from the second point of view. For the most part, coupling constants are obtained in rapidly tumbling systems, and only the isotropic average of the tensor is obtained. The full tensor is very difficult to extract from experiments in oriented molecules, since it is always observed as a sum with the larger dipolar tensor. Since coupling mechanisms other than the Fermi contact mechanism are the ones that give rise to the anisotropy of the tensor, the lack of tensor information leaves us with a severe dearth of critical tests of the *ab initio* calculations. Isotope effects on coupling constants provide additional critical tests, since they depend on the spin-spin coupling surface, not just a single calculated value. The earliest questions asked of theoretical calculations of chemical shifts demanded only that the relative order of chemical shifts be reproduced and that the relative magnitudes agree with experiment. More recently, we have asked how well the calculations reproduce the absolute shielding in specific molecules, not just their relative shifts, and also how well they reproduce the shielding tensor components. These are more stringent tests of theory. In the isotope shift experiments, we ask for even more detailed agreement: how well do the calculations reproduce the shapes of the shielding surfaces as the nuclear coordinates are displaced away from the immediate vicinity of the equilibrium geometry of the molecule? A similar question is posed for the spin-spin coupling surface by the primary and secondary isotope effects on J .

2 ISOTOPE SHIFTS: OBSERVATIONS

We follow the notation introduced by Gombler⁷ for the isotope shift observed for nucleus A upon substitution of the neighboring m' X isotope:

$${}^n\Delta A(m'/m \text{ X}) = \frac{v_A(A^{m'}X \dots) - v_A(A^mX \dots)}{v_A(A^mX \dots)} (m'/m) \quad (1)$$

where $v_A(A^{m'}X \dots)$ is the resonance frequency of the A nucleus in the molecule having the heavier m' X isotope, which is n bonds away from the observed nucleus. The molecules $(A^{m'}X \dots)$ and $(A^mX \dots)$ are isotopomers. The isotope shift can also be written in terms of the nuclear shielding difference:

$$\begin{aligned} {}^n\Delta A(m'/m \text{ X}) &= \sigma^A(A^mX \dots) - \sigma^A(A^{m'}X \dots) \\ &= \sigma - \sigma^* \end{aligned} \quad (2)$$

where the asterisk applies to the heavy isotopomer. Just as for spin-spin couplings, this notation becomes ambiguous when A and X are atoms in cyclic compounds in which there are at least two paths connecting the observed nucleus and substituted atom, in which case the observed quantity is an isotope shift corresponding to two or more bond paths.

There are several general observations that have been made about magnitudes and signs of isotope shifts.^{1,8}

1. Upon substitution with a heavier isotope, the NMR signal of the nearby nucleus usually shifts towards lower frequencies (higher shielding). Thus, as defined in equations (1) and (2), isotope shifts are generally negative in sign.
2. The magnitude of the isotope shift depends on how remote the isotopic substitution is from the observed nucleus. Although there are exceptions, one-bond isotope shifts are larger than two-bond or three-bond shifts. In the examples shown in Table 1, there is a clear attenuation of the isotope shift with the number of bonds separating the NMR nucleus and the substitution site.^{9,10}
3. The magnitude of the isotope shift is a function of the observed nucleus, and reflects its chemical shift range. Comparisons can be made in analogous compounds, as in Table 2.
4. The magnitude of the shift is related to the fractional change in mass upon isotopic substitution. The larger the fractional change in mass, $(m' - m)/m'$, the larger the isotope shift, as is obvious in the examples in Table 3. (The signals can be easily assigned according to the abundance of the masses m' and m .) When two different atoms can be substituted in the molecule, the isotopic shifts are commensurate with the fractional change in masses, as in the example in Table 4.
5. The magnitude of the shift is approximately proportional to the number of equivalent atoms that have been substituted by isotopes. In other words, isotope shifts exhibit additivity. When there are multiple equivalent sites and the labeling is less than 100%, the resonant nuclei in the variously labeled and the unlabeled molecules are observed. For example, for a deuterium fraction d (based on the solvent isotopic composition for the exchange), for N equivalent replaceable hydrogens, the statistical limit for the relative intensity of the $\text{XH}_{N-n}\text{D}_n$ isotopomer will be

$$I_n = \frac{N!}{n!(N-n)!} (1-d)^{(N-n)} d^n \quad (3)$$

This strictly statistical formula neglects any isotope effects on the equilibrium constant for the exchange. By doing more than one labeling experiment (using different heavy atom fractions), the identification of the signals with the isotopomers can be unequivocal. Fortunately, in many cases, there is also spin-spin coupling information in the NMR spectrum, so that only one labeling experiment is necessary. When there are several equivalent substitution sites, the additivity of the isotope shifts is obvious, as in the examples in Table 5.¹⁵⁻¹⁸ Deviations from strict additivity are small, and their 0:3:4:3:0 ratio in CH_4 -like systems has been explained.¹⁹ Additivity is observed in long-range isotope shifts as well. For example, the two-bond deuterium-induced isotope shifts of ^{59}Co in hexaamminecobalt(III) chloride are all -5.2 ppm per D in each of the 18 different isotopomers of $[\text{Co}(\text{NH}_3)_6]^{3+}$. Less obvious, but also observed, is the additivity of isotope shifts due to substitution at nonequivalent sites.

Table 1

n	$^n\Delta^{31}\text{P}(^{13}/^{12}\text{C})$ in Ph_3P (ppm)	$^n\Delta^{13}\text{C}(^{2}/^1\text{H})$ in butane-1- d_1 (ppm)
1	-0.0227	-0.298
2	-0.0039	-0.088
3	-0.0018	-0.0291
4	—	+0.0051

Table 2

X	$^1\Delta\text{X}(^{13}/^{12}\text{C})$ (ppm)	Chemical shift range (ppm)
^{77}Se in Me_2Se	-0.228	2200
^{125}Te in Me_2Te	-0.341	3160
^{29}Si	-0.006	600
^{119}Sn	-0.018	3000
^{207}Pb	-1.089	9000

X	$^1\Delta\text{X}(^{18}/^{16}\text{O})$ (ppm)	Chemical shift range (ppm)
^{29}Si	-0.0218	600
^{13}C	-0.019	680
^{31}P	-0.018 to -0.036	950
^{15}N	-0.056, -0.138	1200
^{55}Mn	-0.599	3440
^{99}Tc	-0.22	4500
^{95}Mo	-0.25	7000
^{129}Xe	-0.58	7850

X	$^1\Delta\text{X}(^{2}/^1\text{H})$ (ppm)	Chemical shift range (ppm)
^{51}V in $[\text{CpVH}(\text{CO})_3]^-$	-4.7	6000
^{93}Nb in $[\text{CpNbH}(\text{CO})_3]^-$	-6.0	5000
^{183}W in $\text{CpWH}(\text{CO})_3$	-10.0	11500

These are the general trends found for all isotope shifts. These general experimental trends provide the testing grounds for the theory of isotope shifts. There are also some tendencies that are less global in nature but that are perceived as correlations in observations of related classes of compounds; for example, one-bond isotope shifts tend to be larger when the bond order between the observed nucleus and the substituted nucleus is higher. These correlations have to be considered separately, since they involve comparisons between different molecules that have many differences other than in the parameters that are being correlated with the isotope shifts.

3 ROVIBRATIONAL THEORY OF ISOTOPE SHIFTS

The effects of intramolecular dynamics (vibration and rotation) on nuclear shielding were theoretically predicted by Ramsey,²⁰ and have been observed in two ways. First, there is an observable temperature dependence of the resonance frequency, even for the 'isolated' molecule (apart from the temperature dependence due to intermolecular interactions). Second, there is an observable shift upon isotopic substitution of neighboring nuclei. Both are effects of differences in averaging over nuclear configuration as the molecule undergoes vibration and rotation.²¹ The temperature dependence of nuclear shielding is observed in the dilute gas phase.²²⁻²⁵ The nuclear shielding in an 'isolated' molecule, $\sigma_0(T)$, is an average of the nuclear magnetic shielding tensor over all possible orientations of the molecule in the magnetic field, and is actually observed as the nuclear shielding in the limit as the pressure approaches zero. One does not extrapolate the results to a true zero pressure, but to a pressure so low that collisional deformation of the molecule no longer contributes to σ , while there are still enough collisions to provide the required rate of transition between vibrational and rotational states. Thus, $\sigma_0(T)$ is an average over all possible rovibrational states of

Table 3

	82	74	$^1\Delta^{19}\text{F}(^{82/74}\text{Se}) = -0.0576$	

Table 4

Molecule	m'	m	Isotope shift ¹⁴ (ppm)
$[\text{CpVH}(\text{CO})_3]^-$	2	1	$^1\Delta^{51}\text{V}(^{2/1}\text{H}) = -4.7$
	13	12	$^1\Delta^{51}\text{V}(^{13/12}\text{C}) = -0.51$

the molecule, weighted according to the fraction of molecules occupying that state at that temperature.

The average shielding for a given rovibrational state is different for each of several isotopically related species, because the masses enter into the solution of the vibrational–rotational Hamiltonian.²⁶ Thus, the thermal average shielding $\sigma_0(T)$ is different for the isotopomers. These differences are measured as isotope shifts. It is important to know which aspects of isotope shifts are due to dynamical factors (rovibrational averaging of internuclear separations) and which can be attributed to electronic factors (changes in nuclear shielding with bond extension or bond angle deformation). If the theory can sort out the former, isotope shifts can be used to extract the latter, thus providing chemically interesting information that would establish the isotope shift as an easily measurable index of the chemical bond.

3.1 Vibrational Averaging in Diatomic Molecules

The potential energy surface (PES) of a diatomic molecule can be written in terms of a Dunham potential, or more approximately in terms of a Morse potential. The Dunham potential function expresses the potential energy in terms of a Taylor series expansion in $x = (r - r_e)/r_e$:

$$V = a_0x^2(1 + a_1x + a_2x^2 + a_3x^3 + \dots) \quad (4)$$

The potential parameters $a_0, a_1, \dots$ can be obtained from the spectroscopic constants of the molecule. The vibrational levels and functions shown in Figure 1 for the H_2^+ molecule are typical. The first thing to note is that the anharmonic nature of the potential function leads to an unsymmetrical probability distribution function: there is a higher probability of finding the diatomic molecule extended than compressed. Second, this asymmetry becomes more pronounced as we move up in the potential well. Third, the vibrational levels for D_2^+ (shown also as dashed lines) lie lower in the potential well than those for H_2^+ , corresponding to its lower vibrational frequency,

$\omega_e = 1643.0 \text{ cm}^{-1}$ for D_2^+ compared with 2323.5 cm^{-1} for H_2^+ . Since we are interested in vibrational averaging and the mass dependence of shielding, we show in Figure 2 the vibrational functions of D_2^+ and H_2^+ . It is obvious that the anharmonic potential will give rise to different vibrational averages for the isotopomers, since the more sharply peaked and compact probability density of D_2^+ should lead to a different average than that for H_2^+ , in which the probability density is more spread out at the larger separations. This is true for the vibrational ground state, and the differences become even more pronounced at higher vibrational levels. The average values $\langle x^n \rangle$ can be obtained. Complete calculations for some isotopomers of H_2^+ lead to the results for the ground vibrational state shown in Table 6, which also shows the results for the case where the vibration is truly that of a harmonic oscillator (HO).

In order to observe more easily the largest terms that contribute to the above equations and explicitly express their mass dependence, we write only the leading terms, expressed in the measured spectroscopic constants of the molecule.⁸

$$\langle x \rangle_{\text{vJ}} = -3(v + \frac{1}{2})a_1 \frac{B_e}{\omega_e} + 4J(J+1) \frac{B_e}{\omega_e^2} \quad (5)$$

$$\langle x^2 \rangle_{\text{vJ}} = 2(v + \frac{1}{2}) \frac{B_e}{\omega_e} \quad (6)$$

Of these quantities, a_1 is mass-independent, and the others depend on the reduced mass of the diatomic molecule as follows:

$$\omega_e^* = \left(\frac{\mu}{\mu^*}\right)^{1/2} \omega_e, \quad B_e^* = \frac{\mu}{\mu^*} B_e \quad (7)$$

Furthermore, the thermal average $\langle v + \frac{1}{2} \rangle^T$ is also mass-dependent, since the populations of the vibrational energy levels over which this average is taken depend on the vibrational frequency ω_e . Note that B_e/ω_e^2 is mass-independent, so the rotational contribution to the thermal average shielding in the diatomic molecule is independent of mass.

Note also that if we include only the leading terms then

$$\langle x \rangle_{\text{v}} = -\frac{3}{2}a_1 \langle x^2 \rangle_{\text{v}} \quad (8)$$

The difference between two isotopomers is

$$\langle x^2 \rangle_{\text{vJ}} - \langle x^2 \rangle_{\text{vJ}}^* = 2 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*}\right)^{1/2} \right] (v + \frac{1}{2}) + \dots \quad (9)$$

4 ISOTOPE EFFECTS ON CHEMICAL SHIFTS AND COUPLING CONSTANTS

Table 5

	PHD_2	-1.6491	-1.6916	-0.042
	PD_3	-2.5373	-2.5373	0
^{15}N	NH_3	0.0	0.0	0
	NH_2D	-0.6264	-0.6229	0.0035
	NHD_2	-1.2491	-1.2458	0.0033
	ND_3	-1.8687	-1.8687	0
^{15}N	NH_4^+	0.0	0.0	0
	NH_3D^+	-0.3077	-0.2933	+0.0144
	NH_2D_2^+	-0.6048	-0.5865	+0.0183
	NHD_3^+	-0.8937	-0.8798	+0.0139
	ND_4^+	-1.1730	-1.1730	0
^{13}C	CH_4	0.0	0.0	0
	CH_3D	-0.2016	-0.19865	+0.003
	CH_2D_2		-0.3973	
	CHD_3	-0.6006	-0.5960	+0.004
	CD_4	-0.7946	-0.7946	0

$$\langle x \rangle_{\text{vJ}} - \langle x \rangle_{\text{vJ}}^* = -3a_1 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \left(v + \frac{1}{2} \right) + \dots \quad (10)$$

The leading term in $\langle x^3 \rangle_{\text{vJ}}$ has the same mass dependence as the next higher order term in $\langle x \rangle$ and $\langle x^2 \rangle$; thus, it is consistent to include only the above two terms. We find the ratios from the full calculations:

$$\frac{\langle x \rangle_{\text{H}_2^+} - \langle x \rangle_{\text{HT}^+}}{\langle x \rangle_{\text{H}_2^+} - \langle x \rangle_{\text{HD}^+}} = 1.370 \quad (11)$$

$$\frac{\langle x^2 \rangle_{\text{H}_2^+} - \langle x^2 \rangle_{\text{HT}^+}}{\langle x^2 \rangle_{\text{H}_2^+} - \langle x^2 \rangle_{\text{HD}^+}} = 1.369 \quad (12)$$

whereas using *only* the leading terms leads in both cases to the ratio

$$\frac{1 - (\mu_{\text{H}_2^+}/\mu_{\text{HT}^+})^{1/2}}{1 - (\mu_{\text{H}_2^+}/\mu_{\text{HD}^+})^{1/2}} = 1.370 \quad (13)$$

Qualitatively, the mass change accompanying the replacement of ^mX by its heavier isotope $^{m'}\text{X}$ leads to a shorter average

bond length. In Figure 2, we show for the lowest vibrational levels the probabilities of finding the diatomic molecule at the various internuclear separations. For the same anharmonic potential, the lighter isotopomer H_2^+ clearly shows greater probabilities of being found in a more extended configuration compared with D_2^+ at each vibrational state. Since the vibrational frequencies are lower for the heavier isotopomer, the populations of its higher vibrational states are somewhat greater. Both effects constitute the mass dependence of the thermal average $\langle x \rangle^{\text{T}}$, with the latter being less important than the former:

$$\{\langle x \rangle^{\text{T}} - \langle x \rangle^{*\text{T}}\} \approx -3a_1 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \left(v + \frac{1}{2} \right)^{\text{T}} \quad (14)$$

If we use a harmonic oscillator density of vibrational states, we get a simple form

$$\left(v + \frac{1}{2} \right)_{\text{HO}}^{\text{T}} = \frac{1}{2} \coth(hc\omega_e/2k_{\text{B}}T) \quad (15)$$

which itself has a mild mass dependence, which is not too important when ω_e is large, in which case $\coth(hc\omega_e/2k_{\text{B}}T)$

Figure 1 Vibrational levels and wavefunctions (squared) for the H_2^+ molecule. Also shown, by dashed lines, are the vibrational levels of the D_2^+ molecule

is very close to 1. A useful form of an approximate potential for the diatomic molecule is the Morse function

$$V = D_e \{1 - \exp[-a(r - r_e)]\}^2 \quad (16)$$

where D_e is the dissociation energy and a is called the Morse parameter, ar_e being a dimensionless quantity related to the ratio

$$\frac{1}{3!} \left(\frac{d^3 V}{dx^3} \right)_e \bigg/ \frac{1}{2!} \left(\frac{d^2 V}{dx^2} \right)_e = -ar_e = a_1 \quad (17)$$

and

$$\langle x \rangle = \frac{3}{2} ar_e \langle x^2 \rangle \quad (18)$$

At this level of theory, the mass dependence of $\langle x^2 \rangle$ is the same as that of $\langle x \rangle$. Thus, we find that for diatomic molecules, neglecting the mass dependence in the coth function,

$$\begin{aligned} \langle x \rangle^T - \langle x \rangle^{*T} &\approx \frac{3ar_e}{2} \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \coth \left(\frac{hc\omega_e}{2k_B T} \right) \\ &\approx \langle x \rangle^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \end{aligned} \quad (19)$$

or

$$\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T} \approx \langle \Delta r \rangle_{\text{vib}}^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \quad (20)$$

Figure 2 Vibrational wavefunctions (squared) for the D_2^+ molecule (heavy lines) and the H_2^+ molecule (light lines)

$$\langle \Delta r \rangle_{\text{vib}}^T \approx \frac{3ar_e^2}{2} \frac{B_e}{\omega_e} \coth \left(\frac{hc\omega_e}{2k_B T} \right) \quad (21)$$

When μ/μ^* is very close to 1 (which is true for most situations not involving hydrogen), $1 - (\mu/\mu^*)^{1/2}$ can be further approximated by $(\mu^* - \mu)/2\mu^*$ or, in the comparison of the isotopomers A^mX and $\text{A}^{m'}\text{X}$, by²⁷

$$1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \approx \frac{1}{2} \frac{(m' - m)}{m'} \frac{m_A}{(m_A + m)} \quad (22)$$

$$\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T} \approx \langle \Delta r \rangle_{\text{vib}}^T \frac{1}{2} \frac{(m' - m)}{m'} \frac{m_A}{(m_A + m)} \quad (23)$$

with an analogous expression for $\langle (\Delta r)^2 \rangle$. Here we find already the origin of general trend 4 in Section 2. The dynamic factors contain the mass dependence, and in diatomic molecules this mass dependence takes a simple form. It is interesting to point out here that, even for polyatomic molecules, this mass dependence has been found to hold: for $m'/m \text{SeF}_6$, a plot of $\langle \Delta r_{\text{SeF}} \rangle^T$ and $\langle (\Delta r_{\text{SeF}})^2 \rangle^T$ versus $(m' - m)/m'$ for $m = 74$ and $m' = 76, 77, 78, 80, 82$ leads to straight lines passing through the origin.²⁸

A very interesting global description of potential functions for diatomic molecules was given by Herschbach and Laurie.²⁹ They found that the second and third derivatives of the potential could be described by exponential functions of the equilibrium internuclear distance, each described by a family of curves which are determined by the locations of the bonded atoms in rows of the Periodic Table:

$$(-1)^n F_n = 10^{-(r_e - p_n)/q_n} \quad (24)$$

where

$$F_3 \equiv \frac{1}{3} \left(\frac{d^3 V}{dr^3} \right)_e, \quad F_2 \equiv \left(\frac{d^2 V}{dr^2} \right)_e \quad (25)$$

and p_n and q_n are parameters that characterize any two rows of the Periodic Table. It was proposed by Jameson and Osten²⁷ that the averages $\langle x \rangle_v$ and $\langle x^2 \rangle_v$ can be determined entirely from a knowledge of the r_e and the rows of the Periodic Table to which the atoms belong, using the following relations:

$$\langle \Delta r \rangle_v = r_e \langle x \rangle_v \approx \frac{3h}{8\pi} \mu^{-1/2} 10^{-D} (2v + 1) \quad (26)$$

$$\langle (\Delta r)^2 \rangle_v = r_e^2 \langle x^2 \rangle_v \approx \frac{h}{4\pi} \mu^{-1/2} 10^{-d} (2v + 1) \quad (27)$$

where

$$D \equiv \frac{r_e - p_3}{q_3} - \frac{3(r_e - p_2)}{2q_2} \quad (28)$$

$$d \equiv \frac{r_e - p_2}{2q_2} \quad (29)$$

Figure 3 shows a plot of $\langle \Delta r \rangle_{\text{vib}}$ calculated at 300 K for a large set of diatomic molecules using their individual spectroscopic constants. It appears that the global relation given in equation (26) provides a reasonably good description of the vibrationally averaged bond displacement for diatomic molecules. It has been shown that these equations can be used as well to estimate the dynamic parts for polyatomic molecules, except that the constant factor is closer to $\frac{3}{7}$ than $\frac{3}{8}$.

3.2 The Shapes of Shielding Surfaces

In the context of the Born–Oppenheimer approximation, analogous to the potential energy surface, which is a mass-independent electronic property of a molecule in a given electronic state, there is likewise a mass-independent nuclear shielding surface that describes the variation of the shielding as a function of nuclear configuration. For a diatomic molecule, this surface can be described entirely in terms of the internuclear separation. Two examples are shown in Figures 4 and 5. At the united atom limit ($r = 0$), the diamagnetic shielding of the He^+ ion is (not shown) 35.5009 ppm. At the equilibrium geometry of H_2^+ , the proton shielding is 11.4296 ppm, and at the separated atom limit, the diamagnetic shielding corresponds to half that of the free hydrogen atom ($\frac{1}{2}$) 17.75 ppm.³⁰ The other example is ^{23}Na shielding in NaH, in which the shielding at the equilibrium geometry is lower than for the separated system (either Na^+ or Na atom).³¹ Figure 4 is a typical shielding surface for diatomic molecules in that the shielding surface has negative first and second derivatives.^{32,33} For example, ^{19}F in the HF molecule and in the F_2 molecule, and ^{35}Cl in the HCl molecule and in the ClF molecule, all have negative first and second derivatives; that is, deshielding accompanies bond extension. It is also typical for the proton shielding in the molecule at its equilibrium geometry to be greater than that for the free H atom in the separated systems. On the other hand, the heavy nuclei

Figure 3 Mean bond displacement in diatomic molecules calculated by vibrational averaging over their individual potential surfaces compared with the global form $\langle \Delta r \rangle_{\text{vib}} \approx (3h/8\pi) \mu^{-1/2} 10^{-D}$ (the straight line), where D is defined in equation (28). (Reproduced by permission of the American Institute of Physics from Jameson and Osten²⁷)

are generally deshielded in the molecule at its equilibrium geometry compared with the diamagnetic shielding of the free atom. For example, nearly all ^{19}F nuclei have shielding less than 470.71 ppm. (^{19}F in ClF is a notable exception, and ^{19}F in CH_3F has an isotropic shielding nearly the same as that of the free F atom.) Every ^{19}F shielding first derivative at the equilibrium geometry, including ^{19}F in the ClF molecule, has been found to be negative, and the second derivative is negative as well.³⁴ On the other hand, the shielding surfaces for ^{23}Na in NaH and ^7Li in LiH have positive first derivatives at the equilibrium geometry.³¹ The shapes of the shielding surfaces in Figures 4 and 5 are fairly similar; the major difference is which point on the shielding surface corresponds to the pocket in the PES and to which side of the shielding minimum this point corresponds. We have seen that the general behavior in vibrational averaging in the anharmonic PES is that the probabilities are greater on the $r > r_e$ side. Thus, dynamic averaging always leads to deshielding when the pocket in the PES is to the short- r side of the shielding minimum, whereas dynamic averaging leads to increased shielding relative to the shielding at the equilibrium geometry when the pocket in the PES is to the longer- r side of the shielding minimum. Most nuclei that are observed in NMR are found on the right-hand side of the Periodic Table, where the shielding surface and the PES are related as in Figure 4; there are fewer observations of the alkali and alkaline earth nuclei, whose shielding surfaces and PES are related as in Figure 5. Therefore, the usual case

Figure 4 The ^1H shielding surface for the H_2^+ molecule is shown with the potential energy surface. The shielding surface is from ab initio calculations by Hegstrom.³⁰ (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

is more like Figure 4. Here then is the explanation for general trend 1 in Section 2: superposition of Figure 2 on Figure 4 would lead to a nucleus in the lighter isotopomer being less shielded than the same nucleus in the heavy isotopomer. Preponderance of this situation would lead to a nearly universal sign of one-bond isotope shifts. The exceptions will be Li and Na in the hydrides, for example.

The magnitudes of the isotope shifts would correspond to the ranges of chemical shifts of the observed nucleus if the shielding surfaces themselves scale to these. Let us see. We present the shielding surfaces in the vicinity of the equilibrium geometry in analogous compounds in Figure 6, where ^{19}F in F_2 is compared with ^{35}Cl in ClF (both are bonded to fluorine). ^{19}F in HF is compared with ^{35}Cl in HCl (both are bonded to an H atom). Finally, ^{23}Na in NaH is compared with ^7Li in LiH . It is found that if the change in shielding, $\sigma(r) - \sigma(r_e)$, is scaled by the factor $r_e \langle a_0^3/r^3 \rangle$, the equilibrium bond distance in the molecule and the purely electronic quantity $\langle a_0^3/r^3 \rangle$ characteristic of the atom, for the observed nucleus, the surfaces that describe the change in the shielding of different nuclei in analogous bonding situations superimpose.³¹ This then is an explanation for general trend 3 in Section 2: the magnitude of the isotope shift is a function of the observed nucleus and reflects its chemical shift range. A general discussion of shielding surfaces is given by de Dios and Jameson.³⁵

3.3 Averaging Over Shielding Surfaces

It is sometimes actually necessary to evaluate the average over a large part of the shielding surface.³⁶ For example, the

Figure 5 The ^{23}Na shielding surface for the NaH molecule is shown with the potential energy surface. The shielding surface is from ab initio calculations by Jameson and de Dios. (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

PES of the NH_3 molecule has a rather broad double minimum in the inversion coordinate. The trace on the ^{15}N shielding surface along this inversion coordinate is shown in Figure 7. To obtain the contribution to the average ^{15}N shielding from this degree of freedom, it was necessary to find the numerical PES (which are highly anharmonic) and solve for the vibrational wavefunctions. These are shown in Figure 7. The average for each state 0^s , 0^a , 1^s , 1^a , 2^s , 2^a was numerically calculated with these functions, $\langle \Psi_v | \hat{\sigma} | \Psi_v \rangle$, and the thermal average is obtained as

$$\langle \sigma \rangle^T = \frac{\sum_v e^{-E_v/k_B T} \langle \sigma \rangle_v}{\sum_v e^{-E_v/k_B T}} \quad (30)$$

For semirigid molecules that we often observe in NMR (excluding molecules that are fluxional or that undergo low-frequency torsion), the motions involved in the averaging take place in a small pocket of the potential energy surface close to the equilibrium configuration. It is therefore not necessary to calculate the entire shielding surface, as we have shown in Figures 4, 5, and 7. In the same way that averages such as $\langle x \rangle$, $\langle x^2 \rangle$, $\langle x^3 \rangle$, etc. could be evaluated in terms of the derivatives of the PES such as represented by the quantities a_0 , a_1 , a_2 , a_3 , etc. in the Dunham potential function, it is possible to calculate the average shielding from derivatives of the shielding surface at the equilibrium geometry, since we only need to average over very small displacements away from the minimum in the PES.

Figure 6 The shielding surfaces of analogous diatomic molecules in the vicinity of the equilibrium geometry, in the range of nuclear displacements spanning the classical turning points of the ground vibrational state. (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

For a diatomic molecule, it is convenient to expand the shielding surface as a power series in $x = (r - r_e)/r_e$. For a particular molecular state characterized by vibrational and rotational quantum numbers v and J ,

$$\langle \sigma \rangle_{vJ} = \sigma_e + \left(\frac{d\sigma}{dx} \right)_e \langle x \rangle_{vJ} + \frac{1}{2} \left(\frac{d^2\sigma}{dx^2} \right)_e \langle x^2 \rangle_{vJ} + \dots \quad (31)$$

Here $\langle x \rangle_{vJ}$, $\langle x^2 \rangle_{vJ}$, ... are the averages over the vibrational-rotational wavefunctions corresponding to the (v, J) level, which we have already described in Section 3.1. The isotope shift is therefore given by

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &= \left(\frac{d\sigma}{dx} \right)_e (\langle x \rangle^T - \langle x \rangle^{*T}) \\ &+ \frac{1}{2} \left(\frac{d^2\sigma}{dx^2} \right)_e (\langle x^2 \rangle^T - \langle x^2 \rangle^{*T}) + \dots \end{aligned} \quad (32)$$

With the approximations described in Section 3.1, using the Morse parameter,

Figure 7 The ^{15}N shielding surface of NH_3 along the inversion coordinate β (the angle between the symmetry axis and a N–H bond) is shown with the vibrational wavefunctions for the lowest inversion levels. The shielding average can be obtained by numerical integration as $\langle \sigma \rangle_v = \int \Psi_v^*(\beta) \sigma(\beta) \Psi_v(\beta) d\beta$. (Reproduced by permission of the American Institute of Physics from Jameson et al.³⁶)

$$\langle x \rangle^T \approx \frac{3}{2} a r_e \langle x^2 \rangle^T \quad (33)$$

the isotope shift in diatomic molecules is given by

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &\approx \left[\left(\frac{d\sigma}{dx} \right)_e + \frac{1}{3a r_e} \left(\frac{d^2\sigma}{dx^2} \right)_e \right] (\langle x \rangle^T - \langle x \rangle^{*T}) + \dots \\ &\approx \left[\left(\frac{d\sigma}{dr} \right)_e + \frac{1}{3a} \left(\frac{d^2\sigma}{dr^2} \right)_e \right] (\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T}) \end{aligned} \quad (34)$$

and, when $\coth(hc\omega_e/2k_B T)$ is close to 1,

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &\approx \left[\left(\frac{d\sigma}{dr} \right)_e + \frac{1}{3a} \left(\frac{d^2\sigma}{dr^2} \right)_e \right] \\ &\times \langle \Delta r \rangle_{\text{vib}}^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \end{aligned} \quad (35)$$

In equations (34) and (35), the first quantity (in square brackets) is a mass-independent purely electronic quantity; the second quantity is a mass-dependent dynamic factor. As we have seen, both the first and second derivatives of the shielding surface are most often negative. Right here, we see that the sign of the isotope shift is negative owing to $(d\sigma/dr)_e$ being negative, since the shift is defined such that the dynamic factor is positive; that is, the nucleus in the light isotopomer is less shielded (appears at higher frequency) than the nucleus in the heavy isotopomer. The unusual (positive) sign of the isotope shift will be observed when the shielding derivative is positive, such as for ^{23}Na in NaH or ^7Li in LiH . For polyatomic molecules, it makes physical sense to expand the nuclear shielding in terms of the normal coordinates Q_s (a concept of significance only for small displacements):^{21,37}

$$\sigma = \sigma_e + \sum_s \left(\frac{\partial \sigma}{\partial Q_s} \right)_e Q_s + \frac{1}{2} \sum_{s,r} \left(\frac{\partial^2 \sigma}{\partial Q_r \partial Q_s} \right)_e Q_r Q_s + \dots \quad (36)$$

where the shielding derivatives are taken at the equilibrium configuration. Normal coordinates are a logical choice for this expansion, since methods of evaluating the average values $\langle Q_s \rangle$ and $\langle Q_r Q_s \rangle$ are well known in vibrational spectroscopy. However, the derivatives of the nuclear shielding with respect to the mass-dependent normal coordinates are not invariant under isotopic substitution. For the purpose of discussing the isotope shift, it is more convenient to expand the shielding in terms of mass-independent internal displacement coordinates:^{5,21}

$$\sigma = \sigma_e + \sum_i \left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e \mathcal{J}_i + \frac{1}{2} \sum_{ij} \left(\frac{\partial^2 \sigma}{\partial \mathcal{J}_i \partial \mathcal{J}_j} \right)_e \mathcal{J}_i \mathcal{J}_j + \dots \quad (37)$$

where $\mathcal{J}_i$ stands for the bond displacements (Δr_i) and the bond angle deformations $(\Delta \alpha_{ij})$.

The theoretical interpretation of isotope shifts in polyatomics therefore involves the mass-independent electronic quantities such as

$$\left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e = \left(\frac{\partial \sigma}{\partial \Delta r} \right)_e, \quad \left(\frac{\partial \sigma}{\partial \Delta \alpha} \right)_e, \quad \dots \quad (38)$$

which describe the change in nuclear shielding with bond extension or angle deformation, and the mass-dependent thermal averages $\langle \mathcal{J}_i \rangle^T$, which are $\langle \Delta r \rangle^T$, $\langle \Delta \alpha \rangle^T$, ... and $\langle \mathcal{J}_i \mathcal{J}_j \rangle^T$, which are $\langle (\Delta r)^2 \rangle^T$, $\langle (\Delta \alpha)^2 \rangle^T$, $\langle \Delta r \Delta \alpha \rangle^T$, The isotope shift is given by

$$\begin{aligned} \sigma - \sigma^* &= \sum_i \left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e (\langle \mathcal{J}_i \rangle^T - \langle \mathcal{J}_i \rangle^{T*}) \\ &+ \frac{1}{2} \sum_{ij} \left(\frac{\partial^2 \sigma}{\partial \mathcal{J}_i \partial \mathcal{J}_j} \right)_e (\langle \mathcal{J}_i \mathcal{J}_j \rangle^T - \langle \mathcal{J}_i \mathcal{J}_j \rangle^{T*}) + \dots \end{aligned} \quad (39)$$

In order to be able to evaluate $\langle \mathcal{J}_i \rangle^T$, $\langle \mathcal{J}_i \mathcal{J}_j \rangle^T$ etc., we need a potential surface in which the vibrational motion of the molecule takes place. The known derivatives of this surface are the quadratic, cubic, etc. force constants. Normal coordinate analysis with the quadratic force constants gives the solutions to the harmonic problem, which are the harmonic frequencies ω_s , the normal coordinates Q_s , and the $\mathbf{L}$ matrix. The internal displacement coordinates $\mathcal{J} = \Delta r_j$, $\Delta \alpha_{ij}$, etc. can be expressed in terms of these normal coordinates in the general relation³⁸

$$\mathcal{J} = \mathbf{Q} \quad (40)$$

where is a tensor containing the transformation coefficients between the curvilinear internal coordinates and various powers of Q_s . The vibrational part of Δr_i is then

$$\Delta r_i = \sum_l L_i^l Q_l + \frac{1}{2} \sum_{r,s} L_i^{rs} Q_r Q_s + \frac{1}{6} \sum_{r,s,t} L_i^{rst} Q_r Q_s Q_t + \dots \quad (41)$$

Thus, the vibrational average $\langle \Delta r \rangle_{\text{vib}}$ can be expressed in terms of $\langle Q_r \rangle$, $\langle Q_r Q_s \rangle$, etc. The analytical expressions for elements of the $\mathbf{L}$ tensor are given by Hoy et al.,³⁸ in which the linear terms L_i^r are identical to the elements L_{ir} of the $\mathbf{L}$ matrix. The above equation is exact, but in practice, of course, the series must be truncated; in general, it converges well, each term being smaller than the preceding by a factor of about 10 for typical vibrational amplitudes. The expectation values of only totally symmetric coordinates Q_s are required:³⁹

$$\langle Q_s \rangle = \left(\frac{h}{4\pi^2 c} \right)^{1/2} \omega_s^{-3/2} \left[3k_{sss} \left(v_s + \frac{1}{2} \right) + \sum_r k_{srr} \left(v_r + \frac{1}{2} g_r \right) \right] \quad (42)$$

where ω_s are the normal frequencies and k_{srr} are the cubic force constants, both in wavenumbers. g_r denotes the degeneracy of the r th vibration. $\langle Q_r Q_s \rangle = 0$ if $\omega_r \neq \omega_s$, and

$$\langle Q_s^2 \rangle = \frac{h}{4\pi^2 c \omega_s} \left(v_s + \frac{1}{2} \right) \quad (43)$$

To obtain the thermal average shielding, we again need $\langle v_s + \frac{1}{2} \rangle^T$. For larger molecules, it becomes impossible to calculate a sufficient number of rovibrational states in order to use the exact method for the thermal averaging, so the only practical way of calculating expectation values of molecular properties over different rotational and vibrational states for a given temperature is by using the harmonic approximation for the vibrational partition function, that is,

$$\langle v_s + \frac{1}{2} \rangle^T = \frac{1}{2} \coth(hc\omega_s/2k_B T) \quad (44)$$

3.4 Relative Magnitudes of Terms That Contribute to the Isotope Shift

Mass substitution at one site in the molecule affects dynamic averages of all electronic properties. If, in particular, we have nuclear spins at various sites, all of these will have different average shifts; some will experience larger changes than others. In general, the entire molecule participates in the dynamic averaging. Depending on the nature of each nuclear shielding surface, the change in chemical shift may be of either sign. Each molecule offers a unique situation, and, especially for the long-range isotope effects, vibrations involving many atoms may play a part. To illustrate the types of terms that contribute to a one-bond isotope shift, we use the

$^1\Delta$ ^{13}C ($^{2/1}\text{H}$) in CH_4 as an example. During vibration, the displacements away from the equilibrium nuclear configuration can be small enough that a Taylor series expansion can be used:⁴⁰

$$\begin{aligned} \langle \sigma^{\text{C}} \rangle = & \sigma_{\text{e}} + P_r(\langle \Delta r_1 \rangle + \langle \Delta r_2 \rangle + \langle \Delta r_3 \rangle + \langle \Delta r_4 \rangle) \\ & + \frac{1}{2} P_{rr}[\langle (\Delta r_1)^2 \rangle + \langle (\Delta r_2)^2 \rangle + \langle (\Delta r_3)^2 \rangle + \langle (\Delta r_4)^2 \rangle] \\ & + P_{rs}(\langle \Delta r_1 \Delta r_2 \rangle + \langle \Delta r_1 \Delta r_3 \rangle + \langle \Delta r_1 \Delta r_4 \rangle \\ & + \langle \Delta r_2 \Delta r_3 \rangle + \langle \Delta r_2 \Delta r_4 \rangle + \langle \Delta r_3 \Delta r_4 \rangle) \\ & + \frac{1}{2} P_{\alpha\alpha}[\langle (\Delta \alpha_{12})^2 \rangle + \dots] + P_{\alpha\beta}(\langle \Delta \alpha_{12} \Delta \alpha_{13} \rangle + \dots) \\ & + P_{r\alpha}(\langle r_1 \Delta \alpha_{12} \rangle + \dots) + P_{\alpha\omega}(\langle \Delta \alpha_{12} \Delta \alpha_{34} \rangle + \dots) \\ & + \text{higher-order terms} \end{aligned} \quad (45)$$

where $P_r \equiv (\partial \sigma^{\text{C}} / \partial r_1)_{\text{e}}$, while P_{rr} and P_{rs} are the second derivatives of the ^{13}C shielding with respect to the C–H bond distances; $P_{\alpha\alpha}$, $P_{\alpha\beta}$, and $P_{\alpha\omega}$ are the second derivatives of the ^{13}C shielding with respect to the HCH bond angles, and $P_{r\alpha}$ is the mixed second derivative $(\partial^2 \sigma^{\text{C}} / \partial r_1 \partial \alpha_{12})_{\text{e}}$. In some molecules, there are first derivatives with respect to the angle as well, for example, for ^{17}O in H_2O and ^{31}P in PH_3 .^{41,42} In yet others, the averaging cannot be carried out by considering small displacements, as in the inversion motion of the NH_3 molecule. The complexity of the equation increases with increasing number of atoms. Nevertheless, many general trends may be observed in the huge body of information represented in tables of thousands of isotope shifts.^{1–3} These trends have become apparent, despite the uniqueness of the dynamic averaging of each molecule, because some terms in the full theory are more dominant than others. It is the persistence of the dominant contributions in most molecules that allows us to consider isotope shifts in much simpler terms, short of full averaging of full shielding surfaces in every case. In Table 7, we examine the relative magnitudes of terms that contribute to the isotope shift in selected molecules, where the calculations of the many terms (as shown above for CH_4) have been carried out to gain some insight into what might be expected in other molecules.^{36,42–46} Clearly, the mixed terms and higher-order terms (listed in Table 7 as ‘Other’) are negligible compared with the total isotope shift. The P_r term, which is due entirely to the anharmonicity of the vibration, provides the largest contribution, but P_{rr} terms are not negligible. The stretch (P_r and P_{rr} terms together) dominate, even in the case of NH_3 , where the inversion mode gives significant angle deformation contributions. If we can extrapolate these results to larger molecules, we can say that the bond stretching contributions dominate one-bond isotope shifts, and the anharmonic part of this, which goes with the first

shielding derivative $(\partial \sigma / \partial r)_{\text{e}}$, gives the largest contribution. However, the terms involving the second derivative $(\partial^2 \sigma / \partial r^2)_{\text{e}}$ are also important. Bond angle contributions are uniformly less important than the bond stretching contributions to the isotope shift.

If we take the experimental isotope shift and use an estimate for the dynamic factor $\langle \Delta r_{\text{XH}} \rangle - \langle \Delta r_{\text{XD}} \rangle$, we arrive at a reasonable estimate of the shielding derivative $(\partial \sigma / \partial r)_{\text{e}}$ in the molecule. Indeed, Table 8 shows that the estimated shielding derivatives compare reasonably well with the derivatives obtained from the ab initio shielding surfaces.

3.5 Additivity of Isotope Shifts

We can use the isotopomers of the CH_4 molecule to illustrate the additivity of NMR isotope shifts. The mean bond displacements in the methane family $\text{CX}_{4-n}\text{Y}_n$ (where X, Y = H, D, T) have been calculated using the anharmonic force field of methane.¹⁹ It has been found that the substitution effects on the vibrational contribution to mean bond displacements are strictly additive. Each substitution of a hydrogen by a deuterium shortens the appropriate bond by nearly the same amount Δ . The mean bond displacements in $^{12}\text{CH}_{4-n}\text{T}_n$ and $^{12}\text{CD}_{4-n}\text{T}_n$ exhibit the same strictly linear dependence on n . We can express $\langle \Delta r_{\text{CH}} \rangle$ and $\langle \Delta r_{\text{CD}} \rangle$ in $^{12}\text{CH}_{4-n}\text{D}_n$ as follows. If we let

$$d = \langle \Delta r_{\text{CH}} \rangle \quad \text{in } \text{CH}_4 \text{ at } 300 \text{ K} \quad (46)$$

Table 7 Isotope Shifts $\sigma^{\text{X}}(\text{XH}_n) - \sigma^{\text{X}}(\text{XD}_n)$ (in ppm) Calculated for ^{13}C , ^{15}N , ^{31}P , ^{17}O , and ^{77}Se Nuclei

^aCalculated by Jameson,⁴⁵ based on the points on the ab initio shielding surface of Tossell and Lazzeretti.⁴⁶

$$d - \Delta = \langle \Delta r_{CD} \rangle \quad \text{in } \text{CD}_4 \text{ at } 300 \text{ K} \quad (47)$$

where $d = 2.0881 \text{ pm}$ and $\Delta = 0.553 \text{ pm}$, we find for $\text{CH}_{4-n}\text{D}_n$ that

$$\langle \Delta r_{CD} \rangle = d - \Delta + (4 - n)\delta_D \quad (48)$$

$$\langle \Delta r_{CH} \rangle = d + n\delta_H \quad (49)$$

Similar relations can be found for the other series of isotopomers. That is, for a given bond, substitution of an isotope involved in this bond had an effect Δ on its own mean bond length (a primary effect on the mean bond displacement); each substitution of an isotope at some other bond has a much smaller effect δ (a secondary effect). The ^2H -induced ^{13}C NMR isotope shift between any two isotopomers of $\text{CH}_{4-n}\text{D}_n$ can then be expressed as

$$\begin{aligned} \sigma^C(\text{CH}_{4-n}\text{D}_n) - \sigma^C(\text{CH}_{4-n'}\text{D}_{n'}) &= \left(\frac{\partial \sigma^C}{\partial r} \right)_e \\ &\quad \times [(n' - n)\Delta + \text{terms in } \delta] \\ &\approx \left(\frac{\partial \sigma^C}{\partial r} \right)_e (n' - n)\Delta \end{aligned} \quad (50)$$

This is the basis for the near-additivity of isotope shifts due to substitution at equivalent sites. If we leave out the terms in δ (which are about two orders of magnitude smaller than Δ), we have strict additivity: the magnitude of the shift is proportional to the number $n' - n$ of atoms that have been substituted by isotopes. Even when all the terms in P_{rr} , P_{rs} , P_{rs} , etc. are included and calculated properly, the nearly strict additivity of isotope shifts is preserved. Although there are many smaller changes that are not quite the same as each ^mX is replaced by $^{m'}\text{X}$, it has been shown that these smaller changes lead to only slight deviations from additivity, which deviations incidentally have been observed^{15–18} just as predicted.¹⁹

4 GENERAL TRENDS IN THE ELECTRONIC FACTORS

We have already seen that the dynamical factors in one-bond isotope shifts are fairly predictable, and can even be estimated without a good force field because the mass-independent part of the dynamic factor is largely determined by the bond length and the rows of the Periodic Table of the pair of bonded atoms. We have also seen that the mass dependence of the isotope shift and its additivity can be explained entirely by the dynamic factors for one-bond isotope shifts. All other trends must therefore be attributable to trends in the electronic factor and the first and second derivatives of the nuclear shielding. If we estimate the dynamic factors $\langle \Delta r \rangle - \langle \Delta r \rangle^*$ as described in Section 3.1, it is possible to obtain the magnitudes and signs of the electronic factor $[(\partial \sigma / \partial r)_e + (1/3a)(\partial^2 \sigma / \partial r^2)_e]$, which we shall denote simply by $(\partial \sigma / \partial r)_e$, with the understanding that the first-derivative terms nearly always dominate, although the ratio of the above two terms may range from 10:1 to 3:1.

Some trends in $(\partial \sigma / \partial r)_e$ have been predicted from the observed trends in isotope shifts.^{5,6} Recent ab initio calculations have explored the generality of these trends and the limits and conditions of their applicability.³⁴

1. $(\partial \sigma / \partial r)_e$ is usually negative. The general shape of the shielding surface shown in Figure 4 seems to be typical for a diatomic molecule, and, for most nuclei, the minimum in the shielding surface occurs at separations larger than the equilibrium internuclear separation, leading to a negative $(\partial \sigma / \partial r)_e$. The exceptional sign of $(\partial \sigma / \partial r)_e$ arises when the minimum in the shielding surface lies inside the equilibrium internuclear separation, as in Figure 5. In polyatomic molecules, negative $(\partial \sigma / \partial r)_e$ are also much more commonly found than positive ones, leading to the usual (negative) sign of the isotope shift.
2. $(\partial \sigma / \partial r)_e$ generally increases with the chemical shift range of the nucleus. We have seen in Figure 6 that changes in the shielding upon displacement away from the equilibrium geometry do scale in analogous compounds according to $\langle a_0^3 / r^3 \rangle$ for the free atom, which is the same factor that varies periodically across the Periodic Table in the same way as the ranges of chemical shifts.^{54,55} Because of this correlation, an easy way to obtain an estimate of an isotope shift is to use the scaling factor of $\langle a_0^3 / r^3 \rangle$ values to provide a Periodic-Table-wide set of 'reduced isotope shifts', which need only be multiplied by the mass factors $[(m' - m)/m'] \times (m_A + m)/2m_A$ to get an estimate of the one-bond isotope shift induced by any isotopic substitution for any nucleus in any molecule.⁵⁶
3. $(\partial \sigma / \partial r)_e$ has been found to correlate with the absolute shielding σ_0 in related molecules: at the equilibrium geometry, the most deshielded environments have more steeply changing shielding surfaces. When the dynamic terms are very similar, this forms the basis for the correlations of $^1\Delta$ with chemical shifts, which have been observed in some cases. Such correlations of isotope shifts are more likely to be noticed in diatomic-like situations such as $^{13/12}\text{C}$ -induced ^{19}F isotope shifts or $^{18/16}\text{O}$ -induced ^{13}C isotope shifts in $\text{O}=\text{C}$ situations.⁵⁷ Chesnut and Wright have found that calculated shielding derivatives do roughly correlate with shielding itself for ^{19}F and for ^{13}C , ^{15}N , and ^{17}O involved in multiple bonds.
4. The magnitudes of the derivatives of shielding with respect to extension of a bond increase with increasing bond order. Since bond lengths tend to anticorrelate with bond order (higher bond order, shorter bond length), this trend in the shielding derivative is also the basis for the observed increasing magnitudes of one-bond isotope shifts for shorter bond lengths between the NMR nucleus and the substitution site.
5. The shielding derivative tends to be more negative with increasing negative net charge and with the presence of lone pairs on the observed nucleus. This has been found in the comparisons of ^{15}N in NO_2^- and NO_3^- , ^{15}N in NH_3 and NH_4^+ , ^{31}P in PH_4^+ , PH_3 and PH_2^- , ^{119}Sn in SnH_3^+ , SnH_4 and SnH_3^- , and ^{13}C and also ^{15}N in HCN and CN^- .
6. Since the one-bond coupling constant is a purely electronic quantity, it must be the electronic factors in the one-bond isotope shifts that allow the observation of linear correlations with the one-bond coupling constant, and likewise the incremental effects of substitution of H by Ph or H by CH_3 in the examples in Table 9.^{10–61} These above data translate to increasingly negative $(\partial \sigma^X / \partial r_{\text{XH}})_e$ upon successive Ph substitution at X.

5 ISOTOPE SHIFTS OVER TWO OR MORE BONDS

Isotope shifts due to substitution with a heavier atom at a site remote from the observed nucleus show the same general trends as one-bond isotope shifts.

1. The sign is still generally negative, although some are positive, with some alternation of signs being observed in the same molecule.
2. The magnitude reflects the chemical shift range of the observed nucleus.
3. The magnitude is related to the fractional mass change.
4. The effect is additive.

These are generally smaller than one-bond shifts; nevertheless, a large number of them have been observed, some over a distance of seven or more bonds. The question is, what information is contained in these long-range shifts? What we propose to show here is that these long-range shifts are a property of the electronic transmission path from the site of substitution up to the resonant nucleus.

To illustrate the types of terms that contribute to a long-range isotope shift, let us consider a two-bond isotope shift such as $^2\Delta^{13}\text{C}(^{2/1}\text{H})$ in CH_4 .¹⁹ The average proton shielding for proton H_1 can be written as

$$\begin{aligned}
 \langle\sigma^{\text{H}_1}\rangle &= \sigma_e + P_r\langle\Delta r_1\rangle + P_s(\langle\Delta r_2\rangle + \langle\Delta r_3\rangle + \langle\Delta r_4\rangle) \\
 &+ \frac{1}{2}P_{rr}(\langle\Delta r_1\rangle^2) + \frac{1}{2}P_{ss}[(\langle\Delta r_2\rangle^2) + (\langle\Delta r_3\rangle^2) + (\langle\Delta r_4\rangle^2)] \\
 &+ P_{rs}(\langle\Delta r_1\Delta r_2\rangle + \langle\Delta r_1\Delta r_3\rangle + \langle\Delta r_1\Delta r_4\rangle) \\
 &+ P_{st}(\langle\Delta r_2\Delta r_3\rangle + \langle\Delta r_2\Delta r_4\rangle + \langle\Delta r_3\Delta r_4\rangle) + \cdots
 \end{aligned} \quad (51)$$

where

$$P_r \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_1}\right)_e, \quad P_s \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_2}\right)_e \quad (52)$$

and P_{rr} , P_{ss} , P_{rs} , and P_{st} are the appropriate second derivatives of the shielding with respect to the various C–H distances. Therefore, the two-bond deuterium-induced proton isotope shifts between CH_3D and CH_4 is (with D replacing proton number 2)

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &= \langle\sigma^{\text{H}_1}\rangle_{\text{CH}_4} - \langle\sigma^{\text{H}_1}\rangle_{\text{CH}_3\text{D}} \\
 &= (P_r + 2P_s)(\langle\Delta r_1\rangle_{\text{CH}_4} - \langle\Delta r_1\rangle_{\text{CH}_3\text{D}}) \\
 &+ P_s(\langle\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_2\rangle_{\text{CH}_3\text{D}}) \\
 &+ (\frac{1}{2}P_{rr} + P_{ss})[(\langle\Delta r_1\rangle^2)_{\text{CH}_4} - (\langle\Delta r_1\rangle^2)_{\text{CH}_3\text{D}}] \\
 &+ \frac{1}{2}P_{ss}[(\langle\Delta r_2\rangle^2)_{\text{CH}_4} - (\langle\Delta r_2\rangle^2)_{\text{CH}_3\text{D}}] \\
 &+ (P_{rs} + 2P_{st})(\langle\Delta r_1\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_1\Delta r_2\rangle_{\text{CH}_3\text{D}}) \\
 &+ (2P_{rs} + P_{st})(\langle\Delta r_1\Delta r_3\rangle_{\text{CH}_4} - \langle\Delta r_1\Delta r_3\rangle_{\text{CH}_3\text{D}}) \\
 &+ \cdots
 \end{aligned} \quad (53)$$

With D replacing proton number 2, $\delta = \langle\Delta r_i\rangle_{\text{CH}_4} - \langle\Delta r_i\rangle_{\text{CH}_3\text{D}}$ is (the same for $i = 1, 3, 4$) a slight change of about 10^{-3} pm in the other C–H average bond lengths due to deuteration, and $\langle\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_2\rangle_{\text{CH}_3\text{D}}$ is the typical $\Delta = \langle r_{\text{CH}} \rangle - \langle r_{\text{CD}} \rangle$, which is of order about 0.5 pm:

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx (P_r + 2P_s)\delta + P_s\Delta + (\frac{1}{2}P_{rr} + P_{ss})\delta_{rr} + \frac{1}{2}P_{ss}\Delta_{rr} \\
 &+ (P_{rs} + 2P_{st})\Delta_{rs} + (2P_{rs} + P_{st})\delta_{rs}
 \end{aligned} \quad (54)$$

If we invoke the relationship $\langle\Delta r\rangle \approx \frac{3}{2}a r_e \langle(\Delta r)^2\rangle$ used earlier, we find

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx \left(P_s + \frac{1}{3a}P_{ss}\right)\Delta + \left(P_r + \frac{1}{3a}P_{rr} + 2P_s + \frac{2}{3a}P_{ss}\right)\delta \\
 &+ \text{mixed terms} + \text{higher-order terms}
 \end{aligned} \quad (55)$$

or, more succinctly,

$$\begin{aligned}
 2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx \mathcal{S}\Delta + (\mathcal{P} + 2\mathcal{S})\delta \\
 &+ \text{mixed terms} + \text{higher-order terms}
 \end{aligned} \quad (56)$$

Here $\mathcal{P}$ stands for the following combination of primary first and second derivatives:

$$\mathcal{P} \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_1}\right)_e + \frac{1}{3a}\left(\frac{\partial^2\sigma^{\text{H}_1}}{\partial r_1^2}\right)_e \quad (57)$$

and is a measure of the sensitivity of the shielding of a nucleus to stretching of a bond to it. $\mathcal{S}$ stands for the following combination of secondary first and second derivatives:

$$\mathcal{S} \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_2}\right)_e + \frac{1}{3a}\left(\frac{\partial^2\sigma^{\text{H}_1}}{\partial r_2^2}\right)_e \quad (58)$$

and is a measure of the sensitivity of the shielding of a nucleus to stretching of a remote bond.¹⁹ When we recall that $\Delta \approx 0.5$ pm whereas $\delta \approx 10^{-3}$ pm, we see that the term $\mathcal{S}\Delta$ would dominate the isotope shift unless $\mathcal{P}$ is two orders of magnitude larger than $\mathcal{S}$. It is therefore valid to consider a long-range isotope shift as largely described by a product of a primary change in the average bond length at the heavy atom substitution site (the dynamic factor) and a secondary shielding derivative(s) that measures the change in shielding upon a change with bond length at the remote site. This is very encouraging, because the secondary dynamic factor δ is so dependent on the entire molecular framework and potential energy surface in which vibrations take place that it is difficult to estimate. On the other hand, we have seen that Δ has a very straightforward dependence on r_e and the masses in the local fragment, and can be easily estimated. This means that if the δ terms are unimportant, the sign and magnitude of the long-range isotope shifts are a direct measure of the sign and

magnitude of $(\partial\sigma/\partial r_{\text{remote}})_e$. This derivative is stereospecific, dependent on electron-withdrawing/donating abilities of substituents, and has the usual electronic-transmission-path dependence of various observables such as long-range spin-spin coupling and substituent effects on chemical shifts. Thus, in $^{13}\text{CH}_3(\text{CH}_2)_{n-2}\text{NHD}$, for example,

$${}^n\Delta^{13}\text{C}^{(2/1)}\text{H} \approx \left[\left(\frac{\partial\sigma^{\text{C}}}{\partial r_{\text{NH}}} \right)_e + \frac{1}{3a} \left(\frac{\partial^2\sigma^{\text{C}}}{\partial r_{\text{NH}}^2} \right)_e \right] \times (\langle\Delta r_{\text{NH}}\rangle - \langle\Delta r_{\text{ND}}\rangle) \quad (59)$$

it is easy to see why n -bond isotope shifts are in general smaller than one-bond isotope shifts. The farther away the substitution site is from the observed nucleus, the smaller the secondary derivative is expected to be. For example, in the H_2O molecule,⁴¹

$$\begin{aligned} \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_{\text{OH}_1}} \right)_e &= -0.353 \text{ ppm pm}^{-1} \\ \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_{\text{OH}_2}} \right)_e &= -0.046 \text{ ppm pm}^{-1} \end{aligned} \quad (60)$$

that is, a trace along the increasing coordinate r_{OH_1} gives a sharply decreasing H_1 shielding surface near the equilibrium geometry, but a trace along the coordinate r_{OH_2} on the same shielding surface is rather flat. Also, the nearly flat portion of the shielding surface could be sloping slightly in either direction; thus, either sign is possible for long-range isotope shifts. The secondary derivatives should still reflect the shielding sensitivity of various nuclei as manifested in the ranges of their chemical shifts.

The experimental evidence for the dominance of the term $S\Delta$ is convincing.

1. The observed additivity of long-range isotope shifts is completely consistent with this. Isotope shifts from equivalent substitution sites such as a remote CH_3 group involve the secondary derivative multiplied by one Δ term for each C–D replacing a C–H.
2. The mass dependence of the two-bond isotope shift is the same as that of the one-bond shift, that is, $1-(\mu/\mu^*)^{1/2}$, where μ and μ^* are the local reduced masses at the substitution site. Furthermore, the ratio of the effects of substitution of H by T to that of H by D is the same as would be expected if the Δ term dominated the isotope shift. Vibrational calculations show that⁴⁸

$$\frac{\langle\Delta r_{\text{CH}}\rangle_{\text{CH}_4} - \langle\Delta r_{\text{CT}}\rangle_{\text{CT}_4}}{\langle\Delta r_{\text{CH}}\rangle_{\text{CH}_4} - \langle\Delta r_{\text{CD}}\rangle_{\text{CD}_4}} = 1.426 \quad (61)$$

In $(\text{CH}_3)_2\text{C}=\text{O}$, the observed ratio of isotope shifts for tritium and deuterium substitution is¹¹

$$\frac{{}^1\Delta^{13}\text{C}^{(3/1)}\text{H}}{{}^1\Delta^{13}\text{C}^{(2/1)}\text{H}} = 1.424 \pm 0.025 \quad (62)$$

That this ratio is indistinguishable from 1.426 serves to reassure us that the leading term is dominant in one-bond shifts, with $(\partial\sigma/\partial r)_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CD}}\rangle)$ for deuterium substitution and $(\partial\sigma/\partial r)_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CT}}\rangle)$ for tritium substitution. The two-bond isotope shifts have also been observed in $\text{CH}_3^{13}\text{C}(\text{O})\text{CH}_3$, and these have the ratio¹¹

$$\frac{{}^2\Delta^{13}\text{C}^{(3/1)}\text{H}}{{}^2\Delta^{13}\text{C}^{(2/1)}\text{H}} = 1.41 \pm 0.12 \quad (63)$$

This ratio is also indistinguishable from 1.426, which indicates that the dominant contribution is $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CH}})_e \times (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CT}}\rangle)$ for tritium substitution and $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CH}})_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CD}}\rangle)$ for deuterium substitution.

3. The relative signs of one-bond and n -bond isotope shifts for the same nucleus in the same molecule are not always the same. Consider, for example, the carbonyl carbon isotope shifts in $(\text{CH}_3)_2^{13}\text{C}=\text{O}$. The ${}^1\Delta^{13}\text{C}^{(18/16)}\text{O}$ and ${}^2\Delta^{13}\text{C}^{(2/1)}\text{H}$ are opposite signs. Thus, the important term in ${}^2\Delta^{13}\text{C}^{(2/1)}\text{H}$ must not involve $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CO}})_e \delta$.
4. The long-range isotope shifts correlate with indicators of electronic transmission paths such as dihedral angle dependence of three-bond isotope shifts (similar to the Karplus relation for three-bond coupling constants, although not with one set of coefficients), stereospecificity (*cis* versus *trans* versus *gauche*, and *syn* versus *anti*) of isotope shifts parallels that of spin-spin coupling, and the correlation of long-range isotope shifts with electron-withdrawing/donating ability of substituents, even across a path traversing seven bonds. These correlations of long-range isotope shifts with purely electronic quantities can only be observed if the isotope shift is itself dominated by an electronic factor that depends on the transmission of electronic information between the observed nucleus and the mass-modified site: a fortunate occurrence, since the long-range electronic factor is far more interesting and useful than the long-range dynamic factor. Since the primary dynamic factor Δ is easily estimated, long-range isotope shifts can provide direct invaluable information about the changes in shielding of a nucleus upon a minor perturbation at a distant site.

In summary, the electronic factor $(\partial\sigma^{\text{A}}/\partial r_{\text{XY}})_e$ in the long-range isotope shifts is found to have the following attributes.

1. The magnitude decreases (usually) as the Y–X bond becomes more remote from nucleus A. Ab initio calculations have shown that for the first- and second-row hydrides XH_n , the ratio $(\partial\sigma^{\text{H}_1}/\partial r_2)_e/(\partial\sigma^{\text{H}_1}/\partial r_1)_e = 0.06\text{--}0.14$. However, the two-bond secondary derivative is not necessarily much smaller than primary derivatives, especially when multiple bonds are involved.³⁴
2. It is stereospecific. For three-bond isotope shifts, it is found that *cis*, *trans* > *gauche*, and in some cases the dihedral angle dependence has been clearly observed and it is not unlike the Karplus relation of three-bond spin-spin coupling with angle ϕ . This stereospecificity is purely electronic in nature.
3. It correlates with other purely electronic quantities that are dependent on the same electronic transmission path, such as substituent effects on chemical shifts by electron-withdrawing or -donating groups. The electronic transmission path is most easily explored by the isotope shift, because substitution of an atom by a heavier one leads to the fewest complications compared with other methods of investigation such as replacement by atoms or groups of different electronegativity or size.

6 ISOTOPE EFFECTS ON SPIN-SPIN COUPLING

The indirect spin-spin coupling constant J is a useful index of the chemical bond, and isotope effects on it provide

information about the sensitivity of J to bond extension. Since the isotope effects on the isotropic average J can be determined more precisely than the individual J tensor components or the anisotropy, the isotope effects can be considered as *the* major source of experimental information for assessing the quality of ab initio theoretical calculations of indirect spin–spin coupling.

The working definitions of the isotope effects on J are as follows.⁴ $\Delta_s {}^n J(AB)[{}^{m'}/{}^m X]$ is the *secondary* isotope effect on the n -bond coupling constant between nuclei A and B due to the substitution of ${}^m X$ by the heavier isotope ${}^{m'} X$ somewhere in the molecule:

$$\Delta_s {}^n J(AB)[{}^{m'}/{}^m X] = |{}^n J(AB)|^* - |{}^n J(AB)| \quad (64)$$

$\Delta_p {}^n J(A^{2/1}H)$ is the *primary* isotope effect on the coupling constant between nuclei A and H due to the substitution of H by D, the coupled nuclei being separated by n bonds:

$$\Delta_p {}^n J(A^{2/1}H) = |{}^n J(AD)|^* \frac{\gamma_H}{\gamma_D} - |{}^n J(AH)| \quad (65)$$

where $\gamma_H/\gamma_D = 6.514\,398\,04(120)$. Of course, if we instead use the purely electronic quantities, namely, the reduced coupling constants

$${}^n K(AH) \equiv 4\pi^2 \frac{{}^n J(AH)}{h\gamma_A\gamma_H} \quad (66)$$

usually expressed in reduced units of $10^{19} \text{ J}^{-1} \text{ T}^2$, then the primary isotope effect is simply a difference:

$$\Delta_p {}^n K(A^{2/1}H) = |{}^n K(AD)|^* - |{}^n K(AH)| \quad (67)$$

Only the absolute values are compared, for practical reasons, since the absolute signs of spin–spin coupling constants are not always known. As in isotope shifts, the asterisk * denotes the heavier isotopomer. Where both secondary and primary isotope effects are observed, the primary isotope effect should be obtained from, for example, $J(\text{SnD})$ in SnH_2D^- and $J(\text{SnH})$ in SnH_3^- , rather than $J(\text{SnD})$ and $J(\text{SnH})$ in the same isotopomer SnH_2D^- . The latter difference includes both primary and secondary isotope effects.

Isotope effects on nuclear shielding are usually visually obvious in a high-resolution NMR spectrum, since the peaks of the isotopomer are shifted from the parent species. On the other hand, isotope effects on coupling constants are only observed as very slightly different multiplet splittings for each isotopomer (secondary isotope effects) or as a slightly smaller (usually) or larger $J(AD)$ than that expected from $J(AH)/6.514\,398\,04$ (primary isotope effects). Because of this factor of 6.514..., the isotope effects on J are less precisely determined than the isotope effects on shielding. According to these working definitions, a positive isotope effect on J means that the reduced coupling is larger in the deuterated species.

6.1 Observed General Trends in Isotope Effects on J

The general trends and their theoretical explanation have been presented by Jameson and Osten.⁴

1. The sign of the primary or secondary isotope effect on the coupling constant is not directly related to the absolute sign of the coupling constant. Whether it is related to the absolute sign of the reduced coupling constant is not yet established, since one-bond coupling isotope effects are presently available for positive reduced coupling constants only.
2. Primary isotope effects are negative or positive, the positive signs being found only in molecules involving one or more lone pairs of the coupled nuclei. For example, primary isotope effects are positive in H_2Se , in PH_3 , and in other 3-coordinate phosphorus, but negative in PH_4^+ and in 4- and 5-coordinate phosphorus. It is positive in SnH_3^- (one lone pair) and negative in SnH_4 and SnH_3^+ (no lone pairs).
3. Secondary isotope effects can have either sign, but are often negative. Positive signs have been observed where triple bonds are involved (as in $\text{HC}\equiv\text{CH}$ and $\text{HC}\equiv\text{N}$), but also in some of the same systems with positive primary isotope effects.
4. Secondary isotope effects are roughly additive upon substitution of several equivalent sites neighboring the coupled nuclei. For example, in the NH_4^+ ion, each D substitution decreases ${}^1J({}^{14}\text{NH})$ by 0.05 ± 0.02 Hz, and in PH_3 , each D substitution decreases ${}^1J(\text{PH})$ by 2.5 Hz. Small deviations from additivity have been observed.
5. The magnitudes of isotope effects are small, the largest primary effect being about 10% of the coupling constant in SnH_3^- , so that only the effects of deuterium (and tritium) substitution, where the largest fractional changes in mass are involved, have been observed. Some of the larger primary isotope effects are +11.5 Hz for $\Delta_p {}^1J(\text{PH})$ in PH_3 and +10.5 Hz in SnH_3^- . Secondary isotope effects as large as -2.0 Hz per D [for ${}^1J(\text{SiF})$] and +3.0 Hz per D [for ${}^1J(\text{SnH})$] have been observed.
6. The magnitudes of the isotope effects are roughly proportional to the fractional change in mass, in the very few instances where effects of isotopic substitution of ${}^1\text{H}$ by ${}^2\text{H}$ and ${}^3\text{H}$ have been reported.

6.2 Rovibrational Averaging of J , the Leading Terms

Just as in isotope shifts, the isotope effect on J can be written in terms of products of electronic and dynamic factors as follows.⁶ For a diatomic molecule,

$$\begin{aligned} \langle J \rangle^* - \langle J \rangle &= \left(\frac{\partial J}{\partial r} \right)_e (\langle \Delta r \rangle^* - \langle \Delta r \rangle) \\ &+ \frac{1}{2} \left(\frac{\partial^2 J}{\partial r^2} \right)_e [\langle (\Delta r)^2 \rangle^* - \langle (\Delta r)^2 \rangle] + \dots \end{aligned} \quad (68)$$

The dynamic factors are the same as we have already discussed (and, indeed, the same for all rovibrational averaging of any molecular electronic properties). Only the electronic factors need be discussed here. Of course, γ of some nuclei are negative, so we really should compare derivatives of the reduced coupling such as $(\partial K/\partial r)_e$, etc., where

$$\left(\frac{\partial J}{\partial r} \right)_e = \frac{h\gamma_N\gamma_{N'}}{4\pi^2} \left(\frac{\partial K}{\partial r} \right)_e \quad (69)$$

One important difference between J and σ is that the latter is a one-center property whereas the former is a two-center

Table 10

	Experimental ¹⁵		Calculated	
	$K(\text{SnH})$ (reduced units)	$K(\text{SnD})$ (reduced units)	$K(\text{SnH})$ (reduced units)	$K(\text{SnD})$ (reduced units)
SnH_3^-	24.09 ± 0.01		24.09	
SnH_2D^-	24.76 ± 0.02	27.09 ± 0.14	24.76	27.08
SnHD_2^-	25.40 ± 0.03	27.72 ± 0.22	25.43	27.75
SnD_3^-		28.53 ± 0.43		28.42

property. In polyatomic molecules, there are usually several electronic factors of comparable size that contribute to the isotope effects on J . For polyatomic molecules, if 1J is most sensitive to the bond length, the one-bond shifts can also be written in the same way as for diatomic molecules, with the terms such as $(\partial J/\partial \alpha)_e(\langle \Delta \alpha \rangle^* - \langle \Delta \alpha \rangle) + \dots$ being less important. 2J and 3J , on the other hand, are very sensitive to bond and torsion angles.⁶²

Let us consider SnH_4 as an example rather than CH_4 , since fairly large isotope effects on SnH coupling have been observed. The types of terms that contribute to the vibrationally averaged spin–spin coupling are the same as those that contribute to the proton shielding in CH_4 as given in equation (51):

$$\langle K(\text{SnH}_1) \rangle = K_e + P_r \langle \Delta r_1 \rangle + P_s (\langle \Delta r_2 \rangle + \langle \Delta r_3 \rangle + \langle \Delta r_4 \rangle) + \text{terms in } P_{rr}, P_{ss}, P_{rs}, P_{st}, P_{\alpha}, \text{ etc.} \quad (70)$$

where the primary derivative is $P_r \equiv (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_1})_e$ and the secondary derivative is $P_s \equiv (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_2})_e$. If we let $d \equiv \langle \Delta r_{\text{SnH}} \rangle$ in SnH_4 and $d - \Delta \equiv \langle \Delta r_{\text{SnD}} \rangle$ in SnD_4 then $d \approx 1.780$ pm and $\Delta \approx 0.5161$ pm can be obtained for $r_e = 170$ pm using the method described in Section 3.1. K_e is the reduced coupling constant at the equilibrium molecular geometry. The leading terms are⁶

$$\text{SnH}_4: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 3P_s)d + \dots \quad (71)$$

$$\text{SnH}_3\text{D}: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 2P_s)d + P_s(d - \Delta) + \dots \quad (72)$$

$$\langle K(\text{SnD}) \rangle = K_e + P_r(d - \Delta) + 3P_s d + \dots \quad (73)$$

$$\text{SnH}_2\text{D}_2: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + P_s)d + 2P_s(d - \Delta) + \dots \quad (74)$$

$$\langle K(\text{SnD}) \rangle = K_e + (P_r + P_s)(d - \Delta) + 2P_s d + \dots \quad (75)$$

$$\text{SnHD}_3: \quad \langle K(\text{SnH}) \rangle = K_e + P_r d + 3P_s(d - \Delta) + \dots \quad (76)$$

$$\langle K(\text{SnD}) \rangle = K_e + (P_r + 2P_s)(d - \Delta) + P_s d + \dots \quad (77)$$

$$\text{SnD}_4: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 3P_s)(d - \Delta) + \dots \quad (78)$$

From the above, we see that the primary isotope effect, the difference⁶³

$$\begin{aligned} \Delta_p {}^1K(\text{Sn}^{2/1}\text{H}) &= {}^1K(\text{SnD})|_{\text{SnH}_3\text{D}}^* - {}^1K(\text{SnH})|_{\text{SnH}_4} \\ &= (428.21 \pm 0.14) - (429.19 \pm 0.02) \\ &\approx -P_r \Delta \end{aligned} \quad (79)$$

leads to $P_r \approx 1.90$ reduced units pm^{-1} . The primary isotope effect may also be taken from any of the differences

$|^1K(\text{SnD})|_{\text{SnH}_2\text{D}_2} - |^1K(\text{SnH})|_{\text{SnH}_3\text{D}}$ or $|^1K(\text{SnD})|_{\text{SnHD}_3} - |^1K(\text{SnH})|_{\text{SnH}_2\text{D}_2}$ or $|^1K(\text{SnD})|_{\text{SnD}_4} - |^1K(\text{SnH})|_{\text{SnHD}_3}$, leading to an average value $P_r = (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_1})_e \approx 2.00$ reduced units pm^{-1} . Note that at this level of approximation, only the primary derivative P_r is involved in the primary isotope effect.

At the same time, the difference

$$\begin{aligned} \Delta_s {}^1K(\text{SnH})[^{1/2}\text{H}] &= |K(\text{SnH})|_{\text{SnH}_3\text{D}}^* - |K(\text{SnH})|_{\text{SnH}_4} \\ &= (428.81 \pm 0.02) - (429.19 \pm 0.02) \\ &\approx -P_s \Delta \end{aligned} \quad (80)$$

leads to $P_s \approx 0.74$ reduced units pm^{-1} . Since this secondary isotope effect may be taken from three other differences such as $|^1K(\text{SnH})|_{\text{SnH}_2\text{D}_2} - |^1K(\text{SnH})|_{\text{SnH}_3\text{D}}$, etc., we get an average value $P_s = (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_2})_e \approx 0.75$ reduced units pm^{-1} and $K_e = 421.63$ reduced units. The primary isotope effect involves largely the primary derivative of the coupling constant, and the secondary isotope effect on the coupling involves largely the (secondary) derivative of the coupling constant with respect to stretching a remote bond.

We can do the same analysis for the isotopomers of SnH_3^- , and we find that the values $P_r = -5.80$ reduced units pm^{-1} , $P_s = -1.30$ reduced units pm^{-1} , and $K_e = 39.04$ reduced units reproduce the experimental values reasonably well, as seen in Table 10.

The agreement with the six experimental numbers is very good. These quantities can be translated back to Hz pm^{-1} as in Table 11.

It is interesting that, although the magnitude of the SnH coupling constant is about one order of magnitude smaller in SnH_3^- than in SnH_4 , the sensitivity of the spin–spin coupling to bond extension is almost three times as great. The lone pair is generally known to be responsible for negative contributions to the reduced coupling, leading to a much smaller magnitude of the spin–spin coupling. Apparently, it is also the lone pair (on Sn in SnH_3^-) that is responsible for the greater sensitivity to bond extension. By similar procedures, the changes in the reduced coupling constant with extension of the bond, $(\partial K/\partial r)_e$, or of an adjacent bond, $(\partial K/\partial r')_e$, can be estimated in other systems such as SnH_3^+ , PH_4^+ , PH_3 , PH_2^- , and SeH_2 from experimental values of $J(\text{AH})$ and

Table 11

	SnH_4	SnH_3^-
$(\partial J(\text{SnH})/\partial r)_e$ (Hz pm^{-1})	−9.00	+26.00
$(\partial J(\text{SnH})/\partial r')_e$ (Hz pm^{-1})	−3.40	+5.80
$\langle J(\text{SnH}) \rangle - J_e$ (Hz)	−34.1	+67.3
J_e (Hz)	−1899.3	−175.8

Table 12 Derivatives of the Reduced Spin–Spin Coupling Constant with Respect to Extension of the Bond Between the Coupled Nuclei (r) and With Respect to Extension of the Other Bond (r')⁶

Molecule	Empirical		Theoretical	
	$(\partial K/\partial r)_e$ (reduced units pm ⁻¹)	$(\partial K/\partial r')_e$ (reduced units pm ⁻¹)	$(\partial K/\partial r)_e$ (reduced units pm ⁻¹)	$(\partial K/\partial r')_e$ (reduced units pm ⁻¹)
Without lone pairs:				
HD			+1.4979	
CH ₄			+0.973 24	+0.5884
PH ₄ ⁺	+1.04 ± 0.20	+0.075 ± 0.02		
SnH ₄	+2.00 ± 0.30	+0.75 ± 0.07		
SnH ₃ ⁺	+6.00 ± 4.00	≈0		
With lone pairs:				
¹³ C ¹⁷ O			negative	
¹⁴ N ¹⁵ N			negative	
HF			−0.5156	
PH ₃	−4.22	+0.465		
PH ₂ [−]	−1.25	−0.26		
SeH ₂	−1.90 ± 0.60	−0.71 ± 0.09		
SnH ₃ [−]	−5.80 ± 0.40	−1.30 ± 0.10		

$J(\text{AD})$ combined with values of the dynamic factor calculated by the methods described in Section 3.1. These values are compared with some published theoretical values in Table 12. Since all are expressed as γ -free reduced coupling constants, these are purely electronic quantities, which can be directly compared with each other in sign and magnitude. Theory has shown that the Fermi contact term is most sensitive to bond stretch.^{64,65} Thus, it is not surprising that the magnitudes of the empirical derivatives in Table 12 increase with increasing spin density at the nucleus, just as the reduced coupling constants are known to do. The secondary derivative is generally smaller than the primary derivative, and both usually have the same sign. The earlier prediction by Jameson and Osten⁴ that $(\partial K(\text{AH})/\partial r)_e$ will generally be negative when A has lone pairs but will be positive otherwise appears to be correct.

In summary, the electronic factor in the one-bond coupling constant $(\partial K(\text{AH})/\partial r_{\text{AH}})_e$ has been found to have the following attributes that explain the observed trends.

1. For A without lone pairs, it is positive; that is, the magnitude of the coupling increases as the bond becomes stretched.
2. It is largely dominated by the Fermi contact term, which is very sensitive to the distance between the two nuclei, much more so than the spin–dipolar and orbital contributions to coupling.
3. Probably because of the dominance of the Fermi contact term, it is larger for nucleus A having larger atomic number.
4. For A with lone pairs, this electronic factor is negative. It is known that lone pairs make negative contributions to the spin–spin coupling. The sign of this electronic factor confirms that the lone pair contributions are very sensitive to bond extension.
5. The secondary electronic factor $(\partial K(\text{AH})/\partial r_{\text{AX}})_e$ is generally 2–5 times smaller than the primary electronic factor, and is a measure of the sensitivity of the coupling across one bond to the lengthening of another bond involving one of the coupled atoms.

In summary, the dynamic factors and electronic factors in isotope effects on NMR parameters have been characterized. The theoretical model is general for any molecular electronic property.²⁶ The effects can be completely understood within

the context of the Born–Oppenheimer approximation. Complete calculations can be carried out for individual molecules within this theoretical framework. Where such calculations have been carried out, the agreement with experiment is good. Under conditions where the leading terms are dominant, the molecule-specific higher order terms can be neglected so as to find explanations for and make predictions of the sweeping generalities that have surfaced empirically in isotope effects on NMR parameters. The dynamic factor that has been derived by assuming dominance of the bond stretching successfully predicted the mass dependence of the isotope effects observed later. The empirical electronic factors deduced from this model are found to be consistent (in sign, in magnitude, and in correlations with various quantities such as net charge, presence or absence of lone pairs, bond order, etc.) with the theoretical electronic factors obtained by ab initio calculations.

1 INTRODUCTION

The principal aspects of high-resolution (HR) NMR which are influenced by magnetic susceptibility (MS) effects in nonconducting materials are spectral resolution and the accurate measurement of chemical shift. Also, with the wide application of NMR to imaging, particularly the imaging of heterogeneously structured materials, MS effects can influence the quality and interpretation of the images obtained. It is also possible to obtain MS information about materials using high-resolution NMR techniques. In this presentation, the physical origins of susceptibility in nonconducting materials are sketched, a few basic equations are given, the tensorial nature of susceptibility is pointed out, and a number of practical considerations are offered including the influence of sample spinning, particularly at the magic angle. Only diamagnetic and paramagnetic susceptibility are considered; ferromagnetism and antiferromagnetism are not discussed. Finally, a few comments are included regarding the use of high-resolution NMR to measure MS values, both molecular MS and the MS of condensed phases.

2 PHYSICAL ORIGINS OF SUSCEPTIBILITY, DEFINITIONS, AND EQUATIONS

In classical electromagnetism, the magnetic induction $\mathbf{B}$ and the magnetic field strength $\mathbf{H}$ inside a medium, are related by the equation

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \quad (1)$$

where $\mathbf{M}$ is the magnetization or magnetic moment per unit volume. Quantities appearing in equation (1) are in rationalized SI units where $\mathbf{H}$ and $\mathbf{M}$ are expressed in A m^{-1} and $\mathbf{B}$ has the units of tesla. Quantities given in bold-face type are either

vectors or tensors. The permeability of free space, μ_0 , takes the value $4\pi \times 10^{-7} \text{ T m A}^{-1}$ (Bennett et al. have published a useful reference paper¹ delineating appropriate conversions from cgs to SI units for quantities related to magnetism.) For isotropic nonferromagnetic materials,

$$\mathbf{M} = \kappa \mathbf{H} = (d/M)\kappa_M \mathbf{H} \quad (2)$$

where κ and κ_M are respectively called the rationalized volume and molar magnetic susceptibilities, d is the density in kg m^{-3} and M is the molar mass in kg mol^{-1} . (κ is equivalent to the quantity $4\pi\chi_v$ in the cgs system, where χ_v is the volume MS; κ and χ_v are both dimensionless. The relationship between κ_{mole} , having units of $\text{m}^3 \text{ mol}^{-1}$, and χ_M in the cgs system, having units of $\text{cm}^3 \text{ mol}^{-1}$, is that numerically $4\pi\chi_M = 10^6 \kappa_{\text{mole}}$.) MS is a bulk property of materials. Thus, MS is associated with an ensemble of molecules and is not intended to describe the details of the response to an external field over molecular distances. At the same time, individual molecules possess molecular susceptibility tensors.^{2,3} Moreover, for nonconducting materials, the uniformity of κ_M for solid, liquid, and gaseous forms of the same material implies that bulk MS values probably derive from summed molecular magnetic susceptibilities.^{3,4} Indeed, the molecular theory of diamagnetism is described in terms of molecular wavefunctions.

2.1 Diamagnetic and Paramagnetic Susceptibility

The two kinds of MS considered are diamagnetic and paramagnetic. Diamagnetic susceptibility is a generalized response to the magnetic field of the orbiting paired electrons in a sample.² This response is most often negative in sign and usually weak,⁵ i.e. $\kappa \approx -10^{-5}$. Owing to the fact that the diamagnetic susceptibility arises from the reaction of electrons in their orbitals to the presence of the magnetic field, this quantity is usually quite independent of temperature. There are generally two terms contributing to the diamagnetic susceptibility,²

$$\kappa_{\text{mole}} = -\frac{Ne^2\mu_0}{4m} \sum_i \overline{x_i^2 + y_i^2} + \frac{Ne^2\mu_0}{2m^2} \sum_{n(\neq 0)} \frac{|\langle 0|\hat{L}_z|n\rangle|^2}{E_n - E_0} \quad (3)$$

where N is Avogadro's number, e is the charge on the electron in coulombs, m is the mass of the electron in kg, i is an index over all electrons in the molecule, and n is an index over all excited electronic states of corresponding energies E_n (in joules) in the molecule. The first term is an average over all of the electrons in the ground state, where the z direction lies along $\mathbf{H}$. The size of this term is usually associated with the ability of the electrons, especially the outer electrons, to circulate freely in planes perpendicular to $\mathbf{H}$. The second term involves the mixing of ground and excited electron states by the angular momentum operator $\hat{L}_z$. The first term is negative and the second term is positive but usually smaller than the first; hence the sum is usually negative.

Paramagnetic susceptibility most often arises from unpaired electrons whose net polarizations in the magnetic field yield an MS which is positive in sign and somewhat larger than

the diamagnetic contribution. The latter is still there but is usually masked by the paramagnetic contribution. The electronic polarization which gives rise to the paramagnetic contribution is temperature-dependent and the paramagnetic susceptibility reflects that. For example, suppose a molecule of molar mass M has unpaired electrons, then, according to Langevin,⁶

$$\kappa_{\text{mole}} = N\mu^2\mu_0/3kT \quad (4)$$

where μ is the magnetic moment of the unpaired spins on the molecule; μ , in J T^{-1} , is given by

$$\mu = 2\beta[S(S+1)]^{1/2} \quad (5)$$

where S is the total spin which is equal to half the number of unpaired spins and β is the Bohr magneton in units of J T^{-1} . Substituting equation (5) into equation (3) gives

$$\begin{aligned} \kappa_{\text{mole}} &= 4N\mu_0\beta^2S(S+1)/3kT \\ &= [6.286 \times 10^{-6}S(S+1)/T] \text{ m}^3 \text{ mol}^{-1} \end{aligned} \quad (6)$$

Paramagnetic susceptibilities are usually larger than diamagnetic susceptibilities; ratios of 10 to 100 are not uncommon. Molecular oxygen has unpaired electrons and a relatively small molar mass; its presence in dissolved form can be a measurable perturbation on the measurement of diamagnetic susceptibility.⁷

2.2 Tensorial Character of Magnetic Susceptibility

In principle, the molecular MS and the bulk MS in solids is anisotropic,^{2,3,8} giving rise to a *tensorial* interaction, i.e. the general definition of $\mathbf{M}$ in equation (2) is

$$\mathbf{M} = \boldsymbol{\kappa} \cdot \mathbf{H} \quad (7)$$

where $\boldsymbol{\kappa}$ is a tensor. Thus, $\mathbf{M}$ may, in principle, depart from the direction of $\mathbf{H}$. Anisotropic bulk MS (ABMS) is most often associated with the crystalline state of matter in contrast with the glassy or liquid states of matter where isotropic bulk MS (IBMS) is most commonly found. For diamagnetic crystals, ABMS can arise because both the magnetic susceptibility of each molecule is anisotropic and the molecules in the unit cell preserve a net orientation of their different susceptibility axes. A common molecular source of ABMS in organic compounds is the aromatic ring.^{3,8,9} Ring currents, which are induced by the magnetic field when there is some projection of the normal to the ring along the magnetic field, offer a significant contribution to the MS tensor. If an aromatic compound has a crystal habit where the ring normals have a net projection along some axis, then there is a high probability that such a crystal will display ABMS. Graphite, as an extreme example, has a very large anisotropy¹⁰ because of its dense planar fused-ring structure.

For paramagnetic materials, the existence of an anisotropic electron $\mathbf{g}$ tensor, for example, can give rise to ABMS since net electron polarization then becomes a function of orientation. The $\mathbf{g}$ tensor can become very anisotropic, particularly for certain transition metal compounds where crystal field splittings and electron spin-orbit couplings both play a role in

determining the anisotropy of $\mathbf{g}$.¹¹ For example, the electrons in high-spin iron in the heme group have $g_{\parallel}$ close to the free-electron value of 2, whereas $g_{\perp}$ is about 6. As will be seen, there is considerable difference in the NMR resolution one obtains with magic angle spinning (MAS) if ABMS, rather than IBMS, is present.

2.3 Relationship Between Sample Shape and Uniform Internal Fields

For many NMR experiments, a uniform internal magnetic field is desired (uniform on a scale significantly larger than the molecular scale) so that interactions on the molecular scale can be exposed. In principle, one can make the external field very homogeneous, but the introduction of a material with finite MS into this homogeneous field generally modifies the field, both outside and inside the material. Thus, one is interested in how sample shape influences the field internal to the material and what shapes will give rise to a uniform internal field when the body is placed in a uniform external field.

For a body described by a single MS tensor, the general ellipsoid is the only finite body shape which, in the presence of a uniform external field, gives rise to a uniform internal field.¹² Cylinders of infinite length and spheres are ellipsoids of rotation; high-resolution NMR samples often approximate these shapes. It is possible, in principle, that if an ellipsoid, probably a single crystal, has an ABMS tensor whose principal axes do not coincide with the axes of the ellipsoid, that the direction of the uniform internal field will not coincide with the direction of the external field. However, for diamagnetic and paramagnetic materials, deviations from the external field direction will be negligible.

At this point we will separately consider MS effects in high-resolution liquid NMR and in solid state NMR. In liquid state NMR the measurement of chemical shifts can often be made very accurately; moreover, resolution is of primary importance. Also, most materials associated with the high-resolution experiment, including the sample, possess IBMS. In contrast, for solid state NMR, the so-called 'high-resolution' techniques generally achieve resolution which is, at best, an order of magnitude worse than in the liquid state and, more typically, two or more orders of magnitude worse. Thus, for solids, one is less concerned with the influence of MS on accurate chemical shift measurements. At the same time, in the solid state, MS effects can influence the measurement of chemical shifts in ways that do not happen for liquids. Of probably greater interest is the role which MS plays in determining resolution in the solid state. The added possibility that samples have ABMS also increases the complexity of dealing with MS, since strategies for reducing IBMS broadening only work partially when ABMS is present.

3 MAGNETIC SUSCEPTIBILITY EFFECTS IN THE HIGH-RESOLUTION NMR OF LIQUIDS

3.1 Resolution

For spectroscopic NMR applications, one generally desires the best resolution possible. MS considerations have dictated

several items in the standard practice of high-resolution NMR. Usually, sample tubes are cylindrical and are ideally filled with liquid which extends both above and below the rf coil so as to approximate an ellipsoid, thereby promoting internal field uniformity in the region of the coil. When sample volume is limited, one often uses a spherical sample tube, again approximating an ellipsoid, although the stem attached to the sphere is a significant perturbation on the uniformity of the field inside the sphere.

Sample spinning is a second way of dealing with MS effects to improve resolution, although a primary motivation for sample spinning is that it averages out inhomogeneities in the static field perpendicular to the spinning axis. Variations in the wall thickness of the NMR tube and/or a lack of concentricity cause the magnetic field to be warped in the sample region since the magnetic susceptibility of the glass is usually different from the liquid. Spinning about the tube axis helps to average these effects to smaller values. This averaging is more effective in the iron magnet geometry, where $\mathbf{H} \perp \mathbf{s}$ ($\mathbf{s}$ is the unit vector in the spinning-axis direction), than it is in the usual superconducting-magnet geometry where $\mathbf{H} \parallel \mathbf{s}$. This difference comes about because only in the former case does the orientation of $\mathbf{H}$, with respect to the vectors connecting the liquid and the tube imperfections, become modulated by spinning.

Discontinuities of MS within the sample also degrade resolution. Air bubbles, precipitates, etc. in a sample are all undesirable. Even a spherical air bubble creates a large perturbation since, in general, an ellipsoid of one susceptibility inside of an ellipsoid of a different susceptibility will result in nonuniform fields inside of both ellipsoids, even though the external field was originally uniform.

Finally, MS effects dictate certain things about probe construction. Aside from electromagnetic interferences, the asymmetric disposition of the probe elements (electronic components, mechanical supports, etc.) perturb the field lines on a distance scale comparable with the size of the object. The strategies for minimizing degradation of resolution include (a) maintaining sufficient distance between the elements and the sample so that the perturbations at the sample change slowly enough, spatially, that shim-coil compensation is possible, (b) distributing perturbing elements symmetrically, and (c) attempting to match the MS of the probe elements to that of air. The method for achieving the latter is usually to combine some paramagnetic character with the diamagnetic character of a material. For example, a substantial improvement in resolution has been demonstrated¹³ by replacing a copper rf coil with one having an MS much closer to that of air. A minor drawback to this approach of MS matching is that the paramagnetic contribution will be temperature-dependent.

3.2 Chemical Shift Measurements

The NMR resonance frequency observed in a liquid for a magnetic nucleus at a given chemical site on a molecule is often a very well-defined frequency, especially for a spin- $\frac{1}{2}$ nucleus. In general, one uses measured frequencies to deduce something about the molecule, about a chemical site in the molecule, or about how a site is influenced by its immediate intermolecular interactions (e.g. hydrogen bonding, solvation shells, etc.) Of less interest are those influences on the chemical

shift which derive from mean fields averaged over many molecules. The MS effects fall into this latter category. The resonance frequency ω_0 ($= 2\pi\nu_0$) for a given nucleus, ignoring spin couplings, is given by the Larmor relationship,

$$\omega_0 = \gamma\mu_0 H_n \quad (8)$$

where H_n is the magnetic field strength seen by the nucleus and γ is the gyromagnetic ratio of the observed nucleus in units of rad T^{-1} . Zimmerman and Foster¹² took the approach that $\mathbf{H}_n$ is the vector sum of five parallel vector fields,

$$\mathbf{H}_n = \mathbf{H}_0 + \mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 + \mathbf{h}_4 \quad (9)$$

where $\mathbf{H}_0$ is the applied external field, $\mathbf{h}_1$ is the demagnetizing field, proportional to the susceptibility, arising from the shape of the sample, $\mathbf{h}_2$ is the contribution due to magnetization external to the Lorentz sphere,^{14,15} $\mathbf{h}_3$ is the field associated with local intermolecular interactions, e.g. hydrogen bonding, and $\mathbf{h}_4$ is the field arising from intramolecular contributions, e.g. the response to the magnetic field of electrons, particularly those surrounding the nucleus observed, plus the influence of molecular conformation, etc. It is the quantity $(\mathbf{h}_3 + \mathbf{h}_4)$ which one seeks to measure and interpret via the chemical shift measurements. For liquid samples of IBMS, having overall ellipsoidal shapes and placed into a uniform field $\mathbf{H}_0$,

$$\mathbf{h}_1 = -\alpha\kappa\mathbf{H}_0 \quad (10)$$

where α is the demagnetizing factor tabulated for the general ellipsoid by Osborne.¹⁶ This factor depends on the axis ratios of the ellipsoid and the direction of the magnetic field with respect to these axes. Values of α for certain ellipsoids are as follows: 0 for $\mathbf{H}_0$ parallel to the axis of a long cylinder and $\frac{1}{2}$ perpendicular to the same cylinder, $\frac{1}{3}$ for a sphere, and 1 for $\mathbf{H}_0$ perpendicular to the plane of a thin disk. The field $(\mathbf{H}_0 + \mathbf{h}_1)$ is considered to be the average magnetic field internal to the liquid. It is thus, perhaps, not so obvious why the field $\mathbf{h}_2$ must be added to this mean internal field in order to take proper account of the mean internal field seen at the nucleus.^{14,15} The quantity $\mathbf{h}_2$ arises, in a sense, from the consideration that the mean internal field $(\mathbf{H}_0 + \mathbf{h}_1)$ is the mean field *after* the liquid has been magnetized. Since the molecule containing the nucleus in question is also in an induced-magnetism state, it is fair to ask whether the mean effective field which magnetized a given volume is not slightly different from the final mean field. The suggestion then is that the mean field seen by the nucleus is this slightly different field. To address this problem, one considers the fictitious removal of a very small sphere of magnetized liquid surrounding a molecule. Removal is especially fictitious because one 'freezes' in the field lines prior to the removal of the sphere so that the sphere is uniformly magnetized and the magnetic field lines in the liquid near the hole are also unperturbed.¹⁵ When one considers this problem in this so-called Lorentz sphere, one finds that the compensating field $\mathbf{h}_2$ is given by

$$\mathbf{h}_2 = (1/3)\mathbf{M} = (1/3)\kappa\mathbf{H}_0 \quad (11)$$

Therefore, the MS-corrected field $\mathbf{H}_c$ seen by the molecule in its average local environment is¹²

$$\mathbf{H}_c = \mathbf{H}_0 + \mathbf{h}_1 + \mathbf{h}_2 = \mathbf{H}_0\{1 + [(1/3) - \alpha]\kappa\} \quad (12)$$

For a spherical liquid sample, $\mathbf{H}_c$ is $\mathbf{H}_0$; for long cylindrical spinning samples,^{12,17}

$$\mathbf{H}_c = \mathbf{H}_0[1 + (1/6)(3 \cos^2 \beta - 1)\kappa] \quad (13)$$

where β is the angle between $\mathbf{H}_0$ and the spinning axis vector, s . equation (13) indicates that the susceptibility corrections are very different for $\mathbf{H}_0$ perpendicular or parallel to s ; moreover, if s assumes the magic angle, $\beta_M = \arccos(3^{-1/2})$, then the susceptibility term vanishes¹⁷ and $\mathbf{H}_c = \mathbf{H}_0$.

A usual method of making a referenced chemical shift measurement in high-resolution NMR is to mix an internal chemical shift standard with a test liquid. This works quite well in that both kinds of molecules experience the same perturbations from MS, assuming the mixture to be a true solution. On occasion, however, chemicals are not compatible or contamination is an important issue. Then one often uses a concentric tube arrangement with one liquid in the central tube and the other in the annular space. It does not matter, from the point of view of the MS corrections to be applied, which of the spaces is occupied by the reference so long as tubes are spun. (Static concentric tubes with $\mathbf{H}_0$ perpendicular to the tube axis, generate a substantial distribution of internal fields over the two sample regions.¹²) Moreover, equation (13) is used to determine $\mathbf{H}_c$ in both liquid regions.

Recognize that the convention for chemical shift, δ , is that shifts to higher resonance frequency imply more *positive* δ values. (Note that this sign convention is also consistent with Knight shifts¹⁸ as well as the more conventionally used chemical shift scales for protons, ^{13}C nuclei, etc.) If one measures the apparent chemical shift difference $\Delta\delta_{\text{obs}}$ ($= \delta - \delta_{\text{ref}}$) between two resonances originating from each of the sample regions, then for the iron-core magnet geometry with $\mathbf{H}_0 \perp s$, the susceptibility-corrected shift $\Delta\delta_{\text{corr}}$ is given by

$$\Delta\delta_{\text{corr}} = \Delta\delta_{\text{obs}} - (1/6)(\kappa^{\text{ref}} - \kappa) \quad (14)$$

and for the superconducting geometry with $\mathbf{H}_0 \parallel s$

$$\Delta\delta_{\text{corr}} = \Delta\delta_{\text{obs}} + (1/3)(\kappa^{\text{ref}} - \kappa) \quad (15)$$

where κ^{ref} is the MS of the reference liquid and κ is the MS of the test-sample liquid.

Application of equations (14) and (15) is not always convenient when one of the MS values is not known. This situation arises often for mixtures as well as neat liquids. It is possible to estimate κ , if one knows the composition and density of a material, using Pascal's constants.^{3,8,19,20} This method assumes additivity relationships for the contributions from the various atoms. Corrections which depend on the nature of the bonding are also included. For known mixtures whose individual κ values are known, a molar-volume additivity assumption works quite well²¹ for estimating κ for the mixture:

$$\kappa_{\text{mixt}} = \phi_1\kappa_1 + \phi_2\kappa_2 \quad (16)$$

where ϕ_1 and ϕ_2 are respectively the volume fractions of components 1 and 2.

4 MAGNETIC SUSCEPTIBILITY EFFECTS IN SOLID STATE NMR

4.1 Influence on Resolution

Solid particles come in all shapes and sizes. Particles can be crystalline, semicrystalline (e.g. polymers), amorphous or glassy materials, or even rubbery liquid-like materials. Generally, solid particles do not naturally occur as ellipsoids with ideal shape factors. This section offers a framework for estimating the spread of internal magnetic fields inside of an arbitrary particle; also an estimate of broadening in a powder sample is given. In addition, the question is raised as to what can be done, if anything, to reduce the susceptibility broadening in an NMR spectrum. The short answer is that magic angle sample spinning (MAS) will fully average to zero broadening from IBMS for particles of any shape, but when ABMS is present, MAS will result in incomplete averaging. In general, one must use single crystals of an ellipsoidal shape to eliminate ABMS broadening.

Given a particle, characterized by a single MS tensor and of a general shape, introduced into a uniform magnetic field, one can calculate the distribution of internal magnetic fields due to particle shape in the following way.¹⁷ About any given point in the particle, where one wishes to calculate the internal field, define a primary sphere which is the largest sphere that remains within the particle. Subdivide the remaining regions of the particle into i spherical volumes, V_i , choosing the spheres of different sizes so as to account for all of the remaining particle volume. According to equation (7), the magnetic field induces a magnetic moment per unit volume in the particle; thus, each of these spheres represents a magnetic moment μ_i given by

$$\mu_i = V_i\kappa\cdot\mathbf{H} \quad (17)$$

and the projection along $\mathbf{H}$ of the dipolar field $\mathbf{h}_i$ due to μ_i , evaluated at the center of the primary spheres will be

$$h_i = (\mu_i/r_i^3)(3 \cos^2 \theta_i - 1) \quad (18)$$

where, in polar coordinates centered at the origin of the primary sphere, r_i is the distance to the center of V_i and θ_i is the angle between the field direction and the line connecting the centers of the primary and the i th spheres. The sample-shape-dependent contribution to the field dispersion at the center of the primary sphere is the sum of the h_i values since the contribution from the first sphere does not contribute to the dispersion. A similar calculation can be performed at all points in the particle in order to obtain the distribution of internal fields for an arbitrary particle shape. We begin by discussing broadening for particles possessing IBMS.

4.1.1 Samples with Isotropic Magnetic Susceptibility

Drain²² estimated the MS broadening of NMR lines in powder samples having IBMS by considering the broadening due to the shape of each particle and due to the packing of the particles. The contribution from shape was calculated by assuming that the particles were isolated prolate or oblate ellipsoids with axial ratios of 2 or 0.5, respectively. A

uniform distribution of ellipsoid orientations in the field [leading to a distribution of α values in equation (10)] gives rise to lineshapes which are asymmetric, resembling powder lineshapes for axially symmetric chemical shift tensors.²³ Drain estimated the interparticle contribution to MS broadening by using the dipole approximation to calculate the distribution within a spherical particle due to spherical cubic-close-packed arrays of neighboring particles. The result was that comparable broadening arose from sample shape and from neighbor distributions. The full width, in Hz, of the resulting resonance was about $\kappa\nu_0/4$, where it is assumed that either air or vacuum surrounds each particle. This corresponds to about 2 ppm for the typical organic material. Obviously, a significant improvement in resolution could be obtained if a liquid with a matching susceptibility were introduced into the sample chamber.²⁴ Then, MS broadening would be reduced to about $\Delta\kappa\nu_0/4$ where $\Delta\kappa$ is the difference in κ between the particles and the liquid. Note that Drain's estimate of line broadening assumes that the overall shape of the powder sample does not deviate strongly from an ellipsoid; if it does, there is an additional MS broadening due to overall sample shape. Another way to eliminate MS broadening in solid materials with IBMS is to melt-cast or melt-crystallize them into ellipsoidal shapes. In the absence of voids, MS broadening then ought to be very small.

One can also average to zero the broadening from IBMS effects by using MAS.¹⁷ The dipolar form of equation (18) suggests that the angular averages of all $\mathbf{h}_i$ will vanish with MAS. Hence, the average dispersion will also vanish. The efficacy of MAS has also been demonstrated for samples containing liquids together with solids, such as glass beads.¹⁷ These authors reported linewidths for the liquid-component nuclei consistent with expectations involving the rotational averages of equation (18), namely, that spinning samples with $\mathbf{s} \perp \mathbf{H}$ simply reduced the static-sample linewidth by a factor of two, whereas MAS eliminated the MS broadening when the diffusion length of the molecules in the liquid over a rotor period was small in comparison to the bead diameter. The success of eliminating MS broadening from solid state spectra is very vividly seen in the MAS ^{13}C spectrum of a cubic material such as adamantane where, in the presence of MAS, broadening due to other sources is also minimal and observed linewidths approach those expected from the inhomogeneities of the applied field.²⁵

4.1.2 Samples with Anisotropic Bulk Magnetic Susceptibility

We turn now to the more complicated case of ABMS where κ is a tensor, rather than a scalar, and this tensor has principal values κ_1 , κ_2 , and κ_3 , given in order of decreasing magnitude. In the sense that the ABMS tensor can formally be separated into an isotropic part, characterized by the mean of the principal values, and an anisotropic part, characterized by deviations from the mean, the behavior of the isotropic part will be the same as discussed above. It is only the anisotropic part which will require further consideration.

As an example of ABMS, let us consider the aromatic ring which is the most common source of diamagnetic ABMS in organic systems. Aromatic molecules typically have anisotropic molecular magnetic susceptibilities;³ thus, their crystalline counterparts often possess ABMS as well. It is useful to think of the aromatic ring itself as an analog of ABMS

Figure 1 Geometry illustrating, at atoms A1 and A2, ring current shifts arising from the induced circulation of electrons in the π orbitals of the benzene ring. The C_6 axis of the ring, i.e. the direction of the maximum induced dipole, lies along x , and A1 is situated on x . Atom A2 lies along y . If, during isotropic tumbling or MAS, atoms A1 and A2 maintain their orientation with respect to the benzene ring, then A1 will experience an average reduction in its local field. This change in field is opposite in sign and twice the magnitude seen at A2. The interaction between the ring and the atoms is a dipolar interaction, but shifts arise because of the orientation dependence of the induced dipole. In glassy materials, aromatic rings give rise to a spread of frequencies for nearby atoms. In the presence of MAS, crystals possessing ABMS produce analogous shifts. Replace the benzene ring by a crystal with an axially symmetric κ tensor oriented along x . Similar shifts will occur for atoms in surrounding regions over distances comparable to the crystal size

in solids since, in liquid state NMR, the aromatic ring gives rise to the familiar ring current shifts.²⁶ These shifts are illustrated in Figure 1 where an aromatic ring is drawn and atoms A1 and A2 are placed outside of the ring, A1 along the hexad axis and A2 in the plane of the ring. If there is isotropic tumbling in a liquid containing an aromatic ring, and if the atoms A1 and A2 maintain their position with respect to this ring, then the resonance of A1 will shift to higher field and the resonance of A2 will shift to lower field. Even though the influence of the ring current on the atoms A1 and A2, at any fixed orientation, can be described as a dipolar interaction, isotropic reorientation does not average this interaction to zero because the *strength of the dipole moment is a function of orientation*. Only for a dipole moment of *fixed* magnitude, will the average dipolar field at all surrounding points vanish upon isotropic tumbling. The sign of the ring current shift at a given point in space usually takes the sign of the dipolar field when the induced moment on the ring is strongest, i.e. when $\mathbf{H}$ is parallel to the hexad axis.

For ABMS in solids, one might think of replacing the aromatic ring in Figure 1 with, say, a spherical single crystal which possesses ABMS. At some distance outside of this sphere, a change in the orientation of $\mathbf{H}$ with respect to the ABMS tensor of the sphere will create a change in the strength of the induced magnetic moment of the spherical crystal. This change will alter the strength of the dipolar fields emanating from this sphere. Hence, the isotropic average of the sphere's dipolar field at all external points will not, in general, vanish.

From the foregoing discussion we may draw qualitative conclusions about ABMS line broadening *in the presence of MAS*, given that MAS was effective in eliminating line broadening when only IBMS is present:

1. An isolated ellipsoidal single crystal will have no ABMS broadening since the field inside of the ellipsoid is uniform for all orientations.
2. A spherical hole inside of a sphere with ABMS will cause broadening.
3. A nonellipsoidally shaped single crystal with ABMS will cause ABMS broadening unless κ is axially symmetric and its unique axis lies along the spinning axis.
4. In a powder sample where each particle is a single crystal, ABMS broadening arises from both particle shape and from interparticle perturbations.
5. Densification via, say, melt crystallization, of a polycrystalline sample possessing ABMS increases ABMS broadening.
6. Dilution of ABMS crystallites with a material having IBMS reduces the interparticle contribution to ABMS broadening for resonances associated with these crystallites but creates ABMS broadening for resonances in the material with IBMS. The efficacy of such dilution depends rather strongly on having ABMS particles which are themselves single crystals, i.e. diluting polycrystalline ABMS particles is not very effective.

An empirical estimate of ABMS line broadening is based on MAS linewidth data²⁷ for hexamethylbenzene, a substance having an axially symmetric MS tensor. In a melt crystallized (densely polycrystalline) sample, ABMS line broadening yielded a full width at a halfheight of 0.93 ppm which, for hexamethylbenzene is a linewidth, in Hz, of $0.18\Delta\kappa\nu_0$ where $\Delta\kappa = \kappa_{\parallel} - \kappa_{\perp}$. In the work just referred to, points 3, 5, and 6 listed above were also demonstrated and a very crude calculation of interparticle broadening was attempted.

In the absence of MAS, ABMS line broadening is, of course, also eliminated for a *static* single crystal in the form of an ellipsoid.

4.2 Influence of Magnetic Susceptibility on Chemical Shift Measurements

4.2.1 Referencing the Anisotropic Chemical Shift

In the discussion which follows, the assumption is made that one wishes to determine the isotropic or anisotropic chemical shift values, relative to some reference material, *to a precision exceeding the magnitude of potential susceptibility corrections*. In many cases, the precision of the determination is such that one cannot justify a preoccupation with MS corrections. For example, MS issues are important in the measurement of chemical shifts for protons in organic materials because of the usually small range (8–10 ppm) of proton chemical shifts. In comparison, MS corrections for ^{13}C shifts are less important; yet MS effects can be seen because of the relatively high resolution achievable on observing dilute spin- $\frac{1}{2}$ nuclei such as ^{13}C . In paramagnetic materials or certain inorganic materials with larger susceptibilities, a consideration of the impact of MS on chemical shift is also in order.

One way to measure a chemical shift tensor is to rotate a single crystal in a magnetic field about orthogonal axes. This allows one to map the chemical shift and, by correlating these shifts with other measurements, e.g. X-ray, one can relate these shifts to directions in the molecules. Since each determination of a resonance position is undertaken using a static sample,

shape effects for the crystal come into play. Obviously, the narrowest lines will be for ellipsoids. If one does not wish to make shape-dependent MS corrections at each orientation, then a sphere should be employed. If the spherical crystal has IBMS, then the chemical shift anisotropy measured will be correct. If the crystal has ABMS, then one knows that $\mathbf{M}$ in equation (7) has a magnitude that is a function of orientation. Yet, according to the foregoing discussion on susceptibility corrections in liquids, where equation (9) was used, if the contribution from the Lorentz sphere is included, then $(h_1 + h_2) = 0$ for a sphere, i.e. there should be no correction term which depends on κ at any orientation. Yet, Spiess et al.,²⁸ in a very careful study of ferrocene, observed small deviations from an axially symmetric shielding tensor for the protons of ferrocene in a spherical single crystal. They attributed these deviations to ABMS effects, arguing that motional averaging of the ferrocene rings and crystal symmetry combine to predict an axially symmetric shift tensor. If ABMS effects persist in a single-crystal sphere, then the appropriateness of the Lorentz correction h_2 is questioned. Since the observed deviations were small, there may be alternative explanations. Nevertheless, it still seems that when the magnitude of the potential susceptibility corrections is a significant fraction of the apparent chemical shift anisotropy, the most reasonable recipe for determining true chemical shift anisotropies in materials with ABMS is to use a spherical single crystal and make no MS corrections.

4.2.2 Referencing the Isotropic Chemical Shift

The question arises as to effective strategies for referencing *isotropic* chemical shifts in solids. For solids with IBMS, an effective approach is to utilize MAS with a sample geometry such that an unknown material surrounds a central glass capillary containing a primary liquid reference, such as tetramethylsilane (TMS) for ^{13}C or ^1H nuclei. It does not matter whether the walls of the glass have uneven thickness or whether the spinning creates bubbles in the liquid. The main precaution, related to $\mathbf{B}_0$ homogeneity, is to distribute the liquid over the same axial range of the rotor that the sample occupies. The chemical shift measured between reference and solid needs no correction for MS, although there can be some other solid state contributions to the apparent chemical shift, e.g. from second-order dipolar effects.^{29,30} Once the chemical shift of a suitable solid is measured in the way outlined above, that solid can be used as a secondary shift standard. For materials with IBMS, unknown and standard can be mixed in any fashion, utilizing MAS, and the measured shift differences will need no further MS correction.

The geometry for referencing the chemical shift in samples with ABMS is a more complicated problem. An approximate method is to employ MAS on a sample in which a liquid reference in a capillary is surrounded by a powder sample of the ABMS material, where the grain size of the powder is much smaller than the wall thickness of the capillary, and the particles in the powder have no preferred orientation. In this case the signal from the powder will have substantial ABMS broadening; yet, to the liquid in the capillary, the powder will look like a material with IBMS. Therefore, within the approximation that ABMS broadening in the powder is symmetric, one will get a chemical shift difference which is correct. Symmetric broadening is not necessarily

expected since broadening arises from effective dipolar interactions which typically have asymmetric, powder-average field distributions associated with them. Also, in contrast to the IBMS case, for arbitrary powder samples having ABMS, it is not required that the mean resonance position, i.e. that position about which the first moment of the resonance intensity vanishes, is without influence from ABMS. Qualitatively, one expects ABMS-induced powder-average shifts to be closely related to the existence of regular and highly asymmetric shapes for the individual powder particles.

This author is unaware of any geometry for a sample, whereby an unknown material with ABMS, *in the form of a single crystal of some shape*, can be combined with a chemical shift reference material possessing IBMS in such a way that differences in the isotropic values of unknown and reference chemical shifts can be measured reliably without a prior knowledge of the orientation of the ABMS tensor in that material. The complicated nature of chemical shift referencing has been demonstrated for a polymer film possessing ABMS.²⁵ In the presence of MAS, variations in shifts of about 1.5 ppm were observed between ¹³C nuclei in TMS, contained in a central capillary tube, and ¹³C nuclei in the oriented polymer film. These differences arose when the orientation of the unique axis of the ABMS tensor was changed from parallel to the rotor axis to perpendicular to the cylindrical walls of the rotor.

If one presumes that the Lorentz sphere correction applies to all diamagnetic and paramagnetic solids, then for a spherical single crystal possessing ABMS as well as for a spherical liquid sample, the field seen by the nucleus is just the external field H_0 . Hence, a true chemical shift difference, in the absence of ABMS broadening, could be measured by sequential substitution of such samples. Of course, the use of MAS for the single crystal or the employment of rotation patterns would be required in order to identify the isotropic chemical shift; moreover, for the liquid sample, the influence of the container wall will be present and this is also most easily dispensed with using MAS.

5 MISCELLANEOUS CONSIDERATIONS

5.1 Influence on Multidimensional NMR

The development of 'high-resolution' techniques in solids has enabled spectroscopists to design multidimensional NMR strategies for solids. When the chemical shifts of one nucleus form the basis for one of the NMR dimensions, then it is possible that MS effects can appear. The author has seen such effects using proton multiple pulse techniques combined with MAS. The dipolar fields arising from either IBMS or ABMS in a glassy or semicrystalline solid can be distributed in a way which is not highly correlated with the anisotropic chemical shift tensors on the molecules. The net influence of MS is to create a distribution of effective chemical shift tensors. For a given chemical site, effective tensors throughout the sample have dispersions of principal values but the same isotropic average for IBMS. For ABMS, a dispersion of isotropic shifts also exists. Thus, in a proton 2D experiment, for example, where MS effects can be a modest fraction of the chemical shift range or of chemical shift anisotropies, one tends to

create spatially based as well as chemically based correlations of polarization as one increments the time for chemical shift evolution. As usual in NMR, this can be a nuisance as well as a source of information.

5.2 Use of NMR to Measure Unknown Magnetic Susceptibilities

From the foregoing discussions, it is clear that if one has two liquids in the concentric-tube geometry and utilizes MAS, any chemical shift difference associated with the two liquids will need no MS correction. A second measurement with either $s \perp H_0$ or $s \parallel H_0$ will yield the susceptibility difference between two liquids [equations (14) and (15)]. Provided the MS is known for one of the liquids, this measurement will yield the MS of the unknown liquid. One could forego the magic angle measurement above and simply use chemical shift data employing internal standards. However, any contribution to the shift arising, for example, from a change in intermolecular associations would produce an error in the susceptibility determination. Another approach³¹ to measuring diamagnetic susceptibilities in liquids involves measuring a chemical shift difference from sequential experiments for some nucleus belonging to a liquid for which κ is desired. First the measurement is made for the neat liquid; then the measurement is repeated for that liquid suspended as a separate phase, in spherical droplets, in another immiscible liquid for which κ is known. This method gave reported κ values to within a few per cent of literature values.

It is also possible to estimate paramagnetic susceptibilities using NMR signals. Feher and Knight³² in 1955 used two capillaries, filled with water, and oriented them inside of a tube filled with Mn_2O_3 powder. One capillary was parallel and one perpendicular to B_0 . The tube axis was in the remaining orthogonal direction. The difference in resonance frequency between the two tubes of water allowed them to estimate κ to within 6% of the listed value. Other variants of this experiment using different geometries have also been employed. For example, Li et al. measured the shift of the proton resonance in a sphere of water when that sphere was sequentially placed in a powder of an unknown and then in a powder of a reference material.³³ It is also possible to estimate the MS of a paramagnetic substance by simultaneously measuring, using concentric-tube geometry, the shift difference for a nucleus in a reference material in two solutions. One solution is the reference dissolved in a pure solvent; the other solution is the same but augmented by a known amount of paramagnetic material.^{34,35}

5.3 Measurement of Anisotropic Molecular Magnetic Susceptibilities

A molecule possessing anisotropic molecular magnetic susceptibility experiences a weak alignment in a magnetic field. Its order parameter is proportional^{36,37} to $\Delta\kappa H^2/kT$, where $\Delta\kappa$ is the anisotropy in the molecular magnetic susceptibility tensor. The first evidence for this alignment³⁶ was observed at 9.3 T in solutions of multiring aromatic compounds where deuterium resonances were split by less than 1 Hz. Subsequently, several halomethanes were examined³⁷ at

14.35 T, again revealing deuteron splittings of a few tenths of a Hz. The precision of these measurements is not high, but clearly the precision ought to improve rapidly as one moves to higher fields. Deuterons are ideal nuclei for observing this alignment since their natural linewidths in low viscosity liquids are quite narrow; yet, the quadrupolar interaction responsible for the splitting is conveniently large. A significant increase in the quadrupolar interaction would make the linewidths unacceptably broad for detecting small splittings.

5.4 A Basic Strategy for Suppressing MS Effects in Magnetic Resonance Imaging

One often wishes to image the density of a liquid, like water, in the vicinity of solid (e.g. bones) or rarified (e.g. as occurs for lungs³⁸) phases (see *Lung and Mediastinum: A Discussion of the Relevant NMR Physics*). Corresponding abrupt changes in MS have the effect of modifying resonance frequencies in a local manner.³⁹ To the extent that the resonance frequency of a nucleus determines its spatial position in an imaging application, where field gradients are applied, the MS shift will create an undesirable apparent 'spatial shift'. A strategy^{40,41} for minimizing such shifts involves creating imaging sequences where chemical shifts and MS-induced shifts are refocused but gradient pulses are applied during the dephasing and rephasing times in such a way that the resonance offsets due to these external gradients do not refocus. The result is that the 'spatial shifts' arising from MS effects get scaled approximately by the ratio of the local gradient field strength to the static field strength; hence the spatial shift becomes negligible in most materials.

1 INTRODUCTION

During the past two decades solid state NMR spectroscopy and its applications have grown rapidly among the chemistry and biochemistry community. The availability of increasingly sophisticated instrumentation and software has created opportunities for conducting experiments in areas that have not previously been available to the general chemical community. These new opportunities have been especially helpful in the study of solids. While the majority of such solid state applications have utilized ^{13}C nuclei, a much broader range of interesting nuclei (e.g., ^{11}B , ^{14}N , ^{15}N , ^{17}O , ^{19}F , ^{23}Na , ^{27}Al , ^{29}Si , ^{31}P , ^{113}Cd , ^{209}Pb , etc.) has emerged for use by solid state scientists and engineers.

Interest in magnetic resonance studies of nitrogen has increased significantly in the past decade. The distribution of nitrogen containing substances in materials important to the chemical, biological, medical, agricultural, and environmental sciences is well documented. The ^{14}N nucleus (99.6% natural abundance, nuclear spin 1) is quadrupolar giving rise to a broad signal while the ^{15}N nucleus has spin 1/2. The relative sensitivity of both nuclei is approximately 1×10^{-3} compared to ^1H . Nitrogen NMR data have been extensively reviewed by Witanowski et al.¹ and by Mason.² Most of the literature describes liquid state isotropic shifts and their relationship to structure elucidation, the importance of solvent effects, and tautomeric equilibria. The combination of a large isotropic shift range, approximately 1350 ppm,¹ and sensitivity to electronic interactions involving the lone pair of electrons make ^{15}N shifts a very sensitive probe of both structural changes and intermolecular interaction.³ These attractive features of the ^{15}N nucleus are off-set by the sensitivity challenges arising from a low natural abundance (0.365%), long relaxation times, small magnetogyric ratio, and a subsequent receptivity factor 2.19×10^{-2} relative to ^{13}C for an equivalent number of nuclei. Hence, much of the data reported has been obtained from ^{15}N

labeled materials although modern high field spectrometers have proven their value in studies at the natural abundance level. A significant amount of attention has recently been focused on the role of nitrogen in biological structures⁴ because of its sensitivity to both hydrogen bonding and intermolecular and long-range interactions. In this document the discussion will be restricted to the ^{15}N nucleus.

2 CHEMICAL SHIELDING

The well known relationship between magnetic field strength B_0 (arbitrary orientation in the z direction), the magnetogyric ratio γ_I of nuclear spin I , and the NMR Larmor frequency ν_0 (in frequency units, Hz) is given in equation (1)

$$\nu_0 = \frac{\gamma_I B_0}{2\pi} \quad (1)$$

where ν_0 is the difference in energy between any two of the allowed states. The magnetic inductive effect at the nucleus is equal to the vector sum of the static magnetic field and an induced magnetization vector arising from electronic currents that exist in the sample. The induced magnetization is proportional to B_0 and the proportionality constant is the sum of the chemical shielding and the magnetic susceptibility of the material surrounding the nucleus of interest. In solids, where rapid motional averaging is absent, all intramolecular currents within the molecule of interest are assigned to chemical shielding. Electronic currents arising from neighboring molecules are assigned to magnetic susceptibility. A more detailed and very useful outline of these interactions is provided by Grant.⁵

The electronic circulation set up by the magnetic induction of the applied field perturbs the effects of B_0 at the nucleus of interest. These electronic currents induce a shielding field, B_s , which may be either paramagnetic or diamagnetic (deshielding or shielding) and this induced field must be added to B_0 in order to obtain the effective field, B_{eff} , experienced by the nucleus of interest (equation (2)).

$$B_{\text{eff}} = B_s + B_0 \quad (2)$$

This effect is portrayed in vector form in Figure 1.

The shielding of the nuclear spin is a tensor quantity, described below, that depends on the electronic environment as well as the molecular orientation in the magnetic field. In solids the molecular orientation is locked into a powder pattern in which the nuclear resonance frequency is a function of the orientation of the microcrystalline particles. The random orientation of these particles leads to broad resonance patterns for each unique nuclear spin. The rich informational content of these powder patterns provides more information about electronic structure than the isotropic shifts observed in rapidly tumbling liquid molecules. Unfortunately, the diversity of the banding arising from multiple unique chemical environments in these broad powder patterns obscures the information content that is available in the isotropic chemical shift. However, the components of the shift tensor in the solid state reveal even more information regarding the subtle differences in electronic and geometrical structural characteristics and

Figure 1 Relationship between the applied field, B_0 , and the shielding field and effective fields (not drawn to scale) B_s and B_{eff}

the various experimental techniques employed to extract this information from solid samples is summarized in Section 3.

The shielding interaction with a nucleus is different for each unique chemical environment or symmetry position relative to the remainder of the lattice structure. Furthermore, the orientation dependence of the magnetic field to the screening currents induced around the nucleus presents an anisotropic environment that can be described by the chemical shift tensor. In principal, a different resonance frequency will be observed for each orientation of the nuclear spin with respect to the external magnetic field and the difference in this screening effect from that of a reference material is defined as the chemical shift. The reference that has emerged in the field is

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zx} & \delta_{zz} \end{bmatrix} \quad (3)$$

external nitromethane ($\delta = 0$) with the convention of negative values for more shielded resonance positions. The chemical shift tensor δ in a general reference frame may be represented by a 3×3 Cartesian matrix that is called a second rank tensor (equation (3)) which can be decomposed into three individual tensors of rank zero, one, and two which are defined as the scalar isotropic chemical shift, the symmetric, and antisymmetric chemical shifts denoted (equation (4)) as

$$\delta = \delta_o + \delta_{\text{sym}} + \delta_{\text{anti}} \quad (4)$$

The isotropic shift, δ_o , of zeroeth rank, is the trace of the Cartesian tensor, e.g., $1/3(\delta_{xx} + \delta_{yy} + \delta_{zz})$, and is invariant to any rotational transformation of the coordinate frame. Hence, δ_o is the only part of the chemical shift tensor that can be measured in solution samples; this the result of rapid tumbling motion of the molecules. The antisymmetric (first rank) and symmetric (second rank,) chemical shifts are given in equations (5) and (6), respectively.

$$\delta_{ij}^{(a)} = \frac{1}{2}(\delta_{ij} - \delta_{ji}) \quad (5)$$

$$\delta_{ij}^{(s)} = \frac{1}{2}(\delta_{ij} + \delta_{ji}) \quad (6)$$

The absence of diagonal elements in the first rank tensor renders these second order infinitesimal shift frequencies immeasurable. The traceless second-rank symmetric matrix contains diagonal elements that can provide first-order anisotropic shifts that add to or subtract from the Zeeman frequencies and are measurable in the NMR spectrum of solids. In the symmetric matrix any change in orientation of the magnetic field in the molecular frame will still leave anisotropic shifts along the diagonal of the transformed second-rank matrix. Unlike the antisymmetric components, the off-diagonal shifts in the symmetric portion of the chemical shift tensor will affect the principal values under the transformations associated with matrix diagonalization.

There always exists some frame in which the matrix in equation (3) is diagonal, in which case the three diagonal elements of the chemical shift tensor are designated as the principal values, δ_{11} , δ_{22} , and δ_{33} . By convention the order of the principal values are given as $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with δ_{11} representing the highest frequency (least shielded) component. The axis system in which the symmetric chemical shift matrix is diagonal is designated the principal axis system (PAS). The diagonal components are the principle values in the PAS while the remaining three (off-diagonal) terms are the Euler angles which define the directions of these principal values in the molecular frame. Hence, the complete description of the chemical shift tensor requires six elements of the shift tensor. The breakpoints in a powder pattern provide the principal values of the chemical shift tensor. The off-diagonal terms can only be obtained experimentally by tracking the chemical shift of each unique nucleus as a molecule (e.g., a molecule in a single crystal) is rotated in the magnetic field. These data can then be transformed into any of a number of reference frames that can be used to determine the orientation of the tensor in the molecular frame. The details of these experiments and transformations are described in a general outline by Orendt⁶ and in detail by Grant⁵ and Sherwood.⁷

The difficulties associated with growing single crystals and then acquiring the necessary orientational data is daunting, time consuming, and complicated by the reality that acquiring a single crystal of sufficient size for NMR experiments is usually not practical. However, sufficient single crystal data, together with theoretical simulations of the shift tensors, have been acquired to demonstrate that quite good approximations can be obtained for the orientation of the shift tensor principal axis system on the molecular frame.^{8,9} Hence, the various types of experiments that provide only the principal values of the shift tensor on powder samples^{6,10} are sufficient, when combined with appropriate theoretical calculations, to describe the off-diagonal elements which fix the orientation in the molecular frame with reasonable accuracy (see Section 4.3). To date, the majority of chemical shift tensor data appearing in the literature has been restricted to the ^{13}C nucleus and the latest, but somewhat dated, compilation of these data together with available data on ^{15}N shift tensor principal values has been provided by Duncan.¹¹ The acquisition of shift tensor data on solid materials, however, has expanded considerably in the past 10–15 years as line narrowing methods and techniques have become available. A review has described these experimental advances⁶ but additional major advances in multidimensional experiments have recently appeared^{12–14} and are described in another article in this encyclopedia,

Magic-angle Turning Spectra of Solids Involving 5π -pulse Sequences.

Despite the challenges faced with obtaining shift tensor data, new experimental techniques now enable investigators to obtain high quality ^{13}C shift tensor data on molecules containing more than sixty unique carbon atoms¹⁰ and ^{15}N shift tensors at the natural abundance level on molecules containing as many as five nitrogens (guanine)¹⁵ and eight non-equivalent nitrogens in potassium penicillin V.¹³

3 EXPERIMENTAL TECHNIQUES

^{15}N chemical shift tensor data have been reported using five different types of experimental techniques: (1) single crystal studies; (2) analysis of static powder patterns and off-magic-angle spinning on simple ^{15}N enriched heterocycles; (3) analysis of powder patterns utilizing the dipolar interaction between ^1H - ^{15}N or adjacent ^{13}C - ^{15}N labeled pairs; (4) powder patterns obtained by means of dynamic nuclear polarization experiments; (5) two-dimensional experiments such as polarization inversion spin exchange at the magic angle (PISEMA), and the five- π pulse experiment five pi replicated magic angle turning (FIREMAT).

3.1 Single Crystals

A single crystal study of L-hystidine-HCl-H₂O¹⁶ reported the full tensor of the two imidazole nitrogens in the amino acid while a single crystal study of $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine}$ provided the principal values of the ^{15}N tensor and its orientation in the molecular frame.¹⁷

3.2 Static Powders and Off-Magic Angle Spinning

The major portion of the ^{15}N shift tensor data has been obtained by static powder pattern analysis. Illustrative examples of static experiments on ^{15}N -enriched materials include: studies of the various phases of NH_4NO_3 ,¹⁸ protonated and non-protonated species in simple five- and six-member nitrogen heterocycles,¹⁹ porphyrin complexes,²⁰ cation binding in a membrane-bound polypeptide,²¹ substituted benzonitriles,²² off-angle fast sample spinning of an isolated ^{15}N - ^{15}N diazo system,²³ static and off-angle fast sample spinning of substituted pyrazoles,²⁴ secondary structure of peptides containing L-alanine²⁵ and poly(β -benzyl L-aspartate),²⁶ substituted benzonitriles,²⁷ the amide fragment of acetanilide and N-methylacetanilide,²⁸ and the relationship of the δ_{33} principal value to the hydrogen bond length in the glycine residue of some oligopeptides.²⁹

3.3 Dipolar Interactions in Powders

^{15}N shift tensor principal values and their orientation in the molecular frame have been determined through the dipolar interaction between proton and nitrogen dipolar coupling in peptides,³⁰ tryptophan and histidine side chains,³¹ the phenylalanine residue,³² the dipolar tensors for the peptide bond in $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine-HCl-H}_2\text{O}$,³³ peptides of the form N-acetyl $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{-X-amide}$ where

X = glycine, alanine, and tyrosine³⁴ and L $[-^{13}\text{C}]\text{alanyl-L-}[^{15}\text{N}]\text{alanine}$,³⁵ an analytical approach for the determination of the principal value σ_{33} of the amide ^{15}N chemical shift tensor element with respect to the molecular frame,³⁶ studies of the nitroso-groups in nitrobenzene and p-nitroso-N,N-dimethyl aniline (in which a very large CSA anisotropy of 1472 ppm was observed),³⁷ the two-dimensional PISEMA data on $[1-^{15}\text{N}]\text{-2'-deoxyguanosine}$,³⁸ the three-dimensional powder patterns of $^{15}\text{N}_{\epsilon 1}$ -tryptophan and $^{15}\text{N}_{\pi}$ -histidine side chains,³⁹ shift tensor values and orientation in the molecular frame in ^{13}C and ^{15}N labeled uracil.^{40,41}

3.4 Dynamic Nuclear Polarization Experiments on Powders

Hu et al.^{42,43} reported large ^{15}N DNP enhancement factors in benzamide (260, compared to CP data) and greater than 900 in carbazole and were able to compare the principal values of the shift tensors in powdered samples of these two molecules with those obtained by standard cross polarization and single pulse experimental techniques.

3.5 Two-Dimensional Experiments

A variety of two-dimensional experiments designed for separating the isotropic and anisotropic chemical shift information were instrumental in advancing resolution and data analysis of complex molecular systems.⁴⁴⁻⁵⁰ The magic angle turning experiments, first conceived by Gan,⁵¹ paved the way

Figure 2 A two-dimensional natural abundance ^{15}N spectrum is shown in which the isotropic shift spectrum with no spinning side bands is plotted vertically on the left while the isolated spinning sideband patterns for the six resolved peaks are plotted on the right, connected to the corresponding isotropic peaks by guide lines

for development of experimental tools^{12,13} that can reveal an amazing amount of detail regarding CSA in complex molecular systems. Recent modifications to the 5- π pulse experiments, FIREMAT¹³ and 2D-PASS¹⁴ have been particularly exciting in significantly expanding the range and complexity of molecules that can be studied. These two experiments, while related by virtue of a common 5- π pulse sequence for generating the two-D data set, possess important differences that are detailed in Ref.¹⁰ Taking advantage of TIGER data processing in the FIREMAT experiment,⁵² one is able to optimize S/N and resolution in the evolution dimension and obtain high quality ¹³C data on molecules with more than 60 different tensors. The power of the FIREMAT experiment can be seen by examining the ¹⁵N spectrum of penicillin V in Figure 2. Potassium penicillin V has two nitrogen atoms and, at ambient temperature, four molecules per asymmetric unit.¹³ Conformational differences in these molecules split the NH nitrogen into the four peaks shown between -271.7 ppm and -275.3 ppm. The conformational differences do not affect the ring nitrogen to the same extent and three of the resonances are degenerate at -212.5 while the fourth is at -214.0 ppm. The FIREMAT experiment has also been used to obtain ¹⁵N shift tensor data at the natural abundance level on nucleic acid bases,¹⁵ purine,⁵³ and indolazines.⁵⁴

4 RESULTS

4.1 Characteristics of Principal Values in Nitrogen Heterocycles

For convenience in consideration of ¹⁵N shift tensors in organic molecules the discussion will be restricted to nitrogen heterocycles since this general class of compounds is ubiquitous in nature. The relatively simple five- and six-member heterocycles have been shown to provide the framework for understanding the shift tensor data in more complex heterocyclic structures including indolazines, the nucleic acid bases and related compounds. Consideration of ionic species also

Figure 3 Definition of the different types of nitrogen atoms present in five- and six-member nitrogen heterocycles. The terms “n” and “p” represent non-bonded lone pair and protonated or bonded, lone pair, respectively

reflects the effects of hydrogen bonding interactions on the nitrogen shift tensors. This is especially interesting because of the lone pair of electrons. The structures portrayed in Figure 3 provide a useful framework from which to understand the experimental shift tensor data.

It is found that four different types of nitrogen tensors are present in simple nitrogen heterocycles. For convenience, the nitrogens with non-bonded lone electron pairs in five- and six-member rings shall be referred to as **5-n** and **6-n** types (such as pyrrole anion and the non-protonated nitrogens in imidazole and benzimidazole) and protonated **5-p** and **6-p** types (e.g., pyrrole, the protonated sites in imidazole and benzimidazole, the imidazolium cation, and the pyridinium cation).

Figure 4 presents a correlation diagram of the principal values of 12 simple heterocyclic structures. Quantum mechanical calculations were used to assign the orientation of the principal values to the molecular frame and to provide insight into the effects of electronic structure on the chemical shielding. These orientation assignments can be made with reasonable accuracy (estimated error of ± 10 degrees based on work on uracil)⁵⁵ if

Figure 4 Correlation of the ¹⁵N chemical shift principal values in 5- and 6-member heterocycles. The principal values are marked by solid lines, and the symbols indicate their approximate orientation in the molecular frames as described in Figure 5

Figure 5 Orientation of the in-plane principal components in nitrogen heterocycles. δ_r and δ_t are depicted in the figure and lie in the plane of the ring approximately in the tangential and radial directions of the ring. $\delta_\perp$ is perpendicular to the ring. (*J. Am. Chem. Soc.*, published with permission)

sufficient structural data (e.g., crystal structure, bond length,) is available.^{56,57}

A cursory inspection of Figure 4 illustrates the differences in the spans of the principal values of the nitrogen types. That the span of pyridine (622 ppm) is not unique as demonstrated by the span of 4-nitropyridine (674 ppm). In pyridine one observes that the δ_{11} shift component is oriented tangential to the ring, a direction that is also perpendicular to the lone pair (see Figure 6). When the hybridization of the nitrogen is changed from the **6-n** to the **6-p** type either by protonation, alkylation, or by *N*-oxide formation the tangential component crosses over the radial component, thus reducing the span of the shift tensor components by approximately 1/2 (to a range of 338–351 ppm). A similar affect is noted for the **5-n/5-p** case. The span in the pyrrole anion (333 ppm) is reduced to 192 ppm in pyrrole. Comparable effects are noted in each molecular pair studied. The data of Hoelger et al.²⁴ exhibit the same phenomena in the amine/imine pair of nitrogens in substituted pyrazoles.

The orientation of the shift tensor on the molecular frame of the compounds containing **5-n** type nitrogens corresponds to that found in pyridine (**6-n**). The span of the **5-n** tensor

Figure 6 Electron orbitals making the largest contributions to the chemical shift principal components in pyridine. R corresponds to the lone pair in pyridine and R=H, O, or CH₃ in pyridine hydrochloride, pyridine-*N*-oxide, and *N*-methylpyridine. (*J. Am. Chem. Soc.*, published with permission)

components is 337–374 ppm, a range that is nearly identical to that of the **6-p** nitrogens. In a manner similar to that noted for pyridine, protonation of the **5-n** lone pair inverts the order of the radial and tangential components and also significantly reduces (again, by approximately 1/2) the span of the **5-p** type nitrogens (to a range of 172–206 ppm). This reduction of span for the **5-n** and **5-p** species, compared to the respective **6-n** and **6-p** species, may be attributed to the larger degree of localization of the six π -electrons in five-member heterocycles compared with the six-member rings.⁵⁸ The increase of the localization of the π -electrons increases the electronic repulsion energy, thereby increasing the energy gaps corresponding to the $\sigma-\pi^*$ and $\pi-\sigma^*$ orbitals which dominate the paramagnetic contribution to the in-plane components. Thus, the paramagnetic contribution to the in-plane components of the shielding term decreases which reduces the shift tensor span.

The effects of interaction of the lone pair with neighboring atoms, whether bonded or non-bonded, is a matter of extreme interest and will be described in Section 4.3.

4.2 The Nucleic Acid Bases

The simple nitrogen heterocycles can be used as a guide to understanding the electronic structure and intermolecular interactions in the nucleic acid bases. Employing a combination of two-dimensional experimental techniques (PHORMAT, TIGER data processing, and FIRMAT) that were dependent on the complexities of the ¹⁵N spectra, the shift tensors were

Figure 7 Correlation diagram of the ¹⁵N shift tensor principal values in nucleic acid bases. Dashed lines are isotropic shift values

obtained on isotopically enriched adenine, and at natural abundance on thiamine, guanine, and cytosine.¹⁵ The principal values obtained, together with data previously reported on uracil,⁴⁰ are presented as a bar graph in Figure 7 in order to visualize the relationship between the various shift tensor patterns.

The ¹³C and ¹⁵N shift tensor data obtained on purine⁵³ provides a useful model for interpreting the patterns observed in the nucleic acid bases. The purine data were obtained under separate sets of conditions and the position of the tautomeric proton could be definitely identified (by means of the ¹³C isotropic shift data) as residing at either the N-7 or the N-9 position. The interpretation of the data is further confirmed by comparing the purine ¹⁵N data with that of the simple nitrogen heterocycles previously described. In the five- and six-member heterocycles (Figure 4) the span ($\delta_{11} - \delta_{33}$) of the shift tensors of the **5/6-p** nitrogens are of the order of 1/2 that of the **5/6-n** nitrogens (compare, for example, the spans of N-1 and N-3 in benzimidazole in Figure 4). The N-7 and N-9 tautomeric structures in purine mirror this effect and, by comparing the spans of the N-7/9 positions in adenine and guanine (Figure 8), the position of the tautomeric proton is clearly evident in these two compounds. Furthermore, the spans of the N-1 and N-3 tensors in uracil and thiamine clearly indicate that the two labile protons occupy these sites while the cytosine data suggest that N-1 is the preferred site, in accordance with x-ray data. In the case of guanine the shift tensor data is consistent with the proton occupying the N-1 site.

Figure 8 Comparison of shift tensor principal values in purine ring structures. The purine data is taken from Ref.⁹ while the adenine and guanine data were taken from Ref.¹⁵

4.3 Effects of Hydrogen Bonding

The large changes in the shift tensor principal values provide a means for assessing hydrogen bonding in a wide range of heterocyclic ring systems. Using density functional theory (DFT) Facelli³ simulated the shift tensor data in benzamide and these results, together with simulations of uracil,⁴⁰ highlighted the importance of including hydrogen bonding, and in general, intermolecular interactions in the calculation of ¹⁵N chemical shift tensors. Further evidence for the importance of these intermolecular interactions in the calculation of ¹⁵N chemical shift tensors can be found by analysis of these tensors in the series of heterocycles portrayed in Figure 4.

For these compounds the rms error between experimental and DFT calculated values, which did not include intermolecular effects, was approximately 30–40 ppm. This large scatter is approximately an order of magnitude greater than that found in simulated data on polyaromatic hydrocarbons.^{56,57}

Utilizing the imidazole structural information obtained from neutron diffraction data it is possible to improve the chemical shift calculations and to examine the effects of hydrogen bonding on the ¹⁵N shift principal values using a dimer model.¹⁹ The correlation between experimental and calculated shift principal values in imidazole, with and without intermolecular interactions, is shown in Figure 9. The rms error of the predicted shift principal values is 40.9 ppm using an optimized geometry and is 13.8 ppm when the structural data includes the position of the hydrogens in the lattice structure along with the effects of hydrogen bonding.¹⁹ Using the neutron diffraction data without including the intermolecular hydrogen bonding

Figure 9 Experimental versus predicted chemical shift values for imidazole. The DFT method was used to calculate the ¹⁵N shift tensor values using the neutron diffraction structure and including the effects of intermolecular interactions due to hydrogen bonding. The letters r, t, and p refer to the radial, tangential, and perpendicular components of the shift tensors. The legends N/HB and NH/HB designate predictions based on intermolecular interactions due to hydrogen bonding for the **5-n** and **5-p** nitrogens, respectively. (*J. Am. Chem. Soc.*, with permission)

effects produces only a modest improvement in the calculated values over those obtained with the optimized geometry. Introduction of intermolecular effects in the simulation of the nucleic acid bases plays a significant role in improving the correlation of experimental and theoretical result, reducing the rms error by a factor of two.¹⁵ Given the 3–4 fold greater span of the nitrogen shift tensor, a rms error of 14 ppm in imidazole and 16 ppm for the nucleic acid bases compares favorably with the 3–5 ppm rms errors obtained in simulations of ¹³C chemical shift tensors in polycyclic aromatic hydrocarbons based on x-ray structure data.^{56,57}

5 CONCLUSIONS

¹⁵N chemical shift tensors in heterocyclic compounds are very sensitive to the hybridization of the nitrogen atom and changes in the tangential component can vary from 200 ppm to as much as 340 ppm in five- and six-member rings, respectively, when the nitrogen lone-pair hybridization is changed. The changes in the magnitude of the in-plane components are so large that these effects may be useful in probing intermolecular interactions associated with hydrogen bonding in biological systems. It is possible to measure and spacially assign the principal components of the ¹⁵N chemical shift tensors obtained from powder samples in heterocyclic compounds. The assignments of the chemical shift tensor components are critical for analyzing the relationship between the electronic structure and shift tensors. In all the compounds studied, the most deshielded component, δ_{11} , is in the plane of the ring and approximately perpendicular to the plane containing the bonding-antibonding or HOMO-LUMO pair of orbitals with the smallest energy gap. The most shielded component, δ_{33} , is always perpendicular to the plane of the ring, as in the ¹³C tensors of aromatic compounds and is less sensitive to changes in the hybridization of the nitrogen atom than the principal components in the plane of the ring.

Employing modern instrumentation and experimental techniques that have been optimized for obtaining shift tensor data, it is now possible to study nucleic acid materials at the natural abundance level or with isotropic enrichment depending on the relaxation times and spectral complexity. The nucleic acid bases exhibit the same sensitivity to small changes in molecular geometry and environment noted for the five- and six-member heterocycles. Even for nitrogens with similar hybridization, differences as large as 50 ppm are found in corresponding principal shift components. Theoretical techniques now available enable the investigator to simulate the molecular environment with reasonable confidence. The agreement between experiment and theory is highly dependent on the molecular model used in the calculations, and molecular models that include the intermolecular interactions show superior correlation with the experimental values.

1 INTRODUCTION

This article concentrates on chemical shifts in nucleic acids as indicators of conformation. Shifts of ^1H , ^{13}C , and ^{15}N are reviewed. A complete treatment of ^{31}P shifts is given elsewhere by Gorenstein (see *Nucleic Acids: Phosphorus-31 NMR*), as is the characterization of unusual bases by Agris (see *RNA Structure and Function: Modified Nucleosides*). The nomenclature used is that of Saenger.¹ In this short article, it is not possible to review the whole subject, so emphasis is placed on areas of major impact, without attempt to be comprehensive or to apply historical credit.

Nucleic acid structures in solution continue to be a major research topic, because of both general chemical interest and the burgeoning industry of understanding the detailed interactions of nucleic acids in biological processes. Two examples of special interest are how proteins and nucleic acids recognize each other and whether there are general rules, and how some ribonucleic acids (RNAs) achieve catalytic activities. The use of chemical shifts continues to be of importance because the structures of many nucleic acids are dynamic and polymorphic. Shift analysis can attempt to achieve the simple objective of defining whether there is predominantly a single structure (or small family) to be analyzed, and can, in favorable cases, achieve the more complex objective of a reasonable level of secondary structural information. To address the more complex biological areas, higher molecular weight complexes require study, since the structures of the nucleic acid components alone rarely provide any clear perspective on the mode of binding and interaction, as vividly illustrated in the dramatic twisting of the deoxyribonucleic acid (DNA) strands in complexes with Transcriptional Binding Protein (TBP)² a result entirely unanticipated from solution studies of the DNA oligomers alone. Higher molecular weight complexes, often with proteins or other nonnucleic acid components, have extensively overlapped spectra, so the additional dispersion from the use of heteronuclei and multidimensional NMR becomes imperative.

2 DNA OLIGOMERS

The naming of atom positions in the bases and in deoxyribose are shown in Figure 1, which also illustrates the base pairing expected in the Watson–Crick form. In this form, imino and amino hydrogens have reduced rates of exchange with solvent hydrogen, and so the appearance of these normally exchangeable hydrogens in the spectrum is diagnostic of base pairing. The observation of well-resolved imino resonances of comparable width and intensity to nonexchangeable hydrogen resonances then provides definitive evidence for a single well-defined structure. Successful structural investigations appear to rely heavily on this characteristic to find conditions of temperature, pH, cations, etc., favorable to the determination.

Standard procedures exist for assignment of most exchangeable^{3,4} and nonexchangeable hydrogens.^{5–8} The shifts of nonexchangeable hydrogens in B type DNA have been thoroughly analyzed in over 600 nucleotides. The shifts of H-2', H-2'', H-3', H-4' and H-6/H-8 are dominated by the identity of the attached base. Cytidine (C) H-5 and thymine (T) CH₃ are influenced by the adjacent 5' base, while H-1' is influenced by the adjacent 3' base. The averaged values and their distribution profiles are for oligonucleotides observed under fairly wide solution conditions and temperatures, so highly precise reference values are probably best obtained by using those from a closely related sequence under similar solution and temperature conditions.⁵

Shifts outside the normal ranges can be used as preliminary identification of sites of binding or modification. For example, the shifts of base and sugar H-1' in a modified duplex with benzopyrene diol epoxide have been used as supporting evidence for the stacking of the benzopyrene ring directly over the sugar of one base in the minor groove.⁹ In closely analogous sequences, similarities of many shifts of the unchanged residues can then be used to infer similarity of structure. For example, the base and 2',2'' shift of an A₃ bulge (A = adenosine) from a duplex are virtually identical to those in an AIA bulge (I = inosine), when the I substitution is used to separate otherwise isochronous A H-8 signals for the purposes of sequential assignment by COSY and NOESY.¹⁰

3 ^{13}C AND ^{15}N SHIFTS

The extension of these uses of shifts of hydrogens to other nuclei was a natural development, impeded by the difficulties of synthetic incorporation of stable isotope labels, and/or by low NMR sensitivity. Incorporation of labels still remains very expensive, and for DNA the precursor deoxynucleotides present difficulties. Labeling of RNA has become practical and efficient for designed sequences,^{11,12} and transfer RNAs have been biosynthetically labeled for assignment purposes for many years. Indirect detection methods, and their elaboration into methods for connectivity determination using multidimensional NMR,¹³ have similarly alleviated sensitivity issues. Indirect detection methods have made it practical to observe ^{13}C and ^{15}N shifts without enrichment, and these have provided, complementarily to earlier studies with short oligonucleotides,¹⁴ an adequate base for assignment and interpretation for DNA oligomers.^{15–17} For example, for ^{13}C shifts, purine C-2 resonances are sufficiently separated from purine C-8 and pyrimidine C-6 resonances, that the overlap in the hydrogen spectra of the appropriate H2, H8, and H6 resonances can be partially resolved by inspection. Similarly, H1' and pyrimidine H5 can be type assigned by two-dimensional (2D) separation of the C-1' and C5 resonances, and H3', H4', H5', and H5'' are separable also. Purine C-8 can be discriminated from pyrimidine C6 by the C8s larger $^1J(^{13}\text{C},^1\text{H})$ value in coupled spectra. For ^{15}N parameters, in the critical imino area, pyrimidine N3 and purine N1 are separated by about 10 ppm, permitting considerable additional resolution of the imino hydrogens in a $^{15}\text{N}/^1\text{H}$ 2D map. These experiments are still relatively little used, despite their clear and rich information content.^{18–20}

4 TEMPERATURE DEPENDENCE OF ^{13}C SHIFTS

The profiles of chemical shifts with temperature have received considerable attention, especially those for hydrogen. This approach provides a potential avenue to understanding the contributions of individual components to the melting phenomena, in contrast to the bulk properties observed by ultraviolet absorption or circular dichroism. The interpretation of the changes of shifts observed has not proved to be entirely simple, and increasingly elaborate models have been used.²¹ Variable temperature studies using ^{13}C have been more limited. This is in spite of the potential for using relaxation dynamics, or the effects of pseudorotation of the ribose ring on shifts.²² Detailed temperature profiles of a small number of oligomers are available for base¹⁶ and sugar²² carbons. These provide a highly detailed grounding from which to consider the origin of shifts in oligonucleotides.

The observations for bases may be summarized as follows. A range of shifts of about 3 ppm for each class of carbon in the low-temperature duplex narrows to <1 ppm range at high temperature. Residues at the termini show smaller transitions than others. The slopes of $d\delta/dT$ are mixed (positive, negative, around zero), with most showing the largest change at around the melting temperature, but with clear evidence for one or more 'pretransitions' below that temperature, especially at carbons at guanosine G2, G6, and T4. There is essentially no obvious neighboring dependence for each pair of base types.

Detailed quantum mechanical calculations of the shifts for bases^{23,24} and sugars²⁵ are available. Naturally, the match of experiment and theory will be limited by neglect of conformation averaging, of solvation, and by the limited orbital sets used. For bases, the melting effects have been summarized¹⁶ as arising from changes in hydrogen bonding, both that to a partner base and that to solvent, from base stacking effects, and from steric compression. Hydrogen bond related changes occur on those carbons adjacent to a nitrogen or carbonyl participating in hydrogen bonding. Since those sites may be involved in hydrogen bonding with other bases, or with solvent water, changes are then the summation of multiple effects depending on the relative strengths of the different hydrogen bonds involved. The expectation is then that substantial negative $d\delta/dT$ values should be seen for C2 and 6 in G, and 4 in T, with lesser effects at 2, 5, and 6 in A, and 2, 4, 5, and 6 in C. Base stacking effects are similarly complex in effect, and it may be concluded that a geometric effect similar to a ring current shift would be expected to produce a positive $d\delta/dT$ going from a stacked to a single-stranded form. It seems unlikely that steric compression effects could play a major role in shifts in such duplexes, where there are considerable degrees of backbone freedom.¹ The most reasonable hypothesis concerning the temperature dependence of base shifts then centers on the cooperative transition of melting changing simultaneously the oppositely signed contributions of geometric stacking and of hydrogen bonding. The individual changes then reflect the different roles of each carbon with respect to the geometry of the stacking, or the adjacency to a hydrogen bonding site. A plausible hypothesis for the premelting changes is that there is apparent weakening of the hydrogen bonding prior to the principal transition.

In the case of deoxyribose sugars,²² the temperature dependence of carbon shifts might be expected to shed light on the much discussed issue of pseudorotation in the sugar ring. Early work²⁶ suggested that fitting the observed vicinal coupling constants in deoxyribosides needed at least a two-state model, incorporating the 'N' (North), 3'-endo, or 'S' (South), 2'-endo conformers of the ring.¹ This is now generally,²⁷ though not universally,^{28,29} accepted for oligonucleotide analysis also, with the caveat that other sugar puckers may be significantly populated, but cannot be easily experimentally analyzed, so Occam's razor reduces us to using the simplest model.²⁷ This and other issues^{30,31} continue to point out possible limitations of high-precision attempts to determine DNA oligomer using single conformer models. Sugar ^{13}C shifts might be a useful additional characteristic of ring pucker, and this has been established for some RNA oligonucleotides,^{20,32} in a relatively straightforward way. Detailed studies of DNA oligomers do not support this kind of analysis, and deviations of shifts with respect to temperature show quite different patterns.²² A general explanation is that indeed multiple ring conformers do exist, and that the deoxyribose and ribose rings naturally have different sets of conformers. The general magnitude of the alteration of shift with melting is, however, quite small (about 1–2 ppm), so it is very difficult to make a complete differentiation of shift effects arising solely through ring conformation, from those arising from ring current (magnetic anisotropy) and other more distant effects. In general, the conclusion that these melting curves require a more complex explanation than an S–N conversion

alone is fully justified, and more detailed studies of the effects of sequence seem appropriate.

5 ISSUES WITH RNA

Spectral assignment in RNA had previously been difficult, because of the overlap of sugar hydrogens in the 4–5 ppm region. Resolution by multidimensional heteronuclear shift correlation with ^{13}C provides a straightforward additional dispersion, with C-5', C-3', C-2', C-4', and C-1' being ordered in increasing shift in relatively well-separated groups.³³ It remains to be seen, in the large structural variations of bulges, internal loop, duplexes, and hairpins, whether these simple classifications will suffice. The success of a multidimensional, triple resonance approach using $^{13}\text{C}/^{15}\text{N}$ dual-labeled duplex dodecamer,³⁴ bodes well for complete assignment of significantly larger RNAs. This approach similarly depends on the large ^{13}C dispersion to separate out sugar hydrogens.

Using the characteristic imino hydrogen region, several laboratories made remarkable progress in assigning larger RNAs, especially transfer RNAs and 5S RNA. Additional information from ^{15}N shifts has also been widely used, mainly for group-specific assignments.

6 ^{15}N SITES AS STRUCTURAL INDICATORS

It will be readily apparent by inspection of Figure 1, that nitrogens are potentially reporters at the sites of the major interactions of the bases. They participate in the Watson–Crick hydrogen bonding (C,3,4; G,1,2; T,3; and A,1,6), serving as donor in all cases, and recipient at C3 and A1. The major groove of a double helix is also lined with the amino groups of A and C, and the nitrogen at position 7 in purines A and G, while the purine position 3 is exposed in the minor groove. The known perturbations of shifts on hydrogen bonding, for donor or recipient, then provide a specific window into the major recognition elements of the bases. This simple reporting may be invaluable in larger complexes where full determination of structure is presently impractical. Some existing studies include the investigation of Hoogsteen hydrogen bonding in triple helices¹⁹ and guanine tetrads,³⁵ investigations of the effects of *O*-methylation,^{36,37} and studies of netropsin/duplex complexes.^{17,38}

DNA triplexes can be readily formed by appropriate sequences in which a purine-rich tract makes Watson–Crick contacts with a pyrimidine-rich strand, and then a subsequent pyrimidine-rich strand make predominantly Hoogsteen pairing to the central purine-rich portion, and the Watson–Crick pairing is readily apparent in the shifts of G1 and T3 nitrogens.¹⁹ In guanine-rich tetrads, the shift variation between duplex, tetrad, and single strand forms for the N-7 of G in two sequences was found to be rather small, and while hydration effects and hydrogen bonding may be usefully investigated in lower molecular weight complexes,³⁵ the prospects for use in larger complexes are not clear.

Several oligomers containing $[1'-^{15}\text{N}]$ - and $[2-^{15}\text{N}]\text{-O}^6\text{-methyl-2'-deoxyguanosine}$ have been studied, confirming expected base pairings in mismatches against C and T. These

studies elegantly illustrate the positional specificity available from NMR studies for base–base hydrogen bonding and for the pH and temperature dependence of such bonding. For the O^6MeGT pair, there is direct hydrogen bonding at N-2 but not N-1, with N-1 probably fully solvated.³⁶ In contrast, the O^6MeGC pair has a very complex, pH-dependent, wobble pairing.³⁷ The low-frequency melting shift of the $[1-^{15}\text{N}]\text{O}^6\text{MeGC}$ resonance (3 ppm) is similar to that for other hydrogen bond acceptors, whereas the high-frequency shift of $[2-^{15}\text{N}]\text{O}^6\text{MeGC}$ (8 ppm) is not similarly matched. This is in line with expected differences in hydrogen bond strength: the apparent high-frequency shift of an $\text{O}^6\text{MeG } ^{15}\text{N}2$ as an sp^3 hydrogen bond donor to an sp^2 nitrogen acceptor is significantly greater than that associated with $\text{NH}_2\text{--O}$ interaction.

The structures of netropsin/DNA oligomer complexes have been extensively studied by X-ray and NMR methods. Nitrogen-15 studies are fully consistent with the general view that netropsin displaces water of hydration from the minor groove, without significant perturbation of the duplex structure. Shifts from positions 3 in A,³⁸ 1 in G, and 3 in T¹⁷ are all indicative of modulated hydrogen bonding on complexation at the expected positions. The suggestion¹⁷ that larger perturbations of 3 in T result from the alterations of the adjacent carbonyl's hydrogen bonding indicates a possible sensor of the critical pyrimidine 2-position in the minor groove, but requires further experimental support.

7 CONCLUSIONS

The major motivation for continuing interest in this area is the need for better tools to study macromolecular interactions involving larger pieces of nucleic acids than are currently normally studied. Shifts on formation of DNA–protein complexes have been reported for several cases.^{39–41} In general, these shifts are interpretable using the same rationales, interrelation, major or minor groove binding, disruption of pairing and/or stacking, and possible displacement of water, and it may be expected that their extension with ^{13}C and ^{15}N labeled nucleic acid components would be invaluable. Continuing efforts in rationalizing the observed shift effects then also remain a priority.

1 INTRODUCTION

A long time has passed since the formulation of relativistic quantum mechanics. Meanwhile, it has become chemistry textbook knowledge that atoms and molecules containing heavy nuclei exhibit so-called relativistic effects which, e.g., cause mercury to be liquid and are responsible for the color and the chemical inertness of gold. A qualitative explanation based on the Bohr model for one-electron atoms is straightforward. Special relativity has to be considered when velocities are no longer small compared to the speed of light. The Bohr formulae can be interpreted such that, in atomic units (see below), the electron in the ground state has a velocity of Z , with Z being the nuclear charge. The speed of light, c , has a value of approximately 137 in the same units. This illustrates that electrons in heavy atoms can reach a substantial fraction of the speed of light, and it is therefore clear that core orbitals in heavy atoms show sizable relativistic effects. It has been somewhat surprising, however, that valence orbitals exhibit relativistic effects of the same order in c^{-2} as core orbitals, which cause significant changes in the chemical properties of heavy element compounds. Relativistic effects for valence orbitals are nowadays well investigated and understood. For elements of the 6th row of the periodic table (Cs–Rn), the correction terms are so large that nonrelativistic quantum chemical computations often do not yield even a qualitatively correct answer. It is generally accepted that relativistic computations have to be carried out for such atoms and their compounds. c^{-2} appears in the relativistic theory – due to its smallness – as an expansion parameter, by which perturbational orders of relativistic corrections are

characterized. The nonrelativistic limit is approached for $c \rightarrow \infty$.

Nuclear shieldings and spin–spin couplings are very sensitive experimental probes for the electronic and geometrical structure of a compound. For the same reason, however, they are difficult to compute accurately. In the presence of heavy nuclei, any attempt to achieve a reasonable agreement between theory and experiment has to consider relativistic effects in the computations. Both the current state of relativistic quantum chemical methods and the art of computing NMR parameters have advanced far enough that a large body of computational results for heavy element systems obtained with a variety of methods is available. Remarkable results have been achieved, e.g., the explanation of certain experimental trends such as the ‘halogen dependence’, or the ability to compute NMR parameters with the heavy nuclei as the probe. Therefore it is appropriate to give a short overview here of the methodologies being used so far as well as results that have been obtained for a number of heavy atom systems.

Concerning the methodology, we focus on methods that are capable of treating both light and heavy nuclei with respect to NMR shieldings and spin–spin couplings on a first-principles basis (meaning *ab initio* methods and approximate Kohn–Sham density functional theory (DFT)). Variational methods are emphasized, but the possibility of treating relativity as a perturbation is frequently mentioned. In particular for nuclear shieldings, certain chemical trends have successfully been explained upon inclusion of spin-orbit coupling to first order alone, and a number of such results are quoted in Section 3. Concerning the spin–spin couplings, we focus on couplings involving a heavy nucleus. Dimensionless atomic units (unit of charge $e = 1$, electron mass $m = 1$, $4\pi\epsilon_0 = 1$, $\hbar = 2\pi$, $c \approx 137.036$) are used in the theoretical section. The electronic g -factor is assumed to be exactly 2, as predicted by the Dirac equation, and not written explicitly.

Computed or experimental nuclear shieldings and chemical shifts are quoted in ppm (10^{-6}), spin–spin couplings either as reduced couplings K in SI units of $\text{kg m}^{-2} \text{s}^{-2} \text{A}^{-2}$, or as coupling constants J in Hertz (s^{-1}). The discussion of theoretical results and interpretations refer to a time-independent treatment of closed-shell molecules with fixed nuclei.

In Section 2, we outline the theoretical approach to heavy atom NMR. Illustrative results and interpretations for chemical shifts and spin–spin couplings presented in Sections 3 and 4, respectively, are chosen in order to cover a range of chemical applications and trends and a number of different methodologies.

2 RELATIVISTIC THEORY OF NMR SHIELDINGS AND SPIN–SPIN COUPLING CONSTANTS

In this section the theoretical methodology that allows for the relativistic computation of NMR parameters of molecules is outlined. Due to the vast amount of literature and the many different techniques in the field of relativistic quantum chemistry, no attempt has been made to give a complete overview. Instead, a hierarchy of currently common approximations from which magnetic properties can be extracted is sketched in a pragmatic way. For details we refer to some of the books and review articles on relativistic quantum chemistry.^{1–4}

2.1 Relativity in Quantum Chemistry

‘Ordinary’ nonrelativistic quantum chemistry deals with the solution of the time-independent many-electron Schrödinger equation

$$\hat{\mathcal{H}}^{\text{nr}}\Psi = \Psi E \quad (1)$$

where Ψ is the many-electron wavefunction of an atom or molecule with fixed nuclei, and E is the total energy.

$$\hat{\mathcal{H}}^{\text{nr}} = \sum_{i=1} \frac{\hat{\mathbf{p}}_i^2}{2} + \sum_{i=1} V_{Ni} + V_{ee} + V_{\text{nuc}} \quad (2)$$

is the nonrelativistic Hamiltonian consisting of the nonrelativistic kinetic energy operator $\hat{\mathbf{p}}_i^2/2$ for each electron i , the electron-nucleus attraction potential V_{Ni} for each electron, the nonrelativistic electron–electron Coulomb repulsion $V_{ee} = \sum_{j>i} 1/r_{ij}$, and the internuclear repulsion potential V_{nuc} . $\hat{\mathbf{p}} = -i\nabla$ is the momentum operator in space representation. Since analytic solutions of equation (1) for many electron systems are not known, approximations have to be made. As a starting point, the N -electron equation is usually separated into N effective one-electron equations for one-particle wavefunctions ψ (so called atomic or molecular orbitals) which depend on an effective potential V . For simplicity, we implicitly refer to such effective one-electron equations (or true one-electron systems) in the following, by using the symbol ψ for the one-electron wavefunction or orbital. Particular details of common approximations are not discussed in this section.

In relativistic quantum chemistry, $\hat{\mathcal{H}}^{\text{nr}}$ in equation (1) is replaced by its relativistic counterpart. All of the problems of the nonrelativistic many-electron theory are present in the relativistic formulation as well. Hence, similar techniques are common in order to find approximate solutions; in particular, use of orbitals is made. However, relativistic quantum chemistry has its own specific problems associated with it, one of them being the lack of a consistent relativistic many-particle Hamiltonian being derived from quantum electrodynamics. Therefore, relativistic many-electron atomic and molecular computations rely on the use of the four-component ‘no-pair’ Dirac–Coulomb–Breit Hamiltonian or some approximation obtained from it:

$$\hat{\mathcal{H}}^{\text{DCB}} = \hat{P}^+ \left[\sum_{i=1}^N (c\boldsymbol{\alpha}_i \hat{\mathbf{p}}_i + \beta_i c^2) + V_{Ni} + V_{ee} + \sum_{j>i=1}^N \hat{\mathcal{H}}_{ij}^{\text{B}} + V_{\text{nuc}} \right] \hat{P}^+ \quad (3)$$

Here, $\boldsymbol{\alpha}$ and β are 4×4 matrices introduced by Dirac in order to obtain a relativistic wave equation for spin-1/2 particles from the ‘classical’ relativistic Hamilton function. In its standard representation, $\boldsymbol{\alpha}$ is written in terms of the well-known Pauli spin-matrices $\boldsymbol{\sigma}_s$ (not to be confused with the symbol for the nuclear shielding tensor). The $\hat{\mathcal{H}}_{ij}^{\text{B}}$ (Breit interaction, see, e.g., Ref.⁴) are relativistic corrections to V_{ee} that contain the so-called magnetic interaction and further account for the fact that the electron–electron interaction is not instantaneous but is transmitted with a finite speed. Use of the projection operators $\hat{P}^+$ cures some of the problematic

features of the Dirac–Coulomb(–Breit) operator by restricting its solutions to the positive energy spectrum, the eigenfunctions of which are identified with the desired electronic states (no-pair approximation^{2,5}). We have to stress here that though $\hat{\mathcal{H}}^{\text{DCB}}$ is in general not truly Lorentz invariant, it “provides an excellent approximation to the full theory”.³

The main difference between the four-component relativistic and the nonrelativistic Hamiltonian is seen to be in the kinetic energy operator for an electron, which is $c\boldsymbol{\alpha}\hat{\mathbf{p}} + \beta c^2$ in equation (3) instead of $\hat{\mathbf{p}}^2/2$ in $\hat{\mathcal{H}}^{\text{nr}}$. It takes into account the relativistic increase of electron mass due to high velocities, it includes the electron’s rest mass energy, it incorporates the electron spin, and also causes the spin-orbit coupling. Although electron spin needs to be considered in the nonrelativistic theory in an ad hoc manner in order to account for experimental facts, a coupling between spin and spatial degrees of freedom occurs only in the relativistic theory. For simplicity of notation, we omit the $\hat{P}^+$ in the following, and we do not explicitly consider the Breit interaction since it is actually being neglected in many computations. Its relative importance to, e.g., total atomic energies was found to decrease with increasing nuclear charge from $\sim 50\%$ in He to $\sim 2\%$ in Hg relative to the one-electron relativistic corrections.⁶

A conceptually straightforward way of performing a relativistic molecular computation in order to obtain a starting point for a calculation of NMR properties is to use directly the time-independent Dirac equation

$$\hat{\mathcal{H}}^{\text{D}}\psi^{\text{D}} = \psi^{\text{D}} E \quad (4)$$

with

$$\hat{\mathcal{H}}^{\text{D}} = c\boldsymbol{\alpha}\hat{\mathbf{p}} + \beta c^2 + V \quad (5)$$

Note that we used here the aforementioned simple notation for (effective) one-electron equations. ψ^{D} is a four-component relativistic orbital. Because $\boldsymbol{\alpha}$ and β are 4×4 matrices, the wavefunction has to be a four-component vector for which each component is a complex function of space. Due to the four components, such molecular computations are unfortunately quite expensive as compared to nonrelativistic ones, and the explicit inclusion of electron correlation is a formidable task.

Many attempts have been made to transform the four-component equation (4) into two-component form, in order to keep interpretations simpler and to reduce the computational effort. However, so-called picture change effects occur, a discussion of which is beyond the scope of this overview (see, e.g., Ref.⁷ and references cited therein.) Here we give an account of some of these methods. Writing $\boldsymbol{\alpha}$ explicitly in terms of the 2×2 Pauli spin-matrices $\boldsymbol{\sigma}_s$, the Dirac equation (4) reads

$$(\hat{\mathcal{H}}^{\text{D}} - E)\psi^{\text{D}} = \begin{pmatrix} V - E & c\boldsymbol{\sigma}_s \hat{\mathbf{p}} \\ c\boldsymbol{\sigma}_s \hat{\mathbf{p}} & V - E - 2c^2 \end{pmatrix} \begin{pmatrix} \varphi \\ \chi \end{pmatrix} = 0 \quad (6)$$

The zero of the energy scale has been shifted in equation (6) to $+mc^2$, $m = 1$, the rest mass energy of the electron, so that bound states have negative energy as usual in nonrelativistic quantum chemistry. Here, φ and χ are the so-called ‘upper’ and ‘lower’ components of the four-component orbital ψ^{D} , each of them made up of two components. The functions φ

and χ are also frequently referred to as the ‘large’ and ‘small’ components because of the $1/2c$ prefactor in equation (7) below. (Note, however that, depending on the potential and the location, the ‘small component’ can be much larger than the ‘large’ one, e.g., for $p_{1/2}$ orbitals close to the nucleus.) From the second row of the matrix one obtains explicitly

$$\chi = X\varphi = \frac{1}{2c}k\sigma_s\hat{p}\varphi \quad (7)$$

with $k = (1 - [(V - E)/2c^2])^{-1}$, which yields the relation between the upper and the lower component. Because φ and χ are not independent of each other, it should be possible to obtain a relativistic two-component equation for φ or χ alone, the solutions of which contain the same information as ψ^D . In the elimination of the small component (ESC) scheme, equation (7) is directly substituted in the equation obtained from the first row of the matrix in (6) and yields the two-component Hamiltonian:

$$\hat{\mathcal{H}}^{\text{ESC}} = V + \frac{1}{2}(\sigma_s\hat{p})k(\sigma_s\hat{p}) \quad (8)$$

In the nonrelativistic limit, $c \rightarrow \infty$, $k \rightarrow 1$, and then, with $(\sigma_s\hat{p})^2 = \hat{p}^2$, the nonrelativistic Schrödinger Hamiltonian is recovered from the ESC operator (8):

$$\hat{\mathcal{H}}^{\text{nr}} = V + \frac{1}{2}(\sigma_s\hat{p})^2 \quad (9)$$

Another way in which to obtain the nonrelativistic limit is to multiply (4) with $\hat{\mathcal{H}}^D$ before taking the limit $c \rightarrow \infty$. Although the ESC equation appears to be very illustrative, the Hamiltonian depends (through k) on the unknown energy and is not usable in actual linear variational calculations. In order to arrive at an energy-independent two-component equation, the Foldy–Wouthuysen (FW) transformation of $\hat{\mathcal{H}}^D$ to block-diagonal form is achieved by

$$\hat{\mathcal{H}}^{\text{FW}} = U\hat{\mathcal{H}}^D U^{-1} \quad (10)$$

When $\hat{\mathcal{H}}^{\text{FW}}$ is block diagonal, this completely uncouples the upper and lower component and yields the desired two-component equation and $\chi = X\varphi$, an energy-independent relation between upper and lower component [see equation (7)]. U can be written in terms of X , see, e.g., the literature cited in Ref.⁷ For many-electron systems, the exact form of X and U and therefore the exact form of $\hat{\mathcal{H}}^{\text{FW}}$ are not known. Different approximations for X yield different approximate two-component Hamiltonians in which the uncoupling of the two components is only achieved to a certain order in c^{-2} . These approximate two-component Hamiltonians are sometimes collectively denoted as ‘quasi relativistic’.

A rather simple approach is to expand (7) to zeroth order in c^{-2} . This yields $X \approx c\sigma_s\hat{p}/2c^2$, which results in the famous Pauli Hamiltonian⁸ after carrying out the transformation (10) with $U(X)$:

$$\hat{\mathcal{H}}^{\text{Pauli}} = \hat{\mathcal{H}}^{\text{nr}} - \frac{\hat{p}^4}{8c^2} - \frac{(\hat{p}^2 V)}{8c^2} + \frac{i}{4c^2}\sigma_s[(\hat{p}V) \times \hat{p}] \quad (11)$$

The second, third, and fourth term on the right-hand side of (11) are the mass–velocity (MV), Darwin (DAR), and

spin-orbit (SO) terms, respectively, representing corrections of order c^{-2} to the nonrelativistic Hamiltonian. The Pauli operator has certain pathological features due to the fact that close to a nucleus where V is very large (it goes to $-\infty$ for point-like nuclei), $(V - E)/2c^2$ is not small and neglecting this term in equation (7) is not justified. As a result, the Pauli operator affords severe singularities. Moreover, it is not variationally stable and permits only a perturbational treatment to first order. Higher order contributions yield diverging terms. Variational computations based on the Pauli operator have been frequently carried out, by using frozen cores and minimal basis sets in the core regions for valence orbitals, under which circumstances the variational instability can be kept somewhat under control in many cases. We refer to such frozen core methods in Sections 3 and 4 when speaking about variational Pauli computations. A *scalar relativistic* approach is obtained by omitting the SO term. This yields a one-component formalism analogous to the nonrelativistic scheme with pure α - and β -spin orbitals, that contain the – in many cases dominant – scalar relativistic effects. It is also possible to separate off a spin-orbit part in the Dirac equation.

One of the possible alternatives for the Pauli Hamiltonian is offered by the so-called zeroth order regular approximation (ZORA) method.⁹ Some authors refer to the ZORA Hamiltonian as the Chang–Pélissier–Durand (CPD) operator. It is obtained from the zeroth order of an expansion of k in powers of $E/(2c^2 - V)$ in equation (7). This expansion parameter remains rather small in particular where the potential V goes to $-\infty$. The two-component ZORA Hamiltonian resulting from the transformation (10) reads

$$\hat{\mathcal{H}}^{\text{ZORA}} = V + \frac{1}{2}(\sigma_s\hat{p})\mathcal{K}(\sigma_s\hat{p}) \quad (12a)$$

$$= V + \frac{1}{2}\hat{p}\mathcal{K}\hat{p} + \frac{i}{2}\sigma_s[(\hat{p}\mathcal{K}) \times \hat{p}] \quad (12b)$$

with $\mathcal{K} = 2c^2/(2c^2 - V)$. Note the formal similarity to the ESC Hamiltonian in (8), with k replaced by $\mathcal{K}$. The nonrelativistic limit corresponds to $\mathcal{K} \rightarrow 1$, $(\hat{p}\mathcal{K}) = 0$. The first and the second term in (12b) yield $\hat{\mathcal{H}}^{\text{nr}}$ plus scalar relativistic corrections, while the third term is the ZORA SO operator. For small V , $(\hat{p}\mathcal{K}) \approx (\hat{p}V)/2c^2$, and the ZORA SO term is similar to the Pauli SO term. Close to a nucleus, both operators differ substantially. The use of the ZORA method in heavy element computations is becoming increasingly popular, and the results are in most cases superior to those obtained with the Pauli operator. Conceptually, the ZORA operator has the disadvantage of not being invariant with respect to a change of the origin of the energy scale (gauge invariance), as can be seen from the fact that only V but not $(V - E)$ occurs in the operator. The standard choice for the potential is $V(\mathbf{r}) \rightarrow 0$ for $\mathbf{r} \rightarrow \infty$. Most of the resulting problems can be circumvented by a ‘scaling’ procedure or by the use of frozen core potentials or model potentials for the construction of $\mathcal{K}$.

A different way of transforming the Dirac Hamiltonian to two-component form is used in the Douglas–Kroll (DK) method. Here, U in equation (10) is obtained via subsequent transformations that uncouple the upper and lower components to some order n in c^{-2} written as

$$U_n = \sqrt{1 + W_n^2} + W_n \quad (13)$$

where W_n is anti-hermitian. For U_0 , the FW transformation for the free electron is used. To higher orders, equations for W_n have to be solved in order to achieve further uncoupling. Already with U_1 , most of the relativistic effects are recovered. We refer the reader to, e.g., Ref.³ for details and original references. In particular due to the work of Hess and co-workers, the DK method has been established as a reliable tool in quantum chemistry for the computation of heavy element compounds. To some extent, the ZORA and the DK method to lowest order yield quite comparable results for many molecular properties. As an advantage, the DK method does not suffer from a gauge invariance problem, at the disadvantage of a somewhat more complicated formalism, if spin-orbit coupling and magnetic fields are included.

In order to arrive at a relativistic perturbation theory that avoids the infinities of the Pauli Hamiltonian to higher orders, so-called ‘direct’ or ‘Dirac’ four-component perturbation theory (DPT) can be employed. By a simple change of metric between upper and lower components in the Dirac equation (6), an expansion of the resulting four-component equation in powers of c^{-2} is straightforward and leads to non-singular first and higher order expressions for E and ψ . A treatment of magnetic properties has been described in detail in the literature.¹⁰ However, higher order expressions become computationally rather expensive, while at the same time it is well known that first-order relativistic perturbation theory is not sufficient for such ‘relativistic’ elements as, e.g., Au, Hg or Pb for the determination of bond energies or molecular geometries. It can be assumed that relativistic corrections up to order c^{-4} at least are also necessary for NMR parameters for such nuclei, in which case a variational procedure (Dirac, ZORA, DK) might be easier to implement and computationally not much more or even less expensive.

As an alternative to the aforementioned methods which incorporate relativity directly into the calculations, the use of relativistic effective core potentials (ECPs) allows for consideration of relativistic effects in molecular computations. Inclusion of spin-orbit coupling is also possible in these methods. Recent benchmark calculations¹¹ have shown that ECPs can yield very reliable properties of heavy element compounds.

As already mentioned, the potential V in the equations in this section might not simply refer to the external potential (e.g., V_{Nf}) for one-electron systems but to an effective many-electron potential. In this case, V implicitly contains effects that are due to the electron–electron Coulomb repulsion $1/r_{ij}$. The explicit transformation of $1/r_{ij}$ to two-component form yields new relativistic operators of order c^{-2} instead, for example the two-electron spin-orbit operator. Use of the effective electronic potential in V in the one-electron SO operator accounts, to some extent, for these two-electron terms in a mean-field sense. Transformation of the Breit interaction to two-component form yields further two-electron terms, such as the spin-other-orbit operator.

2.2 Nuclear Shieldings and Spin–Spin Couplings

A basic quantity that formally allows access to many properties of atoms and molecules is the total (electronic + nuclear repulsion) energy E of the system. It is readily available, to some degree of accuracy depending on the approximations that have been made, from quantum chemical

computations, either from a relativistic or nonrelativistic formalism, based on variational or perturbational approaches. We refer to the wavefunction or the set of orbitals that produced this energy as the ‘zeroth order solution’. In practice, it does not initially contain the effects from external magnetic fields or nuclear spins, but it might incorporate relativistic effects. Many observables, among them NMR shielding and spin–spin coupling tensors, can be defined as derivatives of the total energy of the system under investigation. The shielding tensor σ for a nucleus A is given by

$$\sigma(A) = \left. \frac{\partial^2 E}{\partial \mathbf{B}^{\text{ext}} \partial \mu_A} \right|_{\mathbf{B}^{\text{ext}}=0, \mu_A=0} \quad (14a)$$

while the reduced nuclear spin–spin coupling tensor $\mathbf{K}$ involving two nuclei A and B is obtained from

$$\mathbf{K}(A, B) = \left. \frac{\partial^2 E}{\partial \mu_A \partial \mu_B} \right|_{\mu_A=0, \mu_B=0} \quad (14b)$$

Here, $\mathbf{B}^{\text{ext}}$ is the applied external magnetic field, and μ_A is the magnetic moment of nucleus A , related to its intrinsic angular momentum $\mathbf{I}_A$ by $\mu_A = \gamma_A \hbar \mathbf{I}_A$ with γ_A being the magnetogyric ratio of the nucleus. We refer to some of the many excellent review articles focusing on the nonrelativistic computation of NMR parameters for details.^{12–15} Equations (14a,b) conceptually serve as the starting point for a perturbational approach by which the energy derivatives can be evaluated once the zeroth order solution has been obtained. For the spin–spin coupling, the direct (through space) coupling between two nuclei does not yield a contribution to the coupling constants for rapidly rotating molecules (i.e., for measurements in gas phase or in solution) and is not discussed further. We implicitly refer to indirect spin–spin couplings throughout the rest of this article.

For the general case of two perturbations, described by the perturbation parameters κ and λ with Cartesian components $\kappa_x, \kappa_y, \kappa_z$ etc., the mixed second derivative of the total energy

$$E = \langle \Psi | \hat{H} | \Psi \rangle \quad (15)$$

with respect to the perturbation parameters is given from standard double perturbation theory by equation (16). There it is assumed that the Hellmann–Feynman theorem holds with respect to the first perturbation λ for approximate zeroth-order solutions. In the NMR case, the nuclear magnetic moments or the external magnetic field are directly interpreted as the perturbation parameters due to their relative ‘smallness’.

$$\begin{aligned} E^{(1,1)} &= \left. \frac{\partial^2 E}{\partial \kappa \partial \lambda} \right|_{\kappa=0, \lambda=0} \\ &= \langle \Psi^{(0,0)} | \hat{\mathcal{H}}^{(1,1)} | \Psi^{(0,0)} \rangle + 2\text{Re} \langle \Psi^{(0,1)} | \hat{\mathcal{H}}^{(1,0)} | \Psi^{(0,0)} \rangle \end{aligned} \quad (16)$$

The superscripts denote the order of perturbation with respect to λ and κ , respectively. Because λ and κ are vectors, $E^{(1,1)}$ is a 2nd rank tensor. $\hat{\mathcal{H}}^{(1,0)} = \partial \hat{H} / \partial \lambda|_{\lambda=0}$, $\Psi^{(0,1)} = \partial \Psi / \partial \kappa|_{\kappa=0}$, etc. $\Psi^{(0,1)}$ represents the change of the wavefunction due to the presence of the perturbation denoted by κ , i.e., either the external magnetic field, or the magnetic field arising from one

of the nuclear spins. $\Psi^{(0,1)}$ can be formally obtained from solving the first-order perturbed wave equation

$$(\hat{\mathcal{H}}^{(0,0)} - E^{(0,0)})\Psi^{(0,1)} + (\hat{\mathcal{H}}^{(0,1)} - E^{(0,1)})\Psi^{(0,0)} = 0 \quad (17)$$

showing that $\hat{\mathcal{H}}^{(0,1)}$ has to be known in order to compute $\Psi^{(0,1)}$. In DFT, formally similar expressions involving a sum over the Kohn-Sham orbitals instead of the many-electron wavefunction Ψ are used to compute σ and $\mathbf{K}$.

In the sum-over-states formulation it is assumed that the unperturbed ground state $\Psi_0 = \Psi^{(0,0)}$ with $E_0 = E^{(0,0)}$ and all the excited states (energies E_i and wavefunctions Ψ_i) corresponding to the field-free Hamiltonian $\hat{\mathcal{H}}^{(0,0)}$ are known. The Ψ_i form a complete basis set in which $\Psi^{(0,1)}$ can be expressed as

$$\Psi^{(0,1)} = \sum_{a \neq 0} \Psi_a C_a \quad (18)$$

with yet unknown coefficients C_a . With the first-order equation (17), one obtains for the C_a after some manipulation

$$C_a = \sum_{a \neq 0} \frac{\langle \Psi_a | \hat{\mathcal{H}}^{(0,1)} | \Psi_0 \rangle}{E_0 - E_a} \quad (19)$$

and therefore for the nuclear shielding or spin-spin coupling

$$E^{(1,1)} = \langle \Psi_0 | \hat{\mathcal{H}}^{(1,1)} | \Psi_0 \rangle + 2\text{Re} \sum_{a \neq 0} \frac{\langle \Psi_0 | \hat{\mathcal{H}}^{(0,1)} | \Psi_a \rangle \langle \Psi_a | \hat{\mathcal{H}}^{(1,0)} | \Psi_0 \rangle}{E_0 - E_a} \quad (20)$$

We have to stress here that although equation (20) is *formally* correct, in practice not all (or any) of the excited states of $\hat{\mathcal{H}}^{(0,0)}$ are (or can be) known. However, equation (20) serves as a convenient basis for an interpretation of the final results and approximations to it can be easily identified within orbital models. Employing variational perturbation theory, $E^{(1,1)}$ is in practice usually directly computed from the zeroth order solution based upon the set of occupied and unoccupied (virtual) orbitals that serve as a one-particle basis in most theoretical methods.¹⁶ In simple cases, for each occupied orbital a sum over virtual orbitals similar to (20) can be derived as the contributions to $E^{(1,1)}$, in which $E_0 - E_a$ is replaced by differences between occupied and virtual orbital energies, $\epsilon_i - \epsilon_a$. However, these orbital contributions also take into account possible first-order change in the potential caused by the perturbation, and a possible dependence of the basis set on the perturbation. Neglecting any change in the potential V leads to so-called uncoupled equations that are much easier and computationally cheaper to solve. (In DFT, neglecting the current-density dependence of the density functional leads to the mentioned uncoupled approach when the first-order perturbations of the orbitals due to the external magnetic field are evaluated.) For interpretation purposes, the potential change is often negligible, in which case the orbital contributions can have exactly the form (20), but with Ψ_0 replaced by an occupied orbital ψ_i (with energy ϵ_i) and Ψ_a and E_a replaced by virtual orbitals ψ_a and their energies ϵ_a . In particular the HOMO-LUMO gap plays an important role here, since it leads to the largest individual

$1/(\epsilon_i - \epsilon_a)$. Another factor is, of course, the magnitude of the $\langle \psi_i | \hat{\mathcal{H}}^{(0,1)} | \psi_a \rangle$ and $\langle \psi_a | \hat{\mathcal{H}}^{(1,0)} | \psi_i \rangle$ matrix elements. For chemical shifts (not shieldings) and spin-spin couplings, it turns out that $\langle \Psi_0 | \hat{\mathcal{H}}^{(1,1)} | \Psi_0 \rangle$, the diamagnetic term (see below), is often of only minor importance. It is also possible to write the diamagnetic term in a sum-over-states form.¹⁷ *For simplicity of notation, we refer to equation (20) as the working equation for evaluating σ and $\mathbf{K}$ regardless of the actual method being used.*

Once the zeroth order solution is known, and the perturbation operators with respect to μ_A and $\mathbf{B}^{\text{ext}}$ have been formulated, σ and $\mathbf{K}$ can be computed based on equation (20) in some chosen computational approximation. For the relativistic case of heavy element systems, E , Ψ and the perturbation operators refer to a relativistic zeroth-order treatment. In case relativity is treated as a perturbation itself, this leads to at least second- and third-order perturbation expressions for σ and $\mathbf{K}$ in which the order of derivatives is arbitrary. In this case, relativity can be conceptually regarded as a perturbation of an initially nonrelativistic expression for (14a,b).

In order to apply equation (20) for the computation of NMR shieldings or spin-spin couplings, the presence of the external magnetic field $\mathbf{B}^{\text{ext}}$ and the magnetic field due to the nuclear spins has thus to be considered in the theory. More specifically, within a chosen theoretical level (nonrelativistic, four-component, a variational two-component scheme, relativistic perturbation theory, ...) the Hamiltonian $\hat{\mathcal{H}}(\mathbf{B}^{\text{ext}}, \mu)$ is to be formulated in order to determine $\hat{\mathcal{H}}^{(1,1)}$, $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$. Magnetic fields $\mathbf{B}$ are usually incorporated into quantum chemistry by finding the corresponding magnetic vector potential $\mathbf{A}$ which is related to the magnetic field $\mathbf{B}$ by $\mathbf{B} = \nabla \times \mathbf{A}$, and making the so-called minimal substitution for the momentum operator in the field-free Hamiltonian,

$$\hat{\mathbf{p}} \longrightarrow \hat{\boldsymbol{\pi}} = \hat{\mathbf{p}} - q\mathbf{A} \quad (21)$$

with respect to a particle of charge q . We use $q = -e = -1$ for an electron in the following.

The well-known gauge-invariance problem arises here, viz. a given magnetic field does not uniquely define the vector potential, since adding the gradient $\nabla f(\mathbf{r})$ of any scalar function to $\mathbf{A}$ does not change $\mathbf{B}$, because $\nabla \times \nabla f(\mathbf{r}) = 0$. Often, f is chosen such that $\nabla \mathbf{A} = 0$ (Coulomb gauge). We use this gauge in the following. A different gauge of $\mathbf{A}$ can, e.g., be represented by choosing a different origin for the coordinate representation of $\mathbf{A}$. Although for a large class of variationally determined *exact* wavefunctions, expectation values do not depend on the chosen gauge, this is not generally true for approximate wavefunctions in a finite basis.¹⁶

For a point-like nuclear magnetic dipole, the vector potential is

$$\mathbf{A}_A^\mu = \frac{1}{c^2} \frac{\mu_A \times \mathbf{r}_A}{r_A^3} \quad (22)$$

$\mathbf{r}_A$ being the distance vector with respect to nucleus A , and r_A its length. Due to the strong inhomogeneity of $\mathbf{A}_A^\mu$, the position of the nucleus A is generally used as the origin for $\mathbf{A}_A^\mu$. The vector potential of an external, homogeneous magnetic field reads

$$\mathbf{A}^{\text{ext}} = \frac{1}{2} \mathbf{B}^{\text{ext}} \times \mathbf{r} \quad (23)$$

For a molecule with many atoms there exists no obvious gauge origin since $\mathbf{r}$ refers to an arbitrarily chosen coordinate system. Nuclear shieldings obtained with wavefunctions approximated in a finite basis depend more or less strongly on the chosen origin. The $\mathbf{A}^{\text{ext}}$ gauge problem is circumvented in, e.g., the gauge-independent or gauge-including atomic orbitals (GIAO) or the individual gauge for localized orbitals (IGLO) methods. In these methods, field dependent basis functions or molecular orbitals are employed to ensure gauge invariance of expectation values. Such distributed gauge origin methods are commonly used in computations of nuclear shieldings. Another, less effective procedure is to supplement the basis sets by functions that are chosen such as to remove the gauge dependence to some extent without being of critical importance for the determination of the energy or the molecular structure. The gauge origin problem has been extensively discussed in the literature (see, e.g., Refs.^{12,13,18} and literature cited therein for details).

Equation (22) is the most frequently used expression for the nuclear magnetic vector potential. It is known that for very accurate relativistic results, a finite nucleus model should be adopted both to obtain the zeroth-order solution as well as in the NMR perturbation calculation. However, almost all of the results quoted later in this work have been obtained with the point-nucleus approximation, and the influence of finite-nucleus corrections on the final results does not seem to be of critical importance.

Substituting (21) into the nonrelativistic one-electron Schrödinger Hamiltonian, equation (9), yields the additional ‘magnetic’ terms

$$\hat{\mathcal{H}}_{\text{nr}}^{\text{mag}} = \frac{1}{2}(\mathbf{A}\hat{\mathbf{p}} + \hat{\mathbf{p}}\mathbf{A} + i\sigma_s[\hat{\mathbf{p}} \times \mathbf{A} + \mathbf{A} \times \hat{\mathbf{p}}] + A^2) \quad (24)$$

The operators linear in $\mathbf{A}$ are called the paramagnetic terms, while those proportional to A^2 are called the diamagnetic terms. The second term on the right-hand side of equation (24) describes the interaction of the electronic spin with a magnetic field and is not present if one starts with the one-component Schrödinger equation where $(\sigma_s\hat{\mathbf{p}})^2$ of equation (9) is replaced by $\hat{\mathbf{p}}^2$ before the minimal substitution is made (this implies that the substitution $\hat{\mathbf{p}} \rightarrow \hat{\pi}$ has to be made before transformation to two-component form and then the limit $c \rightarrow \infty$ is taken). In the ZORA or ESC case, formally very similar magnetic operators are obtained that contain relativistic corrections due to the presence of $\mathcal{K}$ or k . For the ZORA case, see Refs.^{19,20} For a derivation of the magnetic terms arising from the second-order DK transformation and from the Pauli Hamiltonian, see Refs.^{21,22} The ESC case is illustrated elsewhere.²³

Substituting $\hat{\mathbf{p}}$ with $\hat{\pi}$ in the one-electron Dirac operator (5) yields a single paramagnetic term

$$\hat{\mathcal{H}}_{\text{D}}^{\text{mag}} = c\alpha\mathbf{A} \quad (25)$$

Since the nonrelativistic limit (24) as well as relativistic two-component Hamiltonians afford a diamagnetic term, this should be contained in a result for $E^{(1,1)}$ obtained from (25). It has been shown that a diamagnetic contribution to $E^{(1,1)}$ in equation (16) indeed arises in the four-component scheme due to the contributions from negative energy eigenfunctions of $\hat{\mathcal{H}}^{\text{D}}$, that are used as a basis set in a sum-over-states expression for $\Psi^{(0,1)}$ in equation (16),²⁴ even though there is only a paramagnetic perturbation operator (25).

Upon explicit substitution of $\mathbf{A} = \mathbf{A}^{\text{ext}} + \sum_A \mathbf{A}_A^\mu$ from equation (23), and equation (22) or a finite-size magnetic dipole version of it, $\hat{\mathcal{H}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu})$ is finally obtained. Taking the derivatives with respect to $\mathbf{B}^{\text{ext}}$ and $\boldsymbol{\mu}_A, \boldsymbol{\mu}_B$ then yields $\hat{\mathcal{H}}^{(1,1)}$, $\hat{\mathcal{H}}^{(0,1)}$ and $\hat{\mathcal{H}}^{(1,0)}$ for a specific nonrelativistic or relativistic theoretical scheme. In the case of nuclear shieldings, it is most economic to take $\hat{\mathcal{H}}^{(1,0)} = \partial\hat{\mathcal{H}}/\partial\boldsymbol{\mu}_A|_{\boldsymbol{\mu}_A=0}$, while $\Psi^{(0,1)} = \partial\Psi/\partial\mathbf{B}^{\text{ext}}|_{\mathbf{B}^{\text{ext}}=0}$. In the nonrelativistic case, one obtains the one-electron operators

$$\hat{\mathcal{H}}_{\text{nr}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu}) = A^{\text{ext}^2} + \hat{\mathcal{H}}^{\text{OZ}} + \hat{\mathcal{H}}^{\text{SZ}} + \hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{DS}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}} + \hat{\mathcal{H}}^{\text{OD}} \quad (26)$$

Here,

$$\hat{\mathcal{H}}^{\text{OZ}} = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot (\mathbf{r} \times \hat{\mathbf{p}}) = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot \hat{\mathbf{L}} \quad (27a)$$

$$\hat{\mathcal{H}}^{\text{SZ}} = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot \boldsymbol{\sigma}_s \quad (27b)$$

$$\hat{\mathcal{H}}^{\text{OP}} = \frac{1}{c^2} \sum_A \boldsymbol{\mu}_A \left(\frac{\mathbf{r}_A}{r_A^3} \times \hat{\mathbf{p}} \right) \quad (27c)$$

$$\hat{\mathcal{H}}^{\text{DS}} = \frac{1}{2c^2} \sum_A \left[(\boldsymbol{\mu}_A \cdot \mathbf{B}^{\text{ext}}) \left(\frac{\mathbf{r}_A}{r_A^3} \cdot \mathbf{r} \right) - (\boldsymbol{\mu}_A \cdot \mathbf{r}) \left(\mathbf{B}^{\text{ext}} \cdot \frac{\mathbf{r}_A}{r_A^3} \right) \right] \quad (27d)$$

$$\hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}} = \frac{1}{2c^2} \sum_A \boldsymbol{\sigma}_s \left[\boldsymbol{\mu}_A \left(\nabla \cdot \frac{\mathbf{r}_A}{r_A^3} \right) - (\boldsymbol{\mu}_A \cdot \nabla) \frac{\mathbf{r}_A}{r_A^3} \right] \quad (27e)$$

$$\hat{\mathcal{H}}^{\text{OD}} = \frac{1}{2c^4} \sum_{B \neq A} \frac{(\boldsymbol{\mu}_A \cdot \boldsymbol{\mu}_B)(\mathbf{r}_A \cdot \mathbf{r}_B) - (\boldsymbol{\mu}_A \cdot \mathbf{r}_B)(\boldsymbol{\mu}_B \cdot \mathbf{r}_A)}{r_A^3 r_B^3} \quad (27f)$$

(27a) is the orbital Zeeman term, (27b) spin Zeeman, (27c) paramagnetic orbital, (27d) diamagnetic shielding, (27e) Fermi-contact + spin-dipole, (27f) diamagnetic orbital term, respectively. The individual FC and SD operators, in particular the well-known δ function for the FC term, are obtained by explicitly carrying out the differentiation of $\mathbf{r}_A/r_A^3$ in (27e). Note that the presence of c in the nonrelativistic magnetic operators does *not* denote any relativistic terms, but c emerges from the magnetic units in equation (22) and the fact that the fine structure constant equals $1/c$ in the chosen atomic units. As already mentioned, the operators in the ZORA or ESC case are formally quite similar to the nonrelativistic ones, but include $\mathcal{K}$ or k and their derivatives, yielding different spatial contributions in particular for the FC term, but similar physical interpretations. We therefore use the same names for the operators when referring to these two-component relativistic schemes.

As compared to the nonrelativistic or two-component ones, the Dirac form of the one-electron magnetic operators look rather simple:

$$\hat{\mathcal{H}}_{\text{D}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu}) = -\frac{c}{2}\mathbf{B}^{\text{ext}} \cdot (\boldsymbol{\alpha} \times \mathbf{r}) - \frac{1}{c} \sum_A \boldsymbol{\mu}_A \cdot \left(\boldsymbol{\alpha} \times \frac{\mathbf{r}_A}{r_A^3} \right) \quad (28)$$

Taking the derivatives with respect to $\mathbf{B}^{\text{ext}}$ and μ_A in order to apply equation (20) is conceptually straightforward. Since (26) is connected to (28) as its nonrelativistic limit, the apparent simplicity of the four-component operators results in the many two-component terms through the coupling of the upper and lower components of the wavefunction by the Dirac operators. The ‘Gordon-decomposition’ of the Dirac shielding tensor provides a route to interpret the four-component results in the more common way of paramagnetic and diamagnetic contributions.²⁵ See, e.g., Ref.²⁶ for numerical examples.

Referring to the two-component scheme, equations (27a–f), it can be seen that the OZ, OP and DS operators contribute to the nuclear shielding. Explicitly,

$$\begin{aligned}\hat{\mathcal{H}}^{(1,1)} &= \left. \frac{\partial^2 \hat{\mathcal{H}}^{\text{DS}}}{\partial \mathbf{B}^{\text{ext}} \partial \mu_A} \right|_{\mathbf{B}^{\text{ext}}=0, \mu_A=0} \\ \hat{\mathcal{H}}^{(1,0)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_A} \right|_{\mu_A=0} \\ \hat{\mathcal{H}}^{(0,1)} &= \left. \frac{\partial \hat{\mathcal{H}}^{\text{OZ}}}{\partial \mathbf{B}^{\text{ext}}} \right|_{\mathbf{B}^{\text{ext}}=0}\end{aligned}\quad (29)$$

are used in equation (20). Here, the external field and the nuclear spin induce electronic paramagnetic orbital currents through $\hat{\mathcal{H}}^{\text{OZ}}$ and $\hat{\mathcal{H}}^{\text{OP}}$, respectively, the magnetic fields of which cause the paramagnetic nuclear shielding. The diamagnetic shielding contribution from $\hat{\mathcal{H}}^{\text{DS}}$ is due to the diamagnetic electronic currents induced in the electronic system. As already mentioned, we restrict the discussion here to the spin-compensated case (closed-shell molecules). Without spin-orbit coupling, the FC and SD terms do not contribute to the nuclear shielding in closed shell systems, i.e., with pure spin-orbitals the contributions from spin-up and spin-down orbitals due to $\hat{\mathcal{H}}^{\text{FC}}$, $\hat{\mathcal{H}}^{\text{SD}}$ exactly cancel because the external magnetic field does not induce spin density.

For nonrelativistic spin–spin couplings, one uses

$$\begin{aligned}\hat{\mathcal{H}}^{(1,1)} &= \left. \frac{\partial^2 \hat{\mathcal{H}}^{\text{OD}}}{\partial \mathbf{B}^{\text{ext}} \partial \mu_A} \right|_{\mu_A=0, \mu_B=0} \\ \hat{\mathcal{H}}^{(1,0)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_A} \right|_{\mu_A=0} \\ \hat{\mathcal{H}}^{(0,1)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_B} \right|_{\mu_B=0}\end{aligned}\quad (30)$$

Similar to NMR shieldings, the OP and OD terms introduce paramagnetic and diamagnetic electronic currents due to a nuclear magnetic moment that can further interact with the perturbations from another nucleus. The SD and in particular the FC term both yield nonzero contributions and cause a different coupling mechanism. These operators introduce a net electronic spin density at or around, say, nucleus A , which is transferred through the electronic system (chemical bonds) to nucleus B and interacts with its spin magnetic moment there. There is also a mixed term between the FC and the SD contribution, that contributes to the anisotropy of the $\mathbf{K}$ tensor. Again, in the nonrelativistic case, where spin and spatial degrees of freedom are completely independent from each other, all ‘mixed’ contributions to $\mathbf{K}$ between orbital-

and spin-dependent operators yield zero (e.g., the contribution due to $\hat{\mathcal{H}}^{\text{FC}}$ in $\hat{\mathcal{H}}^{(1,0)}$ with the one due to $\hat{\mathcal{H}}^{\text{OP}}$ in $\hat{\mathcal{H}}^{(0,1)}$ and vice versa in equation (20)). The same arguments concerning vanishing terms involving both spin- and orbital-dependent operators apply in the scalar relativistic case.

The situation is much different at the presence of SO coupling. Spatial and spin degrees of freedom are then coupled and not longer independent from each other. Not unexpectedly therefore, in, e.g., the Pauli, ESC, DK, or ZORA case including the one-electron spin-orbit (1e-SO) operator, mixed contributions involving both spin- and orbital-dependent operators occur for σ and $\mathbf{K}$ in this case. In particular, the spin-dependent FC and SD terms contribute to the chemical shielding because, through SO coupling, an external magnetic field induces net spin-density even in a closed-shell system. Likewise, for spin–spin couplings, mixed terms between spin- and orbital-dependent operators in $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$ are no longer zero. In variational two-component procedures in which the zeroth-order computation and the magnetic operators are based on the same formalism and no terms have been omitted initially, no new operators or new terms in the expressions for σ or $\mathbf{K}$ arise due to SO coupling. In case that the (usually Pauli) 1e-SO operator is introduced as a first-order perturbation, the additional terms are formulated and calculated explicitly, which is convenient for interpretations. The same holds for additional scalar relativistic corrections. The operators arising from the minimal substitution $\hat{\mathbf{p}} \rightarrow \hat{\boldsymbol{\pi}}$ in the spin-orbit operator itself have thereby been overlooked for a long time.²² For nuclear shielding, the most important contribution due to spin-orbit coupling has been shown to arise from the FC term in the external magnetic field, while for spin–spin couplings, the FC-OP cross term appears to be dominant in the cases being investigated so far. See Sections 3.1 and 4.2 for further comments and explanations. All the 1e-SO contributions are, of course, contained in the four-component treatment based on equation (28).

As already mentioned, transformation of the electron–electron interaction to two-component form yields various new terms, among them the two-component two-electron spin-orbit and spin-other-orbit operators (collectively being denoted here by ‘2e-SO’), which give rise to various additional magnetic contributions in the presence of magnetic fields. See, e.g., Refs.^{4,16,27} for theoretical details. Unless explicitly mentioned, we refer to the 1e-SO effects in the following. Actual program implementations may make use of an effective potential in the 1e-SO operator and the results may therefore contain two-electron SO effects to some extent.

2.3 Computational Methods

While the importance of Hartree–Fock computations in quantum chemistry is generally decreasing in favor of either correlated ab initio methods or DFT, it is still one of the common methods in the field of computation of heavy atom NMR parameters. A four-component implementation of Hartree–Fock shielding tensors and spin–spin couplings has been reported by Visscher and co-workers^{28,29} and an implementation for nuclear shieldings by Nakatsuji and co-workers.^{26,30,31} Both implementations use a common gauge origin for the external magnetic field. Pioneering NMR Hartree–Fock calculations including scalar relativistic effects based on the Pauli operator or the DK transformation, and

spin-orbit effects based either upon explicit consideration of the Pauli SO operator or the use of spin-orbit ECPs, have been reported by Nakatsuji et al.^{32,33} and by Fukui et al.^{21,22,34} Theoretically somewhat less justified ‘mixed’ methods such as using the scalar part of the DK operator together with Pauli SO for the zeroth-order solution and nonrelativistic + Pauli SO operators for NMR shieldings have also been used with reasonable success.³⁵ The main disadvantage of the Hartree–Fock based methods is, of course, the neglect of electron correlation, that has been demonstrated to be of high importance for the determination of NMR parameters in general and of heavy atom spin–spin couplings in particular.

To the best of our knowledge, four-component post Hartree–Fock or DFT implementations of NMR parameters have not yet been carried out, but can be expected in the near future at least for the DFT case. Post Hartree–Fock MCSCF computations of heavy atom nuclear shieldings (employing GIAO) and spin–spin couplings have so far considered spin-orbit effects only, based on a perturbational first-order treatment of the Pauli SO operator.^{36–40} Scalar relativistic effects from the heavy atom were neglected in this case. This method is often suitable for NMR of light nuclei close to a heavy atom and has been successfully applied to small molecules. Likewise, SO ECPs are able to recover the important spin-orbit effects on neighbor atom shieldings that are being neglected by scalar relativistic ECPs.

The first-order SO approach has already been utilized in the pioneering approaches for the computation of nuclear shieldings in heavy atom compounds, involving simple semiempirical wavefunctions.^{41–44} For spin–spin couplings, relativistic effects have been first considered in the form of correction factors applied on top of nonrelativistic Hartree–Fock or semiempirical wavefunctions.^{45,46} Four-component extended Hückel theory (REX) has been developed and extensively applied to both heavy atom shieldings and spin–spin couplings by Pyykkö and co-workers.⁴⁷

The restriction of excluding the heavy nuclei in the NMR computations applies technically to a common use of ECPs in heavy element computations. Existing methodology for NMR parameters that has been derived for all-electron calculations cannot be used without modification for NMR parameters of those atoms for which an ECP is used. In this case, either a NMR methodology directly derived from the pseudopotential formalism would have to be used, or at least the pseudo-orbitals need to be orthogonalized on the relativistic heavy atom cores before applying a standard all-electron code.

Density functional theory (DFT)⁴⁸ has been very successful in the field of heavy atom NMR computations. Methodological development for relativistic NMR computations has been performed in particular by Kaupp, Malkin, Malkina and co-workers^{49–51} (using the IGLO method for shieldings), and by Ziegler and co-workers (GIAO for shieldings).^{19,20,52–54} Taking into account that the electron density, the spin density and the current density define the one-electron magnetic contributions to σ and $\mathbf{K}$, and that these densities are (of course only in principle) obtained exactly from Kohn–Sham DFT,⁵⁵ its application to NMR parameters has a theoretically well founded base. From the experience gained so far it seems that the current-density dependence and also relativistic corrections of the exchange–correlation functional are not very large, and quite reasonable results can be obtained with standard

nonrelativistic local-density (LDA) or generalized gradient (GGA) approximations (in which, however, the density can be a relativistic one). The fact that electron correlation is to some extent accounted for in contemporary Kohn–Sham DFT, and due to its computational effectiveness with regard to the number of atoms that can be treated simultaneously, most of the relativistic NMR computations on larger systems such as transition metal complexes are currently based on DFT. For the heavy atom DFT NMR computations carried out so far, various relativistic methods have been utilized, among them perturbational use of the Pauli SO operator, variational computations with the Pauli operator and frozen cores excluding or including SO coupling, the use of the ZORA Hamiltonian, and use of scalar relativistic and spin-orbit ECPs.

We further note that some authors subdivide the relativistic effects of NMR parameters into ‘direct’ and ‘indirect’ effects, the latter being related to the change of the NMR parameters with respect to a change of the computed molecular structure due to relativity. It is known that small geometrical changes can result in sizeable changes of shieldings and couplings. The choice of experimentally determined structures, if available, for the computations is unambiguous and leaves only the ‘direct’ effects to be discussed.

Apart from acronyms already specified in the previous sections, we make use of the following abbreviations from now on: vPSO, vPSC, vPauli for variational Pauli SO only, scalar only, and scalar + SO, respectively; similarly, pPSO, pPSC, pPauli denote first-order perturbational relativistic calculations; HF for Hartree–Fock; DKSC, DK for Douglas–Kroll, first order without and with SO corrections, respectively, and MCSCF for multiconfigurational Hartree–Fock (ab initio).

3 HEAVY ATOM NUCLEAR SHIELDINGS

Suggestions on the importance of relativistic corrections to nuclear shieldings and first numerical estimates for atoms date back to the 1960s. In 1969, Nakagawa argued that spin-orbit coupling would be an important factor for nuclear shieldings of light nuclei in the neighborhood of heavy halides.⁵⁶ Subsequently, semiempirical calculations of the respective SO effect in hydrogen and methyl halides were carried out by Morishima et al.,⁴¹ Volodicheva and Rebane⁴² and Cheremisin and Schastnev.⁴³ In the early 1980s, several authors published the formalism of nuclear shieldings within the four-component (Dirac) scheme.^{25,57,58} This work and its future importance was subsequently reviewed by Jameson.⁵⁹ We also refer the reader to subsequent articles by Jameson and Jameson et al. who review the literature in the computational NMR field on a yearly basis. In particular the more recent articles show a large increase of publications based on relativistic methods. See, e.g., Ref.⁶⁰ for a relativistic NMR application in solid-state physics. Already anticipated by Pyykkö⁵⁷ in his remark “A rigorous implementation of the present theory will [...] probably take some time”, four-component ab initio (Hartree–Fock) calculations of NMR shieldings in molecules have been reported only rather recently.^{26,28,31}

Following the historical computational development we discuss SO effects on NMR shieldings prior to scalar relativistic effects.

3.1 Spin-orbit Coupling Effects

The proton chemical shift in the series of hydrogen halides HX (X = F, Cl, Br, I) and the ^{13}C shifts in CH_3X are probably the most thoroughly studied parameters in heavy atom NMR computations. The reason is that these molecules are among the smallest samples in which the strong SO dependence of NMR chemical shifts can be computed and compared to experiment. The HX and CH_3X series therefore serve as benchmarks for heavy atom NMR computations where, due to the smallness of the systems, high quality basis sets can be employed nowadays. The trend being obtained from the computations is always similar, regardless of which method has been used: excluding SO coupling does not recover the experimentally observed trend, but with inclusion of SO effects the calculated values follow the experimental trend. The numerical quality of the results is, of course, much dependent on the chosen method, and also somewhat on whether scalar relativistic effects have been additionally considered or not. Table 1 displays some of the results for the HX series that have been obtained during the last three decades. The data establish that the experimental trend can indeed be explained on the basis of SO effects only, while exclusion of SO effects does not reproduce the right trend even if scalar relativistic effects are considered.

Explanations of the SO contribution to nuclear shielding have been given in almost all of the articles quoted in Table 1 and many other papers. Qualitatively, let us consider the singlet (closed shell) ground state wavefunction without SO coupling first. As in equation (18), we assume that Ψ_0 and all the excited states of the Hamiltonian (without SO coupling) are available as a complete basis set. Expanding the spin-orbit coupled wavefunction on this basis means that, due to the nature of the SO operator, contributions also from excited triplet states will enter the SO wavefunction. Now the perturbed SO wavefunction in an external magnetic field, represented in the same basis, will have different coefficients for the singlet and

triplet states and thereby the magnetic field can effectively induce a net spin density in the electronic system. The FC and SD operators also induce spin density and therefore the contribution from these operators to the NMR shielding are no longer zero.

In the case of the shielding of a light nucleus L in the neighborhood of a heavy atom Y, the spin density is induced by the external field around Y, transferred through the chemical bond(s) to the light nucleus L, and is there 'detected' by the FC and SD perturbations (heavy-atom effect on the light-atom shielding (HALA) in contrast to the heavy atom effect on the heavy nucleus shielding itself, HAAA⁶¹). This suggests a qualitative similarity to the nonrelativistic FC/SD mechanism of nuclear spin-spin coupling, where the spin density is not induced by the external field but by the FC and SD perturbation from another nucleus. This similarity has already been proposed in 1969 by Nakagawa et al.,⁵⁶ but no unambiguous numerical evidence could be provided. Recent DFT computations⁶² on a number of systems convincingly demonstrate the correlation between $K(\text{L},\text{Y})$ and the spin-orbit contribution to $\sigma(\text{L})$ induced by Y. In particular, a familiar Karplus-type dihedral angle relation known for three-bond spin-spin couplings has been obtained for the SO contribution to proton shielding in iodoethane that closely follows the behavior of $^3K(\text{H},\text{I})$. Many numerical results obtained by different authors show that the SD contribution to spin-orbit induced shielding can often be neglected, and the FC part is usually dominant. The same holds for nuclear spin-spin couplings (Section 4). Similar to spin-spin couplings, too, is that the magnitude of the FC contribution to nuclear shielding depends on the σ -character of the L-Y bond(s). This allows for similar chemical interpretations.^{51,62}

The case of $\delta(^{13}\text{C})$ in methyl halides is not as spectacular as the hydrogen halides. Still, qualitative agreement with experimental data can only be achieved upon inclusion of SO coupling in the shieldings calculation, while scalar relativistic corrections are of minor importance. Benchmark data for

these and other small molecules have been published, e.g., in Refs.^{32,36,43,47,49,53,63}

The importance of the influence of two-electron ($2e^-$) SO operators or the Breit correction in the Dirac scheme has been investigated by some authors.^{30,36,50} For $\sigma(^1\text{H})$ in HX and $\sigma(^{13}\text{C})$ in MeX , the $2e^-$ -SO contributions were found to be small and of opposite sign to the $1e^-$ -SO shielding terms. The relative importance of the two-electron terms appears to be generally decreasing for these cases as the heavy atom becomes heavier, contributing about 30% to the (small) SO shift caused by F substituents and about 7% to the (large) SO shift caused by iodine substituents. Similar conclusions for the relative importance of the $2e^-$ -SO terms were obtained for the shielding of the heavy atom,³⁶ for which (see next section) the scalar relativistic effects should not be neglected. For increasingly heavy X, the scalar relativistic corrections may be of higher importance than the two-electron SO terms. See, e.g., the DK results in Table 1. On the other hand, the vPSC DFT values of Ref.⁵² do not indicate such large scalar relativistic corrections. At the present level of accuracy that can currently be achieved by either nonrelativistic + pPSO or four component ab initio methods, or relativistic DFT, the two-electron SO contributions appear to be rather negligible for heavy element molecules.

One of the major successes of relativistic NMR shieldings computations has been the explanation of the origin of the 'normal' and 'inverse' halogen dependence (NHD and IHD) in many compounds. Well known to experimentalists and theoreticians, shieldings of light atoms L bound to a halogen X quite often strongly increase as X becomes heavier (NHD) and its electronegativity decreases. Examples are HX , shown above, CH_3X , CH_2X_2 , etc., and many other main group compounds in particular in high oxidation states. However, counter examples are known, where the L nucleus becomes less shielded for decreasing electronegativity (and increasing nuclear charge) of X, at least for Cl (sometimes Br) compared to F. Sometimes, in those compounds the NHD is observed again for $\text{X} = \text{I}$ (and sometimes Br). Examples are SiX_4 , AlX_4^- , and many transition metal compounds. As in HX (Table 1), in the investigated cases the NHD is caused by the

SO contribution to nuclear shielding, while the nonrelativistic computations predict an IHD behavior. Figure 1 displays the Hartree–Fock data obtained for some silicon halides in 1995. Very similar results for these and other compounds were obtained in the same year by a semiempirical approach.⁴⁴

Extremely large SO corrections to the phosphorus chemical shift in PX_4^+ have been reported in Ref.⁶⁴ and were attributed to the pronounced s-character of the L–X bonds due to the high oxidation state of phosphorus. Similar NHD results can be found in many theoretical studies of the SO shielding contribution. The authors of Ref.⁶⁵ investigated a number of Ti tetrahalides and Nb hexahalides. Rather typical for early transition metal halides, almost vanishing net SO effects on the metal shielding were observed even for the tetra- and hexa-iodides, caused by a cancellation of positive SO contributions from the FC term and negative changes of the paramagnetic shielding at the presence of SO coupling. In this case, IHD for the series $\text{F} \rightarrow \text{I}$ is observed for the chemical shifts in agreement with experiment. This has been interpreted in terms of the different nature of the metal d-orbitals binding to the ligands as compared to (s- and) p-orbitals in the case of main group elements exhibiting NHD.

If one bases the interpretation for the IHD on equation (20), the decreasing HOMO–LUMO gap due to decreasing electronegativity of the halogen in the series $\text{X} = \text{F} \rightarrow \text{I}$ results in a larger magnitude of the paramagnetic shielding, if the matrix elements in the sum over excited states are assumed to be approximately constant. (In Ref.⁶⁶, excellent linear correlation of ^{95}Mo chemical shifts with the lowest magnetically allowed d–d* excitation energy has been observed for a number of Mo complexes.) Since the nonrelativistic paramagnetic shielding contribution is typically negative, this results in increasingly positive chemical shifts (IHD). From the investigations quoted above it becomes clear that the NHD, on the other hand, is due to the more pronounced influence of spin-orbit coupling, which often increases the shielding and therefore causes increasingly negative chemical shifts. The diamagnetic shielding, as a core property, is usually found to be of small influence concerning the chemical shifts. From the relativistic nature of the NHD it becomes clear why previous

Figure 1 ^{19}Si chemical shifts with respect to SiF_4 in silane and some silicon halides, from Hartree–Fock data.³³ Scalar rel. and SO effects considered here via ECPs on the halide ligands. (a) experimental vs. computed Si shifts. (b) NHD and IHD along the SiX_4 series. See Section 3.1

explanations of the NHD that only take the (nonrelativistic) paramagnetic shielding into account have not generally been convincing.

Density functional theory (DFT) has been particularly successful in the case of transition metal compounds, and generally in cases for which electron correlation has a strong influence on the NMR shielding, and where a correlated *ab initio* method including relativistic effects has not been available or has not been applicable due to the size of the system (see also the section on spin–spin couplings). An example where electron correlation is believed to be very important is the ^{13}C shift in the series of CX_3^+ . Nonrelativistic DFT and MP2 calculations show very similar results exhibiting IHD. This trend is also observed, but strongly overestimated, by nonrelativistic Hartree–Fock calculations, indicating the importance of electron correlation. Further inclusion of SO coupling in the DFT calculations recovers the experimentally observed NHD for $\text{X} = \text{Cl} \rightarrow \text{Br} \rightarrow \text{I}$ with good accuracy.⁶⁷

Most of the relativistic DFT studies of transition metal compounds include scalar relativistic effects and are discussed in the next section.

3.2 Including Scalar Relativistic Effects

From a computational point of view, the most simple way of including scalar relativistic effects in a NMR shieldings calculation is to use an available scalar relativistic ECP on the heavy atom. When HALA effects are studied, existing nonrelativistic NMR code can be (and is) used without modifications. Many studies have been carried out using this approach, see, e.g., Refs.^{51,68} for overviews of density functional applications in particular to transition metal complexes. In view of the importance of SO corrections to σ as seen in the previous section, however, the range of applications of this method seems to be limited. Spin-orbit ECPs have been applied to a number of NMR ligand shieldings including heavy main group and transition metal compounds.^{33,63} Restrictions with respect to HALA effects also apply to the purely scalar relativistic approach of Ref.⁵², in which HX and a number of transition metal complexes are studied. However, the method is capable of treating the heavy metal shift (and HAH effects) itself, with reasonable accuracy as shown for the W shifts in Table 2. In Ref.⁶⁹, an overview of this variational scalar Pauli method is given. Among other data, a large number of ^{125}Te shifts are presented. In comparison with experiment, the relativistic computations achieved good accuracy, therefore SO effects can be regarded as mostly unimportant for Te chemical shifts. An increase of the scalar relativistic effects of the shielding of the heavy nucleus X with $\sim Z^{3.5}$ has been found from SCDK calculations for the HX series.²¹ This underlines the importance of scalar relativistic corrections for heavy

nucleus shieldings. Computational methods that include both scalar relativistic and SO effects and have been applied to both light and heavy nucleus shieldings are, of course, the four-component methods,^{26,28,30} and, e.g., Douglas–Kroll including SO effects,^{70–72} Pauli including SO,^{22,53} or the ZORA approach.^{19,73} A collection of transition metal tetroxo- and hexacarbonyl complexes appears to represent a benchmark test set for DFT NMR implementations. Oxygen shifts of group 6–8 transition metal tetroxo-complexes were studied, e.g., in Refs.^{52,74} with a scalar relativistic approach. The rather good agreement with experimental shifts suggests that SO coupling does not play an important role in this case. Scalar relativistic effects on the ligand shifts appeared to be of high importance only for the 5d metals and are almost negligible for the 3d metals. The metal shifts in the same set of complexes were studied by variational scalar + SO Pauli and ZORA SO DFT.⁷⁵ Unfortunately, no oxygen shifts were reported there for comparison. The results for the metal shifts have been satisfactory, with ZORA emerging as the superior method in this case. Table 2 displays some ^{183}W shifts that were obtained by DFT methods and by a Hartree–Fock approach⁷⁰ including scalar + SO effects. The results indicate that scalar and SO effects are probably of equal importance for the W shifts. In Ref.⁷⁶, a larger number of W shifts than quoted in Table 2 have been computed by both vPauli and by ZORA DFT. ZORA resulted in a mean error of approximately 3% of the total shift range of 7000 ppm for the investigated samples when compared to experiment. The Pauli approach performed worse in this case, with an error of about 6%. ZORA produced a similar accuracy for a number of ^{207}Pb chemical shifts reported in the same study (4% error compared to the covered shift range), whereas the mean error from the Pauli approach was found to be four times larger in this case. The ZORA computations predicted an enormous SO shift of the Pb shielding of PbI_4 of more than -8000 ppm, a number yet to be supported by experimental results.

Carbon chemical shifts for 5d transition metal carbonyl complexes studied with DFT are displayed in Table 3. SO effects play a less significant role for the ^{13}C chemical shift in these complexes as compared to HX, but systematically improve the computed results. The SO shifts do not easily follow intuitive arguments based on the size of the HOMO–LUMO gap (HLG).⁵³ From equation (20) the individual contributions to the shielding can be expected to decrease with increasing HLG along a row of the periodic table. Despite the fact that the HLG increases from approximately 2 to 6 eV from $[\text{Hf}(\text{CO})_6]^{2-}$ to $[\text{Ir}(\text{CO})_6]^{3+}$, the spin-orbit contribution to the nuclear shielding and to the chemical shift is nevertheless seen to be increasing from Hf to Ir. As illustrated in Ref.⁵³, the trend can be rationalized on the basis that, due to the relative energies of the metal d_σ , d_π and the CO σ and π^*

Table 2 Some ^{183}W Chemical Shifts

orbitals, the bonding in Hf carbonyl is dominated by $d_{\pi}-\pi_{\text{CO}}^*$ interaction, whereas the bonding in Ir carbonyl is dominated by $d_{\sigma}-\sigma_{\text{CO}}$ interaction. CO is more likely to σ -donate charge to the highly positively charged Ir, whereas metal-ligand π -back-donation dominates in the Hf complex. Only in the former case, however, can spin density be effectively transferred to the carbon nucleus, therefore the magnitude of the SO induced carbon shift is increasing along the 5d transition metal carbonyl series despite the increasing HLG. It has been shown previously that the decreasing $\delta(^{13}\text{C})$ along the series at the scalar relativistic level is due to a complex interplay of different factors in which the amount of π -back-donation is predominant.^{77,78}

In a ZORA DFT study of ^{195}Pt chemical shifts,⁷⁹ the authors also found that simple arguments based on the magnitude of $1/(\epsilon_i - \epsilon_a)$ are not always able to provide an explanation of the observed trends. The magnitude of the matrix elements in the numerator of the sum in equation (20) has to be considered as well and needs to be explained by intuitive chemical arguments. In the case of Pt shifts, NHD is observed in many cases. An analysis of the computational data shows that both the SO contributions and the paramagnetic shielding approximately equally contribute to the NHD. For the paramagnetic Pt shielding, this was attributed to a preference of the soft acid Pt(II) to bind to the soft base I instead of Cl. The authors in Ref.⁷⁹ could numerically and graphically illustrate that this results in a smaller magnitude of the (negative) paramagnetic shielding for iodine ligands due to smaller paramagnetic matrix elements in equation (20) that overcompensate the opposite HLG influence. The overall accuracy of the ZORA DFT method for Pt shieldings resulted in a mean error of approximately 10% of the investigated chemical shift range for 23 samples.⁷⁹

Mercury shieldings have been computed by DFT and Hartree–Fock methods.^{19,71,72} Table 4 lists some results that have been obtained. As can be seen from the data for HgMeX and HgX_2 , the mercury halide compounds exhibit NHD, largely caused by the SO effects on the nuclear shieldings.^{19,71} Large ‘coupling’ between scalar and SO corrections to mercury shifts were noted in Ref.⁷¹ This means that the inclusion of both relativistic mechanisms is important in order to achieve reasonable results, because the SO correction based on a non-relativistic zeroth order solution is much different from the one obtained from a scalar relativistic one. It is well known that scalar relativistic effects substantially stabilize and contract the 6s orbital in Hg, while the Hg 5d shell is destabilized and spatially expanded as compared to nonrelativistic computations.

In effect, the scalar relativistic Hg–ligand bonds are much different from the nonrelativistic ones, meaning that the s and d contributions in the occupied and virtual metal-ligand orbitals, that determine to some extent the magnitude of the SO corrections to the chemical shifts, will be very different as well. In Ref.⁷¹, the rather unsatisfactory performance of the computations, in particular the strong overestimation of the SO shift corrections for the HgX_2 series (Table 4, large basis set) was attributed to the missing treatment of 2e-SO terms. The authors proposed that 20–40% of the 1e-SO contribution to the chemical shift may be canceled by the two-electron contributions, which seems to be excessive taking the previously quoted findings about the relative importance of the two-electron SO terms for heavy atom compounds into account. Considering the reasonable overall performance of the DFT calculations for Hg shifts (they do not include 2e-SO operators explicitly), the inaccuracies of the Hartree–Fock results for HgX_2 could also be attributed to the missing treatment of electron correlation. Another problem might be the inconsistent treatment of relativity, viz. the use of the problematic Pauli SO operator in conjunction with the scalar relativistic DK Hamiltonian. This has been criticized by Fukui.²¹

For the series $\text{Hg}(\text{LCH}_3)_2$, L = C, Si, Ge, which has been computed with a DK transformed Hamiltonian including SO coupling, it was found that the rather small magnitudes of Hg chemical shifts are caused by cancellation of large relativistic and nonrelativistic contributions.⁷² Even the usually negligible SD contribution to the chemical shift is here comparable in magnitude to the shift itself. In that respect, the achieved results must be regarded as quite accurate and testify to the accuracy of the relativistic treatment with the DK Hamiltonian. The authors also consider missing solvent effects as a possible source of error, an issue that has already been addressed regarding mercury chemical shifts.¹⁹ Experimentally confirmed, the solvent dependence of, e.g., the Hg shift in HgI_2 can amount to more than 1000 ppm (pyridine vs.

THF). It has been computationally demonstrated in Ref.¹⁹, that direct coordination of the metal by a nucleophilic solvent (pyridine, simulated by NH_3 in the ZORA computations) is largely responsible for the large experimental solvent effects on chemical shifts. The computations were able to qualitatively simulate a strong positive contribution to $\delta(^{199}\text{Hg})$ due to the coordination of the solvent to Hg. The resulting geometry change (bending of X–Hg–X by approximately 30°) upon complexation was found to increase the magnitude of the (negative) chemical shift by ~ 600 ppm for HgCl_2 , while the direct interaction of the solvent with the heavy atom caused a large shift of δ by $\sim +1100$ ppm. THF was supposed to coordinate much less strongly to Hg and not to cause a significant change of the linear structure of HgX_2 . A possible influence on the chemical shift due to THF that might account for the differences between theory and experiment in Table 4 has therefore not been investigated.

It should be noted here that absolute shielding values of, e.g., 8020 ppm from ZORA DFT,¹⁹ and of 15 128 ppm from spin-orbit DK Hartree–Fock⁷² for ^{199}Hg in $\text{Hg}(\text{CH}_3)_2$ have been reported. While the paramagnetic and diamagnetic shieldings are approximately equal in both methods, the reported spin-orbit corrections differ by ~ 7000 ppm. The differences obviously largely cancel regarding the chemical shift and demonstrate that due to cancellation of systematic errors, chemical shifts are much easier to compute accurately than absolute shieldings in particular for such heavy nuclei. We therefore do not list reported absolute shielding values in the tables.

Chemical shifts in compounds containing elements as heavy as uranium have been investigated^{73,80} with DFT. In Ref.⁸⁰, variational Pauli and ZORA calculations have been employed together with standard GGA functionals, as well as a scalar relativistic ECP in conjunction with the B3LYP hybrid functional. ^{19}F chemical shifts in a number of U-halide complexes were obtained with moderate absolute accuracy with both the ZORA and the Pauli approaches, while certain trends between different compounds could not be reproduced by the GGA functionals. SO effects for the F shifts were found to be of low importance (typically ~ 30 ppm for Pauli and somewhat less for ZORA, as compared to experimental shifts between 750 and 790 ppm). The scalar relativistic ECP/B3LYP did yield systematically between 80 and 270 ppm too large chemical shifts, but certain trends were better reproduced. From this, the authors concluded that the ECP approach is beyond its limit for actinide NMR and that improved XC functionals are needed for the nonhybrid DFT methods in order to reproduce some trends among a series of compounds more accurately. A clearly better performance of ZORA vs. Pauli could not be observed in this study.

Many of the studies cited so far also provide relativistic effects on the shielding tensor anisotropy, $\Delta\sigma$. See Refs.^{28,36,37} for examples. The practical application of these quantities for heavy atom systems is, however, rather limited so far. We therefore refer to the literature for detailed discussions of relativistic effects on $\Delta\sigma$, and only mention here that huge effects have been reported so far.

4 HEAVY ATOM SPIN–SPIN COUPLINGS

Nuclear spin–spin couplings are not very easy to compute accurately, in particular for heavy elements, but can often be

measured with high precision. Unlike the case of chemical shifts, where systematic errors in the computation may cancel when the shifts are obtained from the difference of the two computed shielding values of the probe and the reference compounds, there is no such cancellation of errors for spin–spin couplings. Another problem is that the interest is often in couplings involving a heavy nucleus itself, and scalar relativistic effects can be enormously large. Therefore, attempts to calculate spin–spin couplings similarly to the NMR shieldings case just by considering the Pauli SO operator to first order did not yield very satisfactory results for couplings involving a heavy nucleus.^{38–40} However, this method seems to be applicable for the study of HALA effects in some cases.³⁸ Likewise, ECPs can be employed for this type of application (e.g., in Ref.⁸¹). However, in the following we focus on couplings to a heavy nucleus itself. As compared to chemical shieldings, much less computational data are yet available.

4.1 (Mostly) Scalar Relativistic Effects

Scalar relativistic effects are usually believed to yield the major influence on heavy nuclear spin–spin couplings. The reason for this is related to the fact that the FC term (27e) was found to represent the dominant contribution for an overwhelming number of couplings that have been investigated (of course, counter examples are known). In its usual nonrelativistic form for point-like nuclei, the FC term originates from the value of the induced spin-density *directly* at the nuclei, while its relativistic generalizations probe the space very close to the nuclei.^{20,29} There, in particular, the electron density is substantially modified due to the scalar relativistic operators ($\text{MV} + \text{DAR}$ in the Pauli formalism, equation (11)), and a huge influence on the FC perturbations can be expected. This was noted in 1968⁸² regarding the contact term in NMR spin–spin coupling and has been known since 1930⁸³ from the theory of atomic hyperfine splittings.

The authors of Refs.^{45,46} introduced relativistic correction factors (RCFs) for hyperfine integrals of atomic orbitals (AOs), which account for the relativistic increase of the electron density at the respective nucleus. The RCFs can then be used in nonrelativistic molecular computations to scale the AO integrals entering the FC expression for the coupling tensor in equation (20). The authors of Ref.⁸⁴ reported a somewhat related procedure that is applicable to couplings involving a heavy nucleus, based on the variational scalar Pauli treatment. The semiempirical approaches described in, e.g., Refs.^{85–88} also make use of integrals based on four-component atomic computations in an otherwise nonrelativistic formalism.

To give the reader an idea of the magnitude of the RCFs, we note that, e.g., a value of 2.4386 has been reported⁴⁵ for the Hg 6s orbital. This means that, if the coupling Hg–L (L = light nucleus) is dominated, as it is often the case, by the FC contribution and by the 6s orbital on the Hg side, the coupling relativistically increases by almost a factor of 3. Likewise, Hg–Hg and other couplings between 6th row elements can be expected to relativistically increase by almost an order of magnitude. Even for rather light fourth row nuclei, nonnegligible relativistic effects on coupling constants of $\sim 10\%$ can be expected. This should be compared to the celebrated huge relativistic bond contraction of many Au(I) compounds, which is of the order of 10%.

A problem connected with the RCFs is that they do not account for relativistic changes of the molecular orbitals that determine the spin–spin coupling. Such changes would be obtained from a variational or higher than first-order perturbational relativistic molecular computation. The RCFs are also not able to describe relativistic effects of L–L' couplings in the neighborhood of a heavy nucleus for the same reason. In many cases, relativistic changes of the zeroth-order solution may either enhance or quench the strong relativistic effects of the AO integrals and lead to much different answers than obtained from the RCFs. In these, and other cases for which the coupling is not dominated by the FC term, a consistent first-principles variational or perturbational scheme for molecules is desirable.

The four-component formalism of nuclear spin–spin couplings has been subsequently published by Pyykkö, who provided a simple LCAO example for $K(\text{Hg}-\text{C})$ in dimethylmercury.⁸⁹ The results are very typical for heavy-atom spin–spin couplings. They exhibit a huge relativistic increase of $K(\text{Hg}-\text{C})$ by a factor of 2.7, with the new mixed contributions due to spin-orbit coupling being almost negligible for the isotropic coupling and yielding a somewhat larger contribution to the anisotropy ΔK of the coupling tensor. ΔK thereby increased even stronger by a factor of 3.3 due to relativity. A formulation for spin–spin couplings within the four-component scheme based on the polarization propagator method has been published by Aucar and Oddershede.⁹⁰ An implementation for spin–spin couplings within the relativistic extended Hückel theory (REX) was applied to many systems and often recovered the experimentally observed trends and provided explanations.⁹¹ Recently, an ab initio Hartree–Fock four-component implementation and benchmark results for HX , H_2Y , ($\text{Y} = \text{O}, \text{S}, \text{Se}, \text{Te}$), and some plumbanes have been reported.^{24,28,29} Also rather recently, the two-component ZORA DFT approach for spin–spin couplings has been formulated and implemented by the present authors.^{20,54} Earlier semiempirical approaches based on the MNDO, AM1 and PM3 Hamiltonians, and ab initio methods including the Pauli SO operator, have already been mentioned. See Ref.²³ for a review on hyperfine interaction in metals from the solid-state physics point of view.

The series YH_4 , $\text{Y} = \text{C}, \text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$, has been studied as benchmark systems in many of the references cited so far. The results show a strong scalar relativistic increase in the FC contribution to the Y–H coupling, that amounts to roughly a factor of two in the case of $\text{Y} = \text{Pb}$. Table 5 displays spin–spin couplings in plumbanes obtained from different theoretical methods. Nonrelativistically, the FC term to the couplings is dominant and all other contributions are almost negligible. In the relativistic case, the situation is not much different. The new mixed contributions due to SO coupling are not negligible, but rather small.^{40,54,91} The scalar relativistic corrections to FC terms of the Pb–L couplings clearly dominate and it can be seen from Table 5 that the total relativistic corrections to the Pb–L couplings are very substantial. The correlated ab initio study of Kirpekar et al.,⁴⁰ only including SO effects, was not able to achieve qualitative agreement with experiment, but could provide evidence that SO effects on $K(\text{Pb}-\text{H})$ in PbH_4 are indeed not very large (and negative in this case). The largest SO contribution is due here to the OP-FC cross term (which is zero in the nonrelativistic limit).^{40,54} Therefore, large SO effects on the coupling constants can be expected only for those systems where SO coupling is of high importance (typically heavy p-block elements such as Tl, Bi, Pb), and both the FC and the paramagnetic coupling contribution are not very small already at the non- or scalar-relativistic limit. This is not the case for the plumbanes, and therefore the scalar relativistic effects on the FC term dominate the picture. This also rationalizes the quite accurate results for PbH_4 and PbMe_4 in Refs.^{84,86} Compared to other studies of sixth row element one-bond couplings, the data in Table 5 appear to be rather typical and qualitatively similar results have been, e.g., obtained for couplings involving W, Pt and Hg in a number of heavy metal complexes.^{20,84} As for the plumbanes in Table 5, chemical trends for very similar compounds are often already reproduced at the nonrelativistic level while magnitudes of coupling constants typically increase by a factor of two due to scalar relativistic corrections. Already at the scalar relativistic level, good agreement with experiment has been achieved for most of the systems in Refs.^{20,84}.

From the data in Table 5, the importance of electron correlation for obtaining reasonable estimates of spin–spin coupling constants becomes obvious. The effect of correlation

Table 5 Reduced Pb–L Spin–Spin Coupling Constants in Plumbanes, in $10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$

Compound coupling ^a	PbH ₄ Pb–H	PbMe ₂ H ₂ Pb–H	PbMe ₃ H Pb–H	PbMe ₄ Pb–C	PbCl ₄ Pb–Cl

at the nonrelativistic *ab initio* level is seen from a comparison of the *nrel.* number in parentheses listed for the Dirac approach with the one from the MCSCF computation. Based on a respective nonrelativistic ratio for SiH_4 , Enevoldsen et al.²⁹ estimated a Pb–H coupling constant in PbH_4 of $\sim 138 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ for a correlated approach. This is very close to the ZORA DFT result and underlines on the one hand the sensitivity of spin–spin coupling constants with respect to the quality of the zeroth-order solution and on the other hand the fact that standard DFT functionals partially account for the influence of correlation. The semiempirical methods try to incorporate these effects via their parametrization. As seen from Table 5, the results for PbH_4 and PbMe_4 are in rather good agreement with experiment. However, the Pb–Cl coupling in PbCl_4 appears to be strongly underestimated by the AM1 method. The authors list a better coupling constant of $-80.6 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ obtained with the PM3 semiempirical Hamiltonian in Ref.⁸⁶, but on the other hand $K(\text{Pb–H})$ in PbH_4 is overestimated by more than a factor of five with PM3. In a comparison of theory and experiment for the YCl_4 series, $\text{Y} = \text{C, Si, Sn, Pb}$, the semiempirical methods systematically underestimate the magnitude of the Y–Cl coupling constant, with the PM3 results being substantially larger than the AM1 (and MNDO) results. REX performs rather well in comparison.⁹¹ The strong overestimation of some coupling constants in the semiempirical methods has been attributed to the ‘triplet instability’ problem that also plagues the Hartree–Fock approaches.¹² The DFT methods seem to be much more robust in this case. Both scalar and SO ZORA DFT have predicted a negative Pb–C coupling constant for PbMe_4 despite the fact that the nonrelativistic limit, other computations, and the quoted experimental coupling (from 1978) agree on a positive value. In all other cases we have investigated so far, ZORA did yield the experimentally predicted sign of K and in most cases the magnitudes were reproduced with good accuracy.

As already mentioned in Section 3, solvent effects can substantially influence NMR parameters for heavy atom compounds. In particular, it was found that complexation of the heavy atom by solvent molecules, if possible, yields huge effects on shieldings of the heavy nucleus. It is therefore not very surprising that this is the case for NMR spin–spin couplings as well. More surprising, however, is the magnitude of the effects even for rather weakly coordinating solvents that do not cause a significant change in the geometry of the compound under investigation. In Ref.⁹², a number of linear mercury and square-planar platinum complexes have been investigated. Even for such weakly coordinating solvents such as CHCl_3 or CH_2Cl_2 , a significant shift of the FC contribution to the spin–spin coupling has been observed. Experimental trends for different solvents (CHCl_3 vs. DMSO) have been quantitatively reproduced. The solvent coordination effect has been analyzed in detail for $\text{Hg}(\text{CN})_2$. $K(\text{Hg–C})$ increases from 237.9 to 443.4 to $576.2 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ at the nonrelativistic, scalar ZORA relativistic, scalar rel. + $4\text{CH}_3\text{OH}$ solvent molecules level, respectively (DFT, VWN functional). SO corrections were small in the samples studied in Ref.⁹² It was found that charge donation from the solvent into the metal–ligand σ bonds is responsible for the large positive shift of $K(\text{Hg–C})$. It does not seem very likely that unspecific solvent effects for coordinatively saturated complexes are of such high importance, but

they will be not negligible for high-accuracy computations. In Ref.⁹³, complexation of the complex $[(\text{NC})_5\text{Pt–Tl}(\text{CN})]^-$ by water was found to explain a rather unintuitive experimental result for the Tl–C couplings. In aqueous solution, $^2K(\text{Tl–C}) \gg ^1K(\text{Tl–C})$ has been observed experimentally. In the same complex, the huge Pt–Tl coupling (expt. $\sim 57 \text{ kHz}$ in water) has been shown to increase by more than 20 kHz upon coordination by solvent molecules in the ZORA DFT computations.

4.2 Spin-orbit Effects

Not many cases have been investigated so far, where SO coupling is of essential importance for heavy nucleus spin–spin coupling constants. Very often it is possible to achieve a good comparison between theory and experiment at the computationally much cheaper and easier to interpret scalar relativistic level. As a counter example, we would like to emphasize the case of Tl halides, TlX.

Figure 2 shows the coupling constants that have been obtained with the ZORA DFT approach⁵⁴ on different levels of approximation. Clearly, SO effects yield the dominant contribution to the coupling constants for TlI and a completely wrong trend for the series is obtained at the scalar relativistic level. The explanation for the SO effects follows that for the chemical shieldings. Mixed terms between the spin-dependent FC and SD operators and the orbital dependent OP operator are no longer zero in the presence of SO coupling. Through SO coupling, the spin-density that is induced by the FC perturbation at a nucleus ‘leaks’ through into the orbital shapes and causes orbital current densities that yield nonzero coupling contributions with the orbital currents induced by the OP term at the other nucleus. Likewise, the OP operator induces spin-density in the SO coupled system. As for nuclear shieldings, the FC–OP cross term was found to be dominant and the SD–OP term small.^{39,40,54} For TlX, the paramagnetic contribution is dominant at the nonrelativistic level and the FC term represents

Figure 2 Reduced spin–spin coupling constants in thallium halides TlX from ZORA DFT computations (Ref.⁵⁴, BP86 functional), in $10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$. Calculated vs. experimental values. Experimental data compiled in Ref.⁹⁴

the second largest contribution. This leads to the large FC-OP cross terms at the SO coupled level. In the case of TII, this cross term represents the largest individual relativistic correction to the coupling constant and is essential in order to obtain the correct trend for the TIX series.⁵⁴ The DFT approach appears to be of somewhat reduced accuracy for the case of TIBr and TII which has been largely attributed to deficiencies in the GGA functional.⁵⁴

The authors of Ref.³⁸ concluded from a study of $K(\text{H}-\text{H})$ in H_2Y ($\text{Y} = \text{O}, \text{S}, \text{Se}, \text{Te}$) that the SO effects may generally yield the dominant contribution for HALA effects as is the case for many nuclear shieldings. A large relativistic change of $K(\text{H}-\text{H})$ in PbH_4 has been observed from four-component Hartree-Fock computations²⁹ where SO effects are naturally present. On the other hand, Ref.⁴⁰ reports rather small SO corrections to $K(\text{H}-\text{H})$ in PbH_4 , based on a nonrelativistic Hartree-Fock wavefunction. Furthermore, huge changes of the FC term due to electron correlation were found. Clearly, more relativistic studies including both scalar and SO effects are needed in this case in order to draw a definite conclusion.

Available studies have shown that even in those cases where the SO effect on the coupling constant is rather small, the anisotropy ΔK can be quite strongly influenced by SO coupling. Relativistic changes of ΔK have been reported in several of the papers cited so far, e.g., in Refs.^{24,28,38,54,87,91} However, the applications of ΔK for the heavy atom case are, as in the $\Delta\sigma$ case, very limited so far. It is already established that future investigations of ΔK and interpretations of respective experimental findings will need to include relativistic effects if heavy atom systems are studied, and both scalar and SO effects will be of importance in this case. Experimental data for the TIX series have, along with a number of other light and heavy diatomic systems, been investigated in Ref.⁹⁴ and periodic trends of K and ΔK have been analyzed. ΔK can generally be expected to increase with increasing charge of the heavy nuclei involved, with very large anisotropies for couplings with sixth row atoms in particular at the right end of the periodic table.

5 SUMMARY

It is nowadays possible to compute relativistic heavy nucleus NMR parameters by a variety of different approaches at different levels of accuracy and computational expense. A number of available quantum chemical program systems are capable of such computations. From the numerical evidence provided so far by many computational studies of NMR parameters in heavy atom systems, it becomes obvious that relativistic effects can be responsible for the main chemical trends that have been observed experimentally. In particular, spin-orbit coupling must be considered for shieldings of light nuclei in the neighborhood of heavy p-block elements. Both scalar and spin-orbit relativistic corrections are important for shielding tensors of heavy nuclei and ligand shieldings in heavy transition metal complexes. It is imperative to use scalar relativistic corrections in order to compute reliable magnitudes for spin-spin couplings involving heavy nuclei. Spin-orbit corrections to spin-spin couplings can be very substantial if both the paramagnetic and the Fermi-contact contributions

to the coupling are large and a heavy p-block element is involved.

Biographical Sketches

Jochen Autschbach, *b* 1968. M.Sc. (Chemistry), 1996, Ph.D., 1999, Siegen, Germany. Ph.D. thesis on relativistic effects in atoms and chemical bonds. Since 1999 member of Tom Ziegler's research group in Calgary, Canada. Current research interests: computation of heavy atom NMR spin-spin coupling constants and chemical shifts, solvent effects in spectroscopy, theory of optical activity, density functional response theory, relativistic quantum chemistry. J. A.

has contributed, among other code, a program for the computation of heavy atom spin-spin couplings to the Amsterdam Density Functional program.

Tom Ziegler, *b* 1944. T. Z. was raised in Denmark and graduated from the University of Copenhagen in 1972 with a Cand. Scient. degree in theoretical chemistry. He obtained a Ph.D. from University of Calgary (1978) where he has been a full professor since 1991. He has in the last 25 years worked with the development of density functional theory as a practical tool in transition metal chemistry and homogeneous catalysis. This has led to computational methods of use in spectroscopy, thermochemistry, structure determination and molecular dynamics. He is a fellow of both the Royal Danish and Royal Canadian Societies.

Semiempirical Chemical Shift Calculations

1 INTRODUCTION

The measurement of chemical shifts of the resonating nuclei ^1H , ^{13}C , ^{15}N , ^{17}O , ^{19}F , ^{29}Si , and ^{31}P , and their relation to molecular structure has led to NMR spectroscopy becoming the leading method for structural determination in organic and inorganic chemistry. This relationship was recognized^{1–3} only a few years after the discovery of the NMR effect by Purcell⁴ and Bloch⁵ and their co-workers. (see *Carbon-13 Spectral Simulation; Inorganic Chemistry Applications; Chemical Shift Tensors*, and *Organic Chemistry Applications*)

The complicated connection between experimental chemical shifts and molecular structure was first described by Ramsey.⁶ The semiempirical interpretation of chemical shifts mainly goes back to the extended work of Pople, who presented a theory of NMR chemical shifts^{7–9} applied to ^1H and ^{13}C nuclei on the basis of an approximate molecular orbital (MO) theory.¹⁰ Semiempirical chemical shift calculations were an active field of research for about 20 years. The development of the theory accompanied the development of NMR measurement techniques.

Because of the approximate character of semiempirical calculations, two aims may be set:

1. comparing experimental and calculated trends in chemical shifts to obtain information on the electronic structure of molecules and solids in terms of general chemical concepts;
2. obtaining quantitative agreement between experimental and theoretical results by adjusting the empirical parameters.

Since the 1980s high-level ab initio methods have become available for calculating chemical shifts for resonant nuclei up to the second row in medium-sized molecules. Such calculations give good agreement with experimental values without the need for any empirical parameters (see *Shielding Calculations: LORG and SOLO Approaches; Shielding Calculations: IGLO Method; Shielding Theory: GIAO Method; Shielding: Overview of Theoretical Methods; Shielding in Small Molecules*). These methods have brought and are expected to bring more insight into the real connection between chemical shifts and electronic structure, though the interpretation of the results in terms of general chemical concepts is not always easy. Ab initio results may prove the validity and limits of semiempirical correlations and may be used to calibrate semiempirical results.

Semiempirical interpretation continues to have its place in practical NMR structural analysis. The relations between chemical shifts and structural parameters are easy and quick to apply, and there is much experience in their use in different fields of organic and inorganic chemistry. Semiempirical methods are still necessary for very heavy nuclei and for very large molecular systems including nuclei of the first and second rows.

There are a number of books and review articles concerning semiempirical methods and calculations.^{10–22} Since 1972, chemical and physical aspects of nuclear shielding and, inter alia, semiempirical results have been reported annually.²³

2 BASIC CONSIDERATIONS

2.1 NMR Chemical Shifts

The chemical shift δ is measured as the difference between a given NMR signal and that of a reference compound. It is defined as

$$\delta = \frac{\nu - \nu_{\text{ref}}}{\nu_{\text{ref}}} \quad (1)$$

in terms of the measured frequencies. (The 10^6 -fold value is customarily declared, without units or else as ppm.) The resonance condition

$$\nu = \frac{|\gamma|}{2\pi} |B| \quad (2)$$

connects the chemical shift with the electronic structure of the investigated material via the local magnetic field B . γ is the gyromagnetic ratio of the resonating nucleus. The local magnetic field is determined by the externally applied uniform magnetic field, B_0 , and an additional shielding field induced at the nucleus by B_0 owing to its influence on electronic motion, mainly in the vicinity of the resonating nucleus. The total field at the nucleus is given by

$$B = (1 - \sigma) \cdot B_0 \quad (3)$$

where σ is the magnetic shielding tensor describing the spatial magnetic shielding of the resonating nucleus by the surrounding electrons. It is an intrinsic property of the investigated substance. $\mathbf{1}$ is the unit dyadic. (See *Chemical Shift Tensors and Shielding Calculations: Perturbation Methods*.)

In isotropic liquids the molecular motion averages the direction dependence of the shielding to its isotropic shielding constant σ

$$\sigma = \frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}) \quad (4)$$

In high-resolution solid state NMR, the averaging is achieved by experimental techniques, e.g. magic angle spinning (MAS). (see *Magic Angle Spinning*)

The observed chemical shift δ from equation (1) is described in terms of the shielding constant σ and that of a reference nucleus, σ_{ref} , as

$$\delta = \frac{\sigma_{\text{ref}} - \sigma}{1 - \sigma_{\text{ref}}} \quad (5)$$

In the following semiempirical considerations the following approximation is used:

$$\delta = \sigma_{\text{ref}} - \sigma \quad (6)$$

2.2 Magnetic Shielding Constants

Magnetic shielding of the resonating nucleus in an atom has been described by Lamb²⁴ as a diamagnetic shielding σ^d due to electron circulation around the nucleus produced by an externally applied magnetic field. The greater the electron density around the nucleus, the greater the shielding. In molecules, the electron circulation in the atom in question is perturbed by the other nuclei and electrons. The relation between electronic structure and magnetic shielding becomes much more complex. Ramsay^{6,25,26} introduced an additional paramagnetic shielding term σ^p to take these perturbations into account:

$$\sigma = \sigma^d + \sigma^p \quad (7)$$

Knowledge of the electronic groundstate and all excited states, including the continuum states, of the whole molecule is required to calculate the magnetic shielding constant exactly.

Approximate results depend on the gauge origin of the magnetic vector potential. Since the magnetic shielding σ , as a physical quantity, must be independent of the choice of origin of the coordinate system, different methods have been developed to remove the gauge dependence of the results. In semiempirical calculations, the gauge origin is frequently located at the resonating nucleus in question.

Saika and Slichter²⁷ introduced a very useful partition of the magnetic shielding constant in order to consider the main influences on chemical shifts. They took into account the local diamagnetic and paramagnetic contributions due to the atom in question, together with the nonlocal contributions due to all the other atoms in the molecule:

$$\sigma = \sigma_A^d(\text{loc}) + \sigma_A^p(\text{loc}) + \sum_{B \neq A} \sigma_{AB} \quad (8)$$

The local diamagnetic term is similar to the Lamb term for an atom, and depends mainly on the electron density on the atom A. The local paramagnetic term is determined by the electron charge density and its imbalance in the atom in question, as well as on energy excitations. The nonlocal terms may be described as magnetic anisotropy effects, ring current effects, and electric field effects.

There is a distinct difference between the main influences on proton chemical shifts and those on the shifts of nuclei other than protons. For proton chemical shifts, the local paramagnetic term vanishes owing to the symmetry of the electronic wavefunction in the electronic ground state and the high excitation energies of the hydrogen atom. However, all other terms may be important. For nuclei other than protons, the local paramagnetic term is found to be the most sensitive to structural changes. The nonlocal contributions are of minor importance.

3 SEMIEMPIRICAL CALCULATIONS

3.1 Semiempirical Quantum Chemical Methods

The electronic structure of molecules can be calculated approximately using semiempirical quantum chemical methods. These are based on first principles, but take into account serious approximations in the calculation of matrix elements and contain sets of empirical parameters. The advantages of semiempirical methods are their relatively small

demand for computer time and the possibility of describing the results in terms of general chemical concepts, such as orbital occupation and energy, electron density, bond order, and net atomic charge as input quantities for the calculation of magnetic shielding constants.

Some commonly used semiempirical methods include HMO (Hückel molecular orbital) theory²⁸ and the PPP (Pariser–Parr–Pople) method,^{29,30} which take into account only π electrons for the calculation of molecular π systems. Methods that take into account valence electrons include EHT (extended Hückel theory)³¹ and schemes considering the ZDO (zero differential overlap) approximation³² to different extents, such as CNDO³² (complete neglect of differential overlap), INDO³² (intermediate neglect of differential overlap), MINDO (modified intermediate neglect of differential overlap),³³ and MNDO (modified neglect of differential overlap).³⁴

The empirical parameters in all these methods have been determined using different bond characteristics and ab initio results to give reliable results for molecular structure and energy. Parameterizations of the CNDO/S and INDO/S methods³⁵ have been introduced to describe spectroscopic parameters. These parameterizations have led to a good quantitative description of chemical shifts. In general, using semiempirical methods, a correct description of chemical shift *trends* rather than of the actual values may be expected.

3.2 Magnetic Shielding Contributions

3.2.1 Diamagnetic Shielding Constants

Flygare and co-workers^{36–38} have given a widely used expression for the diamagnetic shielding constant of the atom A:

$$\sigma_A^d = \sigma_A(\text{free atom}) + \frac{\mu_0 e^2}{12\pi m} \sum_{B \neq A} \frac{Z_B}{R_{AB}} \quad (9)$$

The free atom term for the atom A is completed by additional terms coming from the point charges at the sites of the other atoms B in the molecule. μ_0 is the vacuum permeability, and $-e$ and m are the electron charge and mass, respectively. Z_B denotes the nuclear charge and R_{AB} is the distance between atoms A and B. The magnetic shielding for free atoms is available from nonrelativistic³⁹ and relativistic⁴⁰ calculations. For the hydrogen atom, $\sigma_H = 17.8$ ppm.¹⁰ The free atom values increase with increasing atomic number: for example, $\sigma_C = 260.7$ ppm, $\sigma_{Si} = 874.1$ ppm, and $\sigma_{Co} = 2166.4$ ppm.³⁹ In equation (9), the diamagnetic shielding constant is calculated considering all atoms in the molecule. It has been shown¹⁶ that for the local contribution only the nearest neighbor atoms of the resonance nucleus need be taken into account.

The quantum chemical expression for the local diamagnetic shielding contribution is^{7,8}

$$\sigma_A^d(\text{loc}) = \frac{\mu_0 e^2}{12\pi m} \sum_{\mu}^A P_{\mu\mu} \langle \phi_{\mu} | r^{-1} | \phi_{\mu} \rangle_A \quad (10)$$

In terms of an independent electron model, the i th molecular orbital (MO) ψ_i is given as a linear combination of atomic orbitals ϕ_{μ} (LCAO) of the valence shells:

$$\psi_i = \sum_{\mu} C_{i\mu} \phi_{\mu} \quad (11)$$

In equation (10), $P_{\mu\mu}$ are the elements of the charge density–bond order matrix:

$$P_{\mu\nu} = 2 \sum_i^{\text{occ}} c_{i\mu} c_{i\nu} \quad (12)$$

where the summation runs over all occupied molecular orbitals. With the radial part of the Slater functions, the matrix element is given as

$$\langle \phi_\mu | r^{-1} | \phi_\mu \rangle_A = Z_{\mu A} / n^2 a_0 \quad (13)$$

where $Z_{\mu A}$ is the effective nuclear charge number for the atom A in a molecule, n is the effective principal quantum number, and a_0 is the Bohr radius. $Z_{\mu A}$ can be calculated from Slater's rules.⁴¹ For atoms of the first and second rows, Z_{nsA} and Z_{npA} are given as

$$Z_{nsA} = Z_{npA} = Z_{0A} + 0.35q_A \quad (14)$$

while for H,

$$Z_{1sH} = 1.00 + 0.30q_H \quad (15)$$

where Z_{0A} is the effective nuclear charge number of the free atom A. The net atomic charge q_A of atom A with N_A valence electrons in the free atom is given by

$$q_A = N_A - \sum_\mu^A P_{\mu\mu} \quad (16)$$

Alternatively, for the determination of $Z_{\mu A}$ Burn's rules⁴² can be used.

The diamagnetic shielding constant σ^d shows a linear dependence on electron density, with a small quadratic correction. Therefore, the respective chemical shift term is proportional to the net charge of the considered atom.

3.2.2 Paramagnetic Shielding Constants

The sum-over-states (SOS) approximation of the local paramagnetic shielding constants in the independent electron model, developed by Pople^{7,8} from second-order perturbation theory, has been extensively used to discuss chemical shift properties (see *Shielding Calculations: Perturbation Methods*). In this model,

$$\begin{aligned} \sigma_A^p(\text{loc}) = & -\frac{\mu_0}{4\pi} \frac{2e^2 \hbar^2}{3m^2} \langle r^{-3} \rangle_{npA} \sum_i^{\text{occ}} \sum_j^{\text{unocc}} (E_j - E_i)^{-1} \\ & \times \left[(c_{iy}^A c_{jz}^A - c_{iz}^A c_{jy}^A) \sum_B (c_{iy}^B c_{jz}^B - c_{iz}^B c_{jy}^B) \right. \\ & + (c_{iz}^A c_{jx}^A - c_{ix}^A c_{jz}^A) \sum_B (c_{iz}^B c_{jx}^B - c_{ix}^B c_{jz}^B) \\ & \left. + (c_{ix}^A c_{jy}^A - c_{iy}^A c_{jx}^A) \sum_B (c_{ix}^B c_{jy}^B - c_{iy}^B c_{jx}^B) \right] \quad (17) \end{aligned}$$

The constants are the same as in equation (9) with $\hbar = h/2\pi$, where h is Planck's constant. The $c_{i\mu}^A$ ($\mu = x, y, z$) are the coefficients of the atomic orbitals p_x , p_y , and p_z on atom A in an LCAO development of the unperturbed MOs as in equation (11). The summation runs over all occupied (i) and unoccupied (j) states. The singlet excitation energy differences are

$$E_j - E_i = \epsilon_j - \epsilon_i + J_{ij} + 2K_{ij} \quad (18)$$

where ϵ_i and ϵ_j are the eigenvalues of the MOs of the unperturbed system. J_{ij} and K_{ij} are the molecular Coulomb and exchange integrals. The sum over B includes B = A and B $\neq$ A. $\langle r^{-3} \rangle_{npA}$ is the mean inverse cube of the radius of the p valence orbitals on atom A. From the matrix element in equation (13), $\langle r^{-3} \rangle_{npA}$ becomes

$$\langle r^{-3} \rangle_{npA} = \langle \phi_{np} | r^{-3} | \phi_{np} \rangle_A = \frac{2}{n(n-1)(2n-1)} \left(\frac{Z_{npA}}{na_0} \right)^3 \quad (19)$$

for $n = 2$ or 3 , with Z_{npA} from equation (14).

The finite perturbation theory (FPT) approach⁴³ using gauge-including atomic orbitals (GIAO) avoids the excited states of the SOS approach (which are difficult to estimate) by considering small perturbations of the magnetic field. The results are given as a sum of one-, two-, and three-center terms (*Shielding Theory: GIAO Method*).

3.2.3 Magnetic Anisotropy Effects of Neighboring Bonds

Nonlocal influences on magnetic shielding of the considered resonating nucleus can have their origin in distant bonds in the molecule. This effect has been described in detail by Raynes.⁴⁴ The externally applied magnetic field induces currents of the electrons forming the distant bonds, which give rise to a small secondary magnetic field at the resonating nucleus of interest. Since the molecule tumbles, this field is partly averaged, corresponding to the anisotropy of the magnetic susceptibility $\Delta\chi$ of the bond. The simplest quantitative equation for this shielding contribution σ_m is the point dipole approximation of McConnell:⁴⁵

$$\sigma_m = \frac{\Delta\chi}{12\pi R^3} (1 - 3\cos^2\theta) \quad (20)$$

where R is the distance from the resonating nucleus to the point dipole at the distant bond, and θ is the angle between the bond and the connection line R between nucleus and dipole. $R > 3$ nm has been recommended in order to minimize errors in the exact location of the dipole. A list of $\Delta\chi$ values has been given.⁴⁶

The shielding effect of the magnetic anisotropy is most frequently observed for proton chemical shifts, since the chemical shift range of ^1H is particularly small. In other elements, the nuclei are much more shielded than in hydrogen, and the magnetic anisotropy effect may be negligible compared with other influences.

The formulation for σ_m in equation (20) is strictly valid only for cylindrically symmetric bonds or groups. It can be applied, for example, to C–H, C–Cl, and CH_3 , but not to NO_2 , C=O , and C=C . In the latter cases, the longitudinal and transverse components of susceptibility with respect to the bond direction and the corresponding geometrical parameters must be taken into account.

3.2.4 Ring Currents

Induced electron motion in neighboring bonds, which is responsible for the magnetic anisotropy effect, can lead to intramolecular currents in molecules with delocalized π -electron systems. The concept of ring currents is widely used in discussing the proton chemical shifts of aromatic hydrocarbons satisfying Hückel's $4n + 2$ rule. Pople^{47,48} calculated the secondary magnetic field due to the ring current by a magnetic

Figure 1 Ring current in the benzene ring caused by an externally applied uniform magnetic field B_0 and the induced secondary magnetic field at the ring

point dipole at the center of the ring. Figure 1 shows the secondary magnetic field for a benzene ring where a static magnetic field is applied perpendicular to the ring plane. The application of a magnetic field in the ring plane does not give rise to a secondary field—thus, a high anisotropy of the shielding arises. The contribution of the ring current to the isotropic proton chemical shift is determined by this high anisotropy. Waugh and Fessenden^{49,50} and Johnson and Bovey⁵¹ refined this model. They described the ring current as two loops above and below the ring according to the delocalized π -electron density. The tables of Johnson and Bovey include the induced secondary field and the changes in the nuclear shielding for the benzene ring⁵² depending on the distance from the ring.

Quantum chemical considerations of ring current effects have been given by Pople⁴⁸ and McWeeny⁵³ using the Hückel theory. The theory of McWeeny gives the secondary field B' at the considered proton as

$$B' = k\beta \frac{S^2 B_0}{a^3} \sum_i J_i [-K(r_i)] \quad (21)$$

where k is a constant factor, β is the resonance integral of the HMO theory, S is the area of the aromatic ring, a is the length of a C–C bond, B_0 is the externally applied magnetic field, J_i is the intensity of the current in the i th ring, and $K(r_i)$ is a geometrical factor depending on the position of the proton in question relative to the ring. Haigh and Mallion⁵⁴ considered the ‘sigma ratio’ B'/B_b' , where B_b' is the secondary field for benzene. The sigma ratio depends only on the induced current intensity, J_i , and the geometric factor $K(r_i)$:

$$\frac{B'}{B_b'} = \sum_{i=1}^N \frac{J_i}{J_b} \frac{K_i(r)}{K_b} \quad (22)$$

where N is the number of rings. Slight nonplanarity of benzenoid hydrocarbons can also be treated using an extension of the McWeeny theory.⁵⁵ Tables of numerical values have been given for the calculation of ring currents.⁵⁶

Ring currents (RC) and local magnetic anisotropy of different bonds (LA) can have influences on proton chemical shifts

in macrocyclic systems. The quantum chemical considerations of Ege and Vogler^{57,58} allow one to calculate and separate these influences:

$$\delta = \delta^{\text{RC}} + \delta^{\text{LA}} + \delta^0 + \delta^q \quad (23)$$

where δ^q is the chemical shift contribution proportional to the net electronic π charge of the contiguous carbon atom, and δ^0 fits the correlation to experimental values.

3.2.5 Electric Field Effects

A strong polar group gives rise to an intramolecular electric field E , which changes the electron density at the resonating nucleus. Additionally, a direct through-space influence on magnetic shielding may become effective. This effect was first discussed by Buckingham⁵⁹ for proton shielding constants, and is described by

$$\sigma_E = -AE_z - BE^2 \quad (24)$$

where E_z is the electric field strength in the X–H direction. A and B are constants depending on the neighboring atom X. (see *Electric Field Effects on Shielding Constants*)

3.3 Some Applications of Semiempirical Calculations

3.3.1 Proton NMR Chemical Shifts

Proton chemical shifts depend mainly on the local diamagnetic shielding and on shielding contributions from nonlocal influences:

$$\sigma = \sigma^d(\text{loc}) + \sum_{B \neq A} \sigma_{AB} + \sigma_r + \sigma_E \quad (25)$$

One or more contributions may be operative, depending on the chemical structure of the investigated molecule. The dependence on the diamagnetic shielding suggests a relation between chemical shift and hydrogen net charge:

$$\delta(^1\text{H}) \propto q_{\text{H}} \quad (26)$$

However, this is only true when large effects can be observed. The relation in equation (26) gives the basis for different shielding rules, such as the Dailey–Shoolery rule for the compounds $\text{CH}_3\text{CH}_2\text{X}$. In these compounds, the proton chemical shift differences of the CH_2 and CH_3 protons are proportional to the electronegativity of the substituents X.⁶⁰

In organic molecules, the net charge of the adjacent carbon atom can be decisive for ^1H chemical shifts. The ‘atom-in-a-molecule’ approximation of the local diamagnetic term in equation (10) may be extended to the ‘atom + ligand’ approximation, taking into account the diamagnetic shielding of the nearest neighbor atom:

$$\delta(^1\text{H}) \propto q_{\text{C}} \quad (27)$$

For a C–H bond with bond length of 0.108 nm a slope of 8.70 ppm/a.u. has been given from theoretical considerations⁶¹ (the atomic unit for the net charge, a.u., is the elementary charge). Spiessacke and Schneider⁶² found an empirical correlation of this kind with HMO π net charges of carbon atoms in aromatic ions, with a slope of 10.0 ppm/a.u. Another

example is the correlation of proton chemical shifts and PPP π net charges of the adjacent carbon atoms in polymethinium salts $[N-(CH)_{2n+1}-N]^+$ with a slope of 7.1 ppm/a.u.⁶³ In both cases, good correlations exist between 1H and ^{13}C chemical shifts of the contiguous nuclei although the origins of the shieldings are different from each other (see below).

In most cases, additional contributions from distant parts of the molecule arise. For the proton chemical shift in *n*-pentanes,⁶⁴ the sum of diamagnetic contributions and anisotropy effects of neighboring bonds gives the right trend for the shift with the decisive influence of the anisotropy of the susceptibility of the C–C bonds in equation (20). The anisotropy effect is also responsible for the trend in the observed 1H chemical shifts to higher frequency in the surprising order of C_2H_6 , C_2H_2 , C_2H_4 . The $C\equiv C$ triple bond has a negative $\Delta\chi$, in contrast to positive $\Delta\chi$ values for C–C and $C=C$ bonds.²¹ With a negative geometrical factor in equation (20), a low-frequency shift results for acetylene owing to the magnetic anisotropy, which works against the high-frequency shift from the diamagnetic shielding due to the positive charge on the H atom in C_2H_2 .

The calculation of proton chemical shifts in alanine oligopeptides⁶⁵ as the sum of the magnetic anisotropy term and the electric field contribution of equation (24) using CNDO/2 calculations illustrates an application to a large system. The proton chemical shifts for all α -CH protons and all NH protons in a series of alanine oligomers were calculated and compared with experimental proton spectra. The agreement with the antiparallel β pleated sheet structure is good. This method may be useful for the study of conformations of oligopeptides and polypeptides.

The high-frequency shift of 1.5 ppm of aryl protons compared with olefinic protons can be understood in terms of the ring current effect using the point-dipole model. Outside the ring in its plane, the secondary field (Figure 1) adds to the field B_0 , leading to deshielding of the protons outside the ring. For [18]annulene (1), the secondary fields in the molecular plane outside and inside the ring determine the observed high-frequency shifts of the outer protons and the low-frequency shift of the inner protons.¹⁹ The ring current contributions for proton chemical shifts in polycyclic systems can be obtained by summation over the different ring contributions, as in equation (22), which depend only on the intensity of the ring currents and a geometrical factor. This concept has been used for large systems.⁵⁴ For the description of 1H chemical shifts in porphyrin molecules, ring currents and magnetic anisotropies are decisive.⁶⁶

Some effort has been made to synthesize molecules to show the whole region of influence of the ring current. As Mallion pointed out⁶⁷ the empirical Johnson–Bovey tables⁵² and the quantum mechanical Haigh–Mallion tables⁵⁶ for the

calculation of ring currents complement each other to a certain extent. The Johnson–Bovey tables overestimate ring current deshielding in the deshielding zone in and near the plane of a benzenoid ring, while the Haigh–Mallion tables are quite good in the deshielding region, but underestimate shielding in the shielding zone above the plane of the ring.

3.3.2 Chemical Shifts of Nuclei Other than Protons

Local diamagnetic and paramagnetic shielding constants of equation (8), mainly contribute to the magnetic shielding of nuclei other than protons:

$$\sigma = \sigma^d(\text{loc}) + \sigma^p(\text{loc}) \quad (28)$$

The two terms are of the same order of magnitude but of different signs. Therefore, small differences of large numbers arise, with the possibility of serious errors in the calculated shielding constants. The diamagnetic shielding term can be calculated from equation (9) or equation (10), in good agreement with ab initio results. Errors arise mainly because of an inadequate description of the paramagnetic term. The excitation energies in equation (1) are mostly overestimated by semiempirical calculations, and the absolute value of the paramagnetic term becomes too small.

On the other hand, the paramagnetic term is much more sensitive to structural changes than the diamagnetic term, and is decisive for the structural dependence of the chemical shift. Therefore, for the interpretation of chemical shift trends, it is recommended that one considers only the paramagnetic term.

Methods for semiempirical calculation of chemical shifts of nuclei other than protons and applications to ^{13}C , $^{14,15}N$, ^{17}O , and ^{19}F have been reviewed by Ebraheem and Webb.¹⁶ (see also **Fluorine-19 NMR**; **Nitrogen NMR** and **Oxygen-17 NMR**).

Jallali–Heravi and Webb used the INDO/S method with gauge-including atomic orbitals (GIAOs) to calculate carbon,⁶⁸ nitrogen,⁶⁹ and oxygen⁶⁹ chemical shifts for a broad variety of compounds in the SOS approach [equations (10) and (17)]. The calculated tensor components, anisotropies, and isotropic chemical shifts are in good agreement with available experimental results (see **Shielding Calculations: Perturbation Methods**). Low-lying excited states should mainly contribute to the paramagnetic shielding constant. The results show, however, that, especially for nitrogen and oxygen, quite a large number of energy transitions contribute to the chemical shift (see **Shielding: Overview of Theoretical Methods**).

The SOS approach has also been used to calculate the ^{13}C chemical shifts in Cr, Fe, and Ni complexes,^{70,71} and the ^{11}B chemical shifts in boron-containing compounds, including metalloboranes of Fe, Rn, and Co.⁷² The heavy atoms were incorporated using SW- $X\alpha$ calculations. The general substituent trends of the chemical shifts could be reproduced by the paramagnetic shielding constant.

Finite perturbation theory (FPT) using INDO wavefunctions has been used for the calculation of ^{13}C chemical shifts of hydrocarbons and carbonium ions⁷³ and substituted hydrocarbons.⁷⁴ This method can also be successfully extended to calculate ^{13}C chemical shifts in iron complexes.^{71,75} ^{13}C and ^{15}N chemical shifts have been calculated using the FPT/INDO method for the sequence analysis of *Bombyx mori* silk fibroin protein,⁷⁶ dealing with very small

differences in chemical shifts. ^{29}Si chemical shifts of zeolites have also been discussed.⁷⁷ The assignment of the ^{13}C chemical shifts of a molecule chemisorbed on zeolites has been investigated using the INDO-CS method.⁷⁸ FPT-CNDO/2 calculations of ^{29}Si chemical shifts in the system $n\text{-Si}_n\text{H}_{2n+2}$ ($n = 7\text{--}15$) have been carried out to assign the conformations of poly(methylphenylsilane).⁷⁹

For a correct description of chemical shifts, reparameterizations of the semiempirical methods is often used. However, the change in the original parameters leads to problems.⁸⁰ The validity of the new parameters is restricted to special applications, and the methods are no longer applicable to the calculation of other electronic properties. Another method for the adaptation of theoretical results to experimental data was used by Chesnut and Zhang.⁸¹ They employed MINDO/3 calculations for hydrocarbons, and found that the occupied orbital energies correspond to the ab initio (STO-5G) energies, while the vacant orbital energies are not equal to but have a linear relation with their ab initio counterparts. Therefore, rather than the MINDO/3 parameters, the ^{13}C shielding constant was fitted, in order to avoid the deficiencies in describing the excitation energies and electron distribution arising in the MINDO/3 method.

Another approach that has been adopted is density functional calculation of shielding. Using GIAOs into the LCAO- $X\alpha$ approach, good results have been achieved for the shielding of the resonating nuclei ^1H , ^7Li , ^{11}B , ^{13}C , ^{15}N , ^{17}O , and ^{19}F in small molecules⁸² compared with IGLO results and available experimental shielding constants in the gas phase (**Chemical Shift Scales on an Absolute Basis and Shielding Calculations: IGLO Method**).

3.3.2.1 Average Excitation Energy (AEE) Approximation.

The average excitation energy (AEE) approximation^{83,84} of the paramagnetic shielding constant is probably the approximation most widely used in discussion of the gross chemical shift trends of related compounds in terms of general chemical and quantum chemical characteristics. For the different excitation energies in equation (17), an average value ΔE is introduced. Simultaneously, in the ZDO approximation in the Pople theory, the following closure relation holds:

$$\sum_i^{\text{occ}} c_{\mu i} c_{\nu i} \sum_j^{\text{unocc}} c_{\mu j} c_{\nu j} = \delta_{\mu\nu} \quad (29)$$

where the Kronecker delta $\delta_{\mu\nu}$ is 1 for $\mu = \nu$ and is 0 for $\mu \neq \nu$. The paramagnetic shielding constant σ_A^{P} of the resonating nucleus A in the average excitation energy approximation is given by

$$\sigma_A^{\text{P}} = -\frac{4}{3} \frac{\mu_0}{4\pi} \frac{e^2 \hbar^2}{2m^2} \langle r^{-3} \rangle_{\text{npA}} (\Delta E)^{-1} \sum_B Q_{AB} \quad (30)$$

The constants have their usual meanings. The paramagnetic term in this Karplus–Pople equation depends only on the ground state of the unperturbed molecular orbitals. It comprises three structure-dependent factors.

The term $\sum_B Q_{AB}$ characterizes the imbalance of the electron distribution around the considered nucleus and the influences of hybridization. Q_{AA} and Q_{AB} ($B \neq A$) are given by

$$\begin{aligned} Q_{AB} = & \delta_{AB} (P_{xAxB} + P_{yAyB} + P_{zAzB}) \\ & - \frac{1}{2} (P_{xAxB} P_{yAyB} + P_{xAxB} P_{zAzB} + P_{yAyB} P_{zAzB}) \\ & + \frac{1}{2} (P_{xAyB} P_{xBY A} + P_{xAzB} P_{xBZ A} + P_{yAzB} P_{yBZ A}) \end{aligned} \quad (31)$$

The Q_{AB} terms depend on the elements of the charge density–bond order matrix of semiempirical calculations according to equation (12). They arise from the p orbital occupation of the atom of interest and the other first- and higher-row elements in the molecule.

The average excitation energy ΔE in equation (30) is a parameter that may also be structure-dependent. However, there is no explicit instruction for the calculation of ΔE . It follows from equation (17) that the smallest possible energy transition mostly contributes to σ_A^{P} . Therefore, sometimes the difference of the eigenvalues of the LUMO (lowest unoccupied MO) and the HOMO (highest occupied MO) of an MO calculation is used as ΔE . However, only the MOs with sufficiently high p character of the atom A contribute to the paramagnetic shielding. Alternatively, ΔE has also been taken from optical and X-ray spectra.

The term $\langle r^{-3} \rangle_{\text{npA}}$ from equation (19) depends nearly linearly on the atomic net charge q_A according to equation (19).

Usually, all three structure-dependent factors contribute to the chemical shift. In molecules of similar structure, one of the three structure-dependent quantities may dominate in structural change, or all factors may have the same structural dependence. Sometimes, an explanation can be given for empirical correlations.

3.3.2.2 Empirical Relations. Empirical relations between NMR chemical shifts and characteristics of the geometrical and electronic structure, substituent parameters, and spectroscopic and physical properties have been established to classify the overwhelming number of chemical shift data, to support the assignment of resonance signals to molecular structure, and to obtain insight into the mutual connections between the considered quantities. Care has to be taken in using these correlations, because they are restricted to special applications. Some examples will be given in the following.

δ versus q . Linear correlations between chemical shifts δ and atomic net charges q have been found—for example, for ^{13}C ^{14,15,85} and ^{19}F ⁸⁵ chemical shifts. In conjugated carbon chains, hetero atoms have an influence on ^{13}C chemical shifts over many bonds. Simultaneously, changes in π electron net charges q_π on the carbon atoms have a linear effect on chemical shifts:

$$\Delta\delta(^{13}\text{C}) \propto \Delta q_\pi \quad (32)$$

For polymethinium salts, for example, a factor of proportionality of 184 ppm/a.u. was found when q_π was calculated using the PPP method.⁸⁶ This value is in the typical region for related correlations¹⁴ for carbon chemical shifts. The local diamagnetic term, equation (10), or the term $\langle r^{-3} \rangle_{2\text{pC}}$ from the local paramagnetic term, equation (30), might be responsible for this correlation. Since the regression coefficient with the diamagnetic term is about 8 ppm/a.u.¹⁴ the origin of the observed relation for ^{13}C is mainly due to the factor $\langle r^{-3} \rangle_{2\text{pC}}$ in the local paramagnetic term of equation (30). For polymethinium salts, there is a good correlation between the ^{13}C and ^1H chemical shifts of the related C and H atoms (see above), showing the carbon chemical shift to be about 20 times more sensitive than the proton chemical shift. It is evident that the same qualitative correlations have different origins: diamagnetic shielding is responsible for ^1H chemical shifts, while paramagnetic shielding is mainly responsible for ^{13}C chemical shifts.

The correlations between substituent chemical shifts and substituent parameters of the Hammett type that have been observed for *para*-substituted benzenes and related systems can also be regarded to a certain extent as correlations with net charges of the considered resonating atoms^{13,15,85} (see **Organic Chemistry Applications**).

δ versus r . Correlations between chemical shifts and bond distances r can be understood as correlations of chemical shifts with the bond order terms and hybridization in $\sum Q_{AB}$ from σ_A^p . An example is the correlation between parallel components of the silicon shielding tensor $\sigma_{\parallel}$ for solid silicates with C_{3v} symmetry and the corresponding Si–O bond lengths.⁸⁷ The correlations between the isotropic ^{29}Si chemical shifts and the mean Si–O bond lengths in silicates were given by⁸⁸

$$\overline{\delta(^{29}\text{Si})}(\text{ppm}) = -2014 + 1.187 \times 10^4 \overline{d(\text{Si-O})}(\text{nm}) \quad (33)$$

showing the very high sensitivity of silicon chemical shifts to bond length differences (see **Silicon-29 NMR of Solid Silicates**).

δ versus $f(\varphi)$. In solid silicates, the Si–O bond lengths are closely related to the OSiO angles at the resonating nucleus and to the SiOT ($T = \text{Si}$ or Al) angles φ at the neighboring oxygen atoms. Relations of silicon chemical shifts to different functions of the SiOT angles in silicates have been given.⁸⁹ These relations have been found to arise from the influence of hybridization of the oxygen bonding orbital in the term $\sum Q_{AB}$ from σ_{Si}^p of equation (30).^{90,91} The s character α_O^2 of the bonding oxygen orbital, given by

$$\alpha_O^2 = \cos \varphi / (\cos \varphi - 1) \quad (34)$$

is a suitable function to correlate with silicon chemical shifts of silicates. Another function χ'' of structural parameters of silicates was deduced by Sherriff and Grundy⁹² and gives good correlation with ^{29}Si chemical shifts over a range of 60 ppm:

$$\chi'' = \sum_i s_i \frac{1 - 3 \cos^2 \theta_i}{3R_i^3} \frac{\cos \varphi_i}{\cos \varphi_i - 1} \quad (35)$$

where s_i is an empirical parameter for bond strength in the solid state, R_i is the distance between the midpoint of the O–T bond and the considered silicon atom, and θ_i is the angle between R_i and the O–T bond, i runs over the second neighbors of the silicon atom in question. The formula for χ'' connects the s character α_O^2 in equation (34) with a term similar to the magnetic anisotropy of McConnell in equation (20).

For the same systems, other linear correlations have been established between silicon chemical shifts and electronegativities,⁹³ ΔE of σ_{Si}^p in equation (30),⁹⁴ and negative silicon net charges q_{Si} .^{95,96} These correlations can be brought together by the results of semiempirical CNDO/2 calculations,⁹⁷ which show that all three factors of the paramagnetic term are linearly correlated with the same quantity, namely, the silicon net charge. The correlation with $\langle r^{-3} \rangle_{3p\text{Si}}$ is positive, while the correlations with $\sum Q_{AB}$ and $(\Delta E)^{-1}$ are negative. The latter two factors are responsible for the correct description of the trend of silicon chemical shifts due to SiOT bond angle variations in silicates (see **Silicon-29 NMR and Silicon-29 NMR of Solid Silicates**).

δ versus λ . A correlation between ^{59}Co chemical shifts^{3,98} and the wavelengths of the first optical absorption maximum for each compound of a series of cobalt complexes has been

observed and interpreted as an effect of the average excitation energy in the paramagnetic shielding constant of equation (30).¹⁰

3.3.2.3 Semiempirical Correlations. In general, more than one term of equation (30) is decisive for the chemical shift. For the interpretation of the ^{19}F chemical shifts of fluorobenzenes, Karplus and Das⁹⁹ reduced the imbalance term to Q_{AA} and discussed its influence on the chemical shift. Saika and Slichter²⁷ calculated the difference in magnetic shielding between the F_2 molecule and the F^- ion. This difference represents the whole chemical shift range of about 800 ppm, because of the extreme values for the imbalance term Q_{AA} in both cases. For the symmetric F^- ion, the electron distribution is fully symmetric, and Q_{AA} vanishes. In contrast, the covalently bonded F_2 molecule has the highest possible imbalance of the electron distribution (i.e. 1). The ^{19}F chemical shifts for other compounds fall into this region (see **Fluorine-19 NMR**).

The bonding situation in carbon compounds is completely different. The charge distribution around a carbon nucleus is usually more symmetric than that for a fluorine nucleus. The Q_{AA} term is approximately constant, and, therefore, less important than the Q_{AB} terms for $B \neq A$ in equation (30), especially if multiple bonds are present. The ^{13}C chemical shifts to higher frequency in the order ethane, acetylene, and ethylene were interpreted by Pople.⁸⁴ The anisotropy of the Q_{AB} term for acetylene is greater than that for ethylene. However, a smaller value for acetylene results because of the averaging of the isotropic chemical shift values. This smaller value for acetylene is responsible for the relatively low-frequency position of the resonance signal compared with that of ethylene. Good agreement with the experimental values was found with $\Delta E = 10 \text{ eV}$ for ethane and a smaller $\Delta E = 8 \text{ eV}$ for ethylene and acetylene.

Jameson and Gutowsky¹⁰⁰ included d orbital influences in the paramagnetic term to extend the chemical shift calculations beyond the first row:

$$\sigma^p(\text{loc}) = -\frac{4}{3} \frac{\mu_0}{4\pi} \frac{e^2 \hbar^2}{2m^2} \frac{1}{\Delta E} [\langle r^{-3} \rangle_{np} P_u + \langle r^{-3} \rangle_{nd} D_u] \quad (36)$$

where $P_u = Q_{AA}$ as in the Karplus–Das equation; the imbalance term D_u for the d electron distribution was given explicitly. This theory was used by Letcher and Van Wazer¹² to develop a semiempirical theory of ^{31}P NMR chemical shifts. In equation (36) the $\langle r^{-3} \rangle_{nd}$ term is found to be smaller than the $\langle r^{-3} \rangle_{np}$ term by a factor of about 100 for P(III) and P(V). For the same coordination number, the quotient $\langle r^{-3} \rangle_{np}/\Delta E$ was considered to be constant. The imbalance term P_u was studied as a function of electronegativity for a number of phosphorus-containing molecules, and as a function of bond angles using valence bond (VB) orbitals constructed from s , p_x , p_y , and p_z atomic orbitals and bond polarity indices h_{AB} of an A–B bond. The latter can be expressed as

$$h_{AB} = 1.0 + (0.16 + 0.035|E_A - E_B|)(E_A - E_B) \quad (37)$$

where E_A is the electronegativity of the considered atom A and E_B is the electronegativity of the nearest neighbor atom B.

It has been shown for a manifold of parameter combinations that, as a function of electronegativity, P_u first increases, reaches a maximum, and then decreases. This pattern of the P_u term yields an explanation of the ‘sagging pattern’ observed

for ^{31}P chemical shifts in substitution series like $\text{PX}_{3-n}\text{Y}_n$ ($n = 0, \dots, 3$) in dependence of n or on the phosphorus net charge¹² (see **Phosphorus-31 NMR**).

The same theory was applied to the interpretation of ^{29}Si chemical shifts in the substitution series $(\text{CH}_3)_{4-n}\text{SiX}_n$ ($n = 0 \dots 4$).^{101,102} The d orbital term in equation (36) was neglected and ΔE was regarded as constant. To consider only the structure-dependent term in the ‘electronegativity model’, a relative paramagnetic shielding constant $\sigma^{\text{P}*}$ was introduced as

$$\sigma^{\text{P}*} = R_{\text{p}}^* P_{\text{u}}^* \quad (38)$$

by relating the first term of equation (36) to the paramagnetic shielding constant of a nucleus in a totally unpolar surrounding. P_{u}^* and R_{p}^* are given by

$$P_{\text{u}}^* = \frac{1}{2} \sum_{\text{B}} h_{\text{AB}} - \frac{1}{6} \sum_{\text{B} > \text{B}'} h_{\text{B}} h_{\text{B}'} \quad (39)$$

$$R_{\text{p}}^* = [1 + 0.35(f/Z_{0\text{A}})q_{\text{A}}]^3 \quad (40)$$

with

$$q_{\text{A}} = 4 - \sum_{\text{B}} h_{\text{AB}} \quad (41)$$

where f is an empirical factor that fits the results to experimental values. Simultaneously, f corrects for the possible structural dependence of ΔE . P_{u}^* has a similar pattern, as described by Letcher and Van Wazer, for the phosphorus paramagnetic shielding constant. The R_{p}^* term increases approximately linearly with increasing net charge. The factor f changes the slope of R_{p}^* and fits $\sigma^{\text{P}*}$ to experimental values by changing the maximum and the form of P_{u}^* . The latter consideration is also applicable to ^{13}C chemical shifts of carbon atoms of coordination number four.¹⁰¹ In this way, the observed differences in the influence of electronegative substitution on ^{13}C and ^{29}Si chemical shifts can be understood. For ^{13}C chemical shifts, the R_{p}^* or $\langle r^{-3} \rangle_{\text{p}}$ part is decisive, and leads to high-frequency shifts with increasing net charge at the respective carbon atom. For ^{29}Si , the P_{u}^* or P_{u} term explains the high-frequency ^{29}Si chemical shift with increasing net charge in the region of small charges and the low-frequency shift with increasing net charge in the region of greater charges (a roughly parabolic dependence—‘sagging pattern’). For a restricted part of the whole range of silicon chemical shifts as in SiO_2 polymorphs with four surrounding oxygen atoms and large silicon net charge, the correlation

$$\delta(^{29}\text{Si}) \propto -q_{\text{Si}} \quad (42)$$

holds for the structural dependence of the imbalance term P_{u} (see **Silicon-29 NMR of Solid Silicates**).

The roughly parabolic dependence of ^{31}P and ^{29}Si chemical shifts on substituent electronegativity has also been observed for ^{27}Al chemical shifts. Using equation (36) and the ‘electronegativity model’ for silicon chemical shifts, Hallas and Sternberg¹⁰³ verified this pattern, ranging from $[\text{AlH}_4]^-$ to $[\text{Al}(\text{OH})_4]^-$ and from $[\text{AlCl}_6]^{3-}$ to $[\text{Al}(\text{H}_2\text{O})_6]^{3-}$. To describe the wide range of ^{27}Al chemical shifts observed in systems having AlO_4 units, they used the bond polarization energy that can be calculated from the charges on the next neighbor atoms and their geometrical arrangement. This model can be

applied to explain the influences of substituents of the second coordination sphere if the directly bonded substituents remain unchanged, as for ^{31}P chemical shifts in phosphates, ^{29}Si chemical shifts in SiO_2 polymorphs, ^{13}C chemical shifts in vinyl compounds, and ^1H chemical shifts of hydrogen-bonded protons.¹⁰⁴

The interpretation of magnetic shielding in transition metal complexes can be improved over the $\sigma \propto -1/\Delta E$ relation mentioned above for cobalt complexes, taking into account the nephelauxetic ratio β , which varies with the complex.^{80,105,106}

$$\sigma \propto -\beta/\Delta E \quad (43)$$

The slope is the effective r^{-3} value $\langle r^{-3} \rangle_{\text{nd}}/\beta$ describing the influences of the ligands on the radial term in equation (36). The ligand shielding can be discussed using the partition

$$\sigma = \sigma(\text{free ligand}) + \sigma_{\text{cov}} + \sigma_{\text{m}} \quad (44)$$

The shielding of the covalency of the metal–ligand bond σ_{cov} and the shielding σ_{m} due to the neighboring atoms (mainly the transition metal) in terms of the McConnell equation, equation (20), complete the shielding in the free ligand to give the ligand shielding in the complex.

Magnetic shielding calculations of nuclei in very heavy elements require relativistic corrections.^{22,107} They have a strong influence on σ^{d} ⁴⁰ and σ^{p} .²² Calculations of σ^{p} have been carried out—for example, for linear molecules involving ^{13}C , ^{17}O , ^{33}S , ^{77}Se , and ^{125}Te using the REX (relativistic extended Hückel) theory.¹⁰⁸ Since relativistic effects are largest for the 1s core, they may be less important for chemical shifts than for absolute shieldings. Using nonrelativistic wavefunctions, the ^{207}Pb chemical shifts of lead halides correlate with the paramagnetic shielding constant in equation (36) on the basis of pseudopotential calculations of the electronic structure.¹⁰⁹ P_{u} and D_{u} are calculated from the orbital populations of p and d valence orbitals. The average excitation energy ΔE is taken as the mean difference between LUMO and occupied valence MOs. Heavy atoms such as bromine and iodine cause abnormally low frequency shifts of their neighbor nuclei, e.g. proton shifts in HX and ^{13}C shifts in CH_3X .¹¹⁰ This ‘heavy atom effect’ has been interpreted in terms of a third-order perturbation theory as spin–orbit interaction.^{108,110} The interaction gives 51% of the total proton shielding in HI .¹¹⁰

1 INTRODUCTION

Until about 1980, the *ab initio* calculation of NMR chemical shifts was regarded as possible in principle, but rather demanding as far as computer time was concerned, and only calculations on rather small systems with moderate accuracy had been published. A considerable breakthrough came with the invention of the IGLO (individual gauge for localized orbitals) method,^{1,2} which made *ab initio* calculations on chemically interesting molecules possible. Early applications included the *ab initio* derivation of an increment system for hydrocarbons,³ a definite confirmation of the nonclassical structure of the 2-norbornyl cation,⁴ the assignment of the shift tensors of cyclopropane, bicyclobutane and [1.1.1]propellane,⁵ and the prediction⁵ of the ¹⁹F shift in SF₂ prior to its measurement.⁶ (For other applications, see, e.g., the review by Kutzelnigg et al.⁵)

In an investigation of various carbocations,⁴ it was observed that the agreement between computed and experimental chemical shifts was usually very good for nonclassical carbonium ions, but less so for classical ones. At this point, P.v.R. Schleyer suggested that the disagreement might be due to the use of generally assumed incorrect—in fact too symmetric—structures for the classical ions. It turned out that, for example, the isopropyl cation HC(CH₃)₂⁺ has only C₂ rather than C_{2v} symmetry.⁵ Subsequently, the combination of NMR measurements, *ab initio* structure optimizations, and IGLO calculations for competitive structures has become an efficient approach to decide which structure is realized under the conditions of an experiment. This need not be the structure of lowest energy for the isolated molecule. Especially in the chemistry of boron hydrides,⁷ this combined method has led to the determination of improved structures, which differ from the X-ray or electron diffraction structures—in some cases significantly. IGLO calculations have often been helpful in ruling out assumed structures. It has been shown⁸ that a reaction product of P₄ with alkali metal in an organic solvent, characterized by its NMR spectrum, was not P₄H[−] as had

been claimed⁹—at least not in the suggested bicyclobutane-type structure.⁹ The measured ³¹P shifts (71, −330, and −355 ppm) did not agree with those computed⁸ for either an *endo* (161, 172, and −319 ppm) or an *exo* structure (−51, −176, and −352 ppm). In many other cases (see Section 6), IGLO calculations served to confirm proposed structures; for example, for the adamantanediyl dication,⁵ where the IGLO values for $\delta(\text{C})$ were 6.6 and 35.6 ppm, and the corresponding experimental shifts were 7 and 33 ppm. For more examples, see Section 6.

A few years after the advent of the IGLO method, the LORG approach was presented.¹⁰ It is similar to IGLO in the basic idea of using individual gauge origins for different localized orbitals, but rather different in technical details and in the way in which errors are controlled. We believe that IGLO is better justified, since it can be derived from a stationarity principle.^{11–13} Nevertheless, it is most noteworthy that the results of calculations with the two methods are usually rather close. Which method performs better computationally depends somewhat on which versions one compares. The most recent IGLO implementation¹⁵ is probably hard to beat. Various types of shift calculations are described in Ref. 14.

The GIAO method is, in principle, older than both IGLO and LORG, but really efficient implementations have been possible only quite recently¹⁶, taking advantage of knowledge from gradient evaluations (see *Shielding Theory: GIAO Method*). The main difference between GIAO and IGLO is that in the former different gauge origins are used for different basis functions, while in IGLO (or LORG) they are used for different localized MOs. Again, the results are close to those of IGLO calculations. Recent comparisons between GIAO and IGLO by authors of GIAO programs have mainly stressed that GIAO calculations converge somewhat faster to basis limit results than IGLO calculations, while for sufficiently large basis sets the agreement is very good¹⁷. In noting the faster convergence with extension of the basis sets for GIAO versus IGLO or LORG (the three together are often referred to as *distributed-gauge* methods), one must not forget that all three methods converge spectacularly faster to the basis set limit than the traditional coupled Hartree–Fock (CHF) approach with a *common gauge origin*. The somewhat slower convergence of IGLO versus GIAO is due to the evaluation of the so-called exchange coupling terms in IGLO by means of a completeness insertion. However, this very step implies that in IGLO no more two-electron integrals are needed than in an ordinary SCF calculation, while GIAO also needs the derivatives of the integrals with respect to the nuclear coordinates. Therefore, for the same basis size, GIAO is significantly more expensive than IGLO, so that, for the same computational cost, one can afford a larger basis in IGLO than in LORG. For molecules of high symmetry such as C₆₀, a special implementation of GIAO¹⁸ has some advantages. A nice feature of IGLO is that the computed chemical shifts result as sums of contributions of localized orbitals, which helps in interpreting the results. IGLO has also the advantage that it furnishes magnetic susceptibilities in addition to chemical shifts, which for some of the other methods is either not possible (as for LORG) or has not yet (or only very recently) been implemented (as for GIAO¹⁷).

It has recently been shown¹⁹ that for very small molecules (essentially diatomic or triatomic with one hydrogen), high accuracy can be achieved using a common gauge origin. A

rather powerful implementation of CHF with a common gauge has allowed reliable calculations even of benzene,²⁰ but this is probably the absolute limit, since extremely large basis sets are needed.

A fourth distributed gauge origin method has recently been proposed.²¹ Here the balance between diamagnetic and paramagnetic terms is treated differently from IGLO, LORG, or GIAO. While in the latter methods the diamagnetic terms are obtained exactly, and one tries to get the paramagnetic ones *almost* exactly, here one introduces an error into the diamagnetic terms that should cancel that of the paramagnetic ones. An apparently different method proposed by Bader et al.²² was later shown by Lazzeretti et al.²³ to be equivalent to that of Geertsens.²¹

All methods mentioned so far, such as IGLO, LORG, GIAO, and CHF, are of coupled Hartree–Fock type, i.e., the many-electron wavefunction is approximated as a single Slater determinant. Effects that go beyond the single Slater determinant approximation are usually referred to as ‘electron correlation’ and are obviously neglected. One further neglects relativistic effects. These effects are important only in exceptional cases, to which we shall come in Section 7.

Details of the IGLO method and its applications can be found in a recent review⁵ and a complementary one.¹² For technical details, especially for prospective users, a description of the most recent release of IGLO is recommended.¹⁵

2 THE HAMILTONIAN IN A MAGNETIC FIELD AND THE GAUGE PROBLEM

We are only interested in closed-shell states, where the interaction of the electron spin with the external magnetic field can be ignored. We also limit ourselves to the nonrelativistic regime, where spin–orbit interactions can be neglected.

The Hamiltonian for a one-electron system in a magnetic field described by the vector potential $\mathbf{A}$ is

$$\hat{\mathcal{H}} = \frac{1}{2m} \left(\hat{\mathbf{p}} + \frac{e}{c} \mathbf{A} \right)^2 + V = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_{10} + \hat{\mathcal{H}}_{20} \quad (1)$$

$$\hat{\mathcal{H}}_{10} = \frac{e}{mc} \mathbf{A} \cdot \hat{\mathbf{p}}, \quad \hat{\mathcal{H}}_{20} = \frac{e^2}{2mc^2} A^2 \quad (2)$$

Here $\hat{\mathbf{p}}$ is the momentum, V is the nuclear potential, $\hat{\mathcal{H}}_0$ is the Hamiltonian in the absence of the magnetic field, e and m are the electron charge and mass, and c is the velocity of light. The magnetic field strength $\mathbf{B}$ is related to the vector potential by

$$\mathbf{B} = \text{curl } \mathbf{A} \quad (3)$$

The inverse of equation (3) is not unique. One can, in fact, add to $\mathbf{A}$ the gradient $\nabla\chi$ of an arbitrary scalar function χ without affecting the validity of equation (3). For a homogeneous magnetic field $\mathbf{B}$, a possible choice of $\mathbf{A}$ compatible with equation (3) is

$$\mathbf{A}(\mathbf{r}) = \frac{1}{2} \mathbf{B} \times (\mathbf{r} - \mathbf{R}) \quad (4)$$

where $\mathbf{R}$ is a fixed point in space, called the ‘gauge origin’. In choosing $\mathbf{A}$ in the form given in equation (4), we have

considerably reduced the arbitrariness of $\mathbf{A}$. Now only the choice of $\mathbf{R}$ is arbitrary. To get the eigenvalue E and eigenfunction ψ of $\hat{\mathcal{H}}$ as functions of $\mathbf{B}$, one can apply perturbation theory. There are two perturbations, $\hat{\mathcal{H}}_{10}$ and $\hat{\mathcal{H}}_{20}$, the first of which is linear in the field strength and the second quadratic. One sees easily that for the choice in equation (4), both $\hat{\mathcal{H}}_{10}$ and $\hat{\mathcal{H}}_{20}$ contain $\mathbf{R}$, i.e., that $\hat{\mathcal{H}}$ depends on the gauge origin. All measurable quantities must be gauge-independent. This means that if one solves the Schrödinger equation exactly, E as well as its derivatives with respect to the field strength $\mathbf{B}$ will be independent of $\mathbf{R}$. However, the wavefunction (which is not measurable) will depend on $\mathbf{R}$, and so will the contributions to the perturbation expansion to be discussed later.

One can show that a change of the gauge origin in $\hat{\mathcal{H}}$ from $\mathbf{R}$ to $\mathbf{R}'$ is equivalent to a unitary transformation (gauge transformation)

$$\hat{\mathcal{H}} \rightarrow \hat{\mathcal{H}}' = \hat{U}^\dagger \hat{\mathcal{H}} \hat{U} \quad (5a)$$

$$U = \exp(i\Lambda), \quad \Lambda = \frac{e}{2c} \mathbf{B} \times (\mathbf{R}' - \mathbf{R}) \cdot \mathbf{r} \quad (5b)$$

If ψ is an eigenfunction of $\hat{\mathcal{H}}$ then the eigenfunction ψ' of $\hat{\mathcal{H}}'$ is given as $\psi' = \hat{U}^\dagger \psi$.

In perturbation theory, one expands the energy and the wavefunction in analogy to equation (1) as

$$E = E_0 + E_{10} + E_{20} + \dots \quad (6a)$$

$$\psi = \psi_0 + \psi_{10} + \psi_{20} + \dots \quad (6b)$$

which yields

$$E_{10} = \langle \psi_0 | \hat{\mathcal{H}}_{10} | \psi_0 \rangle \quad (7)$$

$$\begin{aligned} E_{20} &= E_{20}^d + E_{20}^p \\ E_{20}^d &= \langle \psi_0 | \hat{\mathcal{H}}_{20} | \psi_0 \rangle \\ E_{20}^p &= \text{Re} \langle \psi_0 | \hat{\mathcal{H}}_{10} | \psi_{10} \rangle \end{aligned} \quad (8)$$

where ψ_{10} is the solution of

$$(\hat{\mathcal{H}}_0 - E_0) \psi_{10} = (\hat{\mathcal{H}}_{10} - E_{10}) \psi_0 \quad (9)$$

If the system has no permanent magnetic moment—which is what we usually assume—then $E_{10} = 0$.

E_{20} can be written as

$$E_{20} = -\frac{1}{2} \sum_{\alpha, \beta} B_\alpha \chi_{\alpha\beta} B_\beta, \quad \alpha, \beta = x, y, z \quad (10)$$

where $\chi = \{\chi_{\alpha\beta}\}$ is the magnetic susceptibility tensor. E_{20}^d and E_{20}^p are called the *diamagnetic* and *paramagnetic* contributions to E_{20} . Both E_{20}^d and E_{20}^p are strongly gauge-origin-dependent. In their sum E_{20} , this dependence only cancels if equation (9) is solved exactly, otherwise E_{20}^d is obtained rather accurately but E_{20}^p has a possibly large error. All this holds for the individual $\chi_{\alpha\beta}$ and for the isotropic susceptibility

$$\chi = \frac{1}{3} (\chi_{xx} + \chi_{yy} + \chi_{zz}) \quad (11)$$

There are, in principle, two ways to solve the gauge origin problem (at least to a high degree of accuracy).

1. One tries to solve equation (9) as accurately as possible. In a basis expansion method, this means that one uses nearly saturated basis sets.
2. One tries to find an optimum gauge origin $\mathbf{R}$ for which the error with respect to an exact solution is as small as possible—even if the basis is small.

For atoms, the second approach is successful. There is, in fact, a *natural gauge origin* at the position of the nucleus. For this choice, $E_{20}^p = 0$, and E_{20}^d is evaluated rather easily. For molecules, there is no natural gauge origin, but one should try to find something similar, as one does in the distributed gauge methods.

While in closed-shell atoms E_{20} is always positive (energy-raising), corresponding to diamagnetism, in molecules E_{20}^p may be larger in absolute value than E_{20}^d , so that an overall paramagnetism may result. This is often the case if a low-lying excited state has a nonvanishing matrix element of a relevant angular momentum operator with the considered state. This paramagnetism is temperature-independent, and is often called *van Vleck paramagnetism*. It must be clearly distinguished from the ordinary temperature-dependent paramagnetism that arises for atoms or molecules in a degenerate state with the degeneracy split by the magnetic field.

3 CHEMICAL SHIFTS

In the preceding section, we have considered a single (external) magnetic field. To study chemical shifts, we have to add the magnetic field $\mathbf{B}_N$ created by the magnetic moment of a nucleus. In equation (1), we must replace $\mathbf{A}$ by $\mathbf{A} + \mathbf{A}_N$. We use the first label to count orders in $\mathbf{A}$ and the second for orders in $\mathbf{A}_N$:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_{10} + \hat{\mathcal{H}}_{01} + \hat{\mathcal{H}}_{11} + \hat{\mathcal{H}}_{20} \quad (12)$$

$$\hat{\mathcal{H}}_{01} = \frac{e}{mc} \mathbf{A}_N \cdot \hat{\mathbf{p}}, \quad \hat{\mathcal{H}}_{11} = \frac{e^2}{2mc^2} \mathbf{A} \cdot \mathbf{A}_N \quad (13)$$

[The other terms are as in equations (1) and (2)]. A possible expression for $\mathbf{A}_N$ is

$$\frac{\mathbf{A}_N = \boldsymbol{\mu} \times (\mathbf{r} - \mathbf{q})}{|\mathbf{r} - \mathbf{q}|^3} \quad (14)$$

This choice corresponds to taking the gauge origin for $\mathbf{A}_N$ at the position $\mathbf{q}$ of the respective nucleus (with magnetic moment $\boldsymbol{\mu}$). Other gauges are possible, but there is no point in *not* choosing the ‘natural’ gauge origin $\mathbf{q}$ for $\mathbf{A}_N$. Only for the vector potential $\mathbf{A}$ of the *external* field does the gauge origin $\mathbf{R}$ remain arbitrary.

Expanding the energy in analogy to equations (5) and (10), one obtains E_{11} as the term bilinear in $\mathbf{A}$ and $\mathbf{A}_N$. Like E_{20} , E_{11} consists of two contributions,

$$\begin{aligned} E_{11} &= E_{11}^d + E_{11}^p \\ E_{11}^d &= \langle \psi_0 | \hat{\mathcal{H}}_{11} | \psi_0 \rangle \\ E_{11}^p &= 2 \operatorname{Re} \langle \psi_0 | \hat{\mathcal{H}}_{01} | \psi_{10} \rangle \end{aligned} \quad (15)$$

in perfect analogy to equation (8).

The relation of E_{11} to the chemical shift tensor $\boldsymbol{\sigma}$ is

$$E_{11} = \sum_{\alpha, \beta} \mu_\alpha \sigma_{\alpha\beta} B_\beta, \quad \alpha, \beta = x, y, z \quad (16)$$

For a closed-shell atom and with the gauge origin $\mathbf{R}$ (for the homogeneous external field) at the position of the nucleus, the paramagnetic contribution E_{11}^p vanishes, and the expression for E_{11}^d becomes very simple.

If one uses an off-center gauge origin for an atom, one gets a spurious nonvanishing E_{11}^p . This cancels with an extra term in E_{11}^d only if the basis is large enough that ψ_{10} , which is needed in equation (15) and which is constructed from equation (9), is obtained with sufficient accuracy. The extra term in E_{11}^d is usually obtained much more accurately than E_{11}^p .

Both E_{20} and E_{11} are formally defined in terms of second derivatives of the energy, i.e., as second-order response properties, but one can also rationalize these quantities by means of a two-step mechanism. We note that the external homogeneous field induces a current density in the atom or molecule. This current density generates an induced magnetic field, which interacts both with the external field (giving rise to diamagnetism) and with the magnetic moments of the nuclei (giving rise to the chemical shift). Current density plots^{5,12} may contribute to a better understanding of the origin of chemical shifts.

A characteristic feature of the IGLO method is that E_{11} (as well as E_{20}) is obtained as a sum of MO contributions, but that for different MOs different gauge origins are used, so that the decomposition of E_{11} into E_{11}^d and E_{11}^p refers to a different gauge origin for each MO. The sum of E_{11}^d for all MOs is then a *local diamagnetic contribution*, which must not be confused with a *global* contribution, where the same gauge is used for all MOs.

While the susceptibility tensor χ is symmetric (i.e. $\chi_{xy} = \chi_{yx}$), the shift tensor $\boldsymbol{\sigma}$ is asymmetric. Eigenvectors and eigenvalues of $\boldsymbol{\sigma}$ are constructed from its symmetric part, i.e., by replacing $\sigma_{\alpha\beta}$ by $\frac{1}{2}(\sigma_{\alpha\beta} + \sigma_{\beta\alpha})$.

The sign convention for shieldings is such that $\sigma > 0$ means shielding and $\sigma < 0$ deshielding. For the relative shift $\delta = \sigma_{\text{ref}} - \sigma$, the sign has the opposite meaning.

4 BASIC PRINCIPLES OF THE IGLO METHOD

We are now prepared to understand the main features of the IGLO method, at least qualitatively. More detailed presentations can be found elsewhere.^{5,12,15}

Let us first consider a supersystem of two H_2 molecules with a large distance r between them. If r is large enough, the two H_2 molecules can be regarded as independent. One could calculate $\sigma(\text{H})$ for each separately, choosing the midpoint of either molecule as respective gauge origin. If, however, we want to treat $(\text{H}_2)_2$ as one supermolecule, and choose one gauge origin, the best choice would be the center of mass of this supermolecule. This gauge origin would be largely off-center for either H_2 subunit. Errors of the type illustrated in Section 3 will arise. One would certainly try to avoid this by using independent gauge origins for the two subunits.

However, if r is no longer very large, the two subunits can no longer be regarded as independent. If one now wants to introduce independent gauge origins for either H_2 , one gets

rather complicated coupling terms, which are the price to pay for the freedom to take independent gauge origins. Fortunately, this price is not very high as far as computer time is concerned.

The IGLO method is, like most existing methods like LORG or GIAO, of coupled Hartree–Fock (CHF) type. This means that the $2n$ -electron wavefunction is approximated as a Slater determinant, Φ , built up from $2n$ spin orbitals. We consider closed-shell states, where spin orbitals with α and β spin have the same orbital factor. The energy expectation value

$$E = \langle \Phi | \hat{\mathcal{H}} | \Phi \rangle \quad (17)$$

is made stationary with respect to variation of the spin orbitals, subject to their orthogonality condition. The $\hat{\mathcal{H}}$ in equation (17) is that given by equation (12), i.e., it is expanded in powers of the field strength $\mathbf{B}$ and the magnetic moment $\boldsymbol{\mu}$ of the nucleus. The orbitals φ_i occupied in Φ will also be expanded in powers of $\mathbf{B}$ and $\boldsymbol{\mu}$, so that E will be given as an expansion of the same type. If we require stationarity of E for all values of $\mathbf{B}$ and $\boldsymbol{\mu}$ (in a neighborhood of $\mathbf{B} = 0$ and $\boldsymbol{\mu} = 0$), we end up with coupled Hartree–Fock theory.

To zeroth order, one has to solve the ordinary Hartree–Fock equations

$$\hat{F}^{(0)}\varphi_i^{(0)} = \varepsilon_i^{(0)}\varphi_i^{(0)}, \quad \hat{F}^{(0)} = \hat{h}^{(0)} + \sum_{j=1}^n (2\hat{J}_j^{(0)} - \hat{K}_j^{(0)}) \quad (18)$$

where $F^{(0)}$ is the unperturbed Fock operator, $\varphi_i^{(0)}$ are the unperturbed orbitals and $\varepsilon_i^{(0)}$ their energies, $\hat{h}^{(0)}$ is the one-electron part of the unperturbed Hamiltonian, and $\hat{J}_j^{(0)}$ and $\hat{K}_j^{(0)}$ are the contributions of $\varphi_j^{(0)}$ to the Coulomb and exchange operators, respectively.

To first order in $\mathbf{B}$, one gets an equation for the first-order corrections $\varphi_i^{(1)}$ to the orbitals. In terms of the $\varphi_i^{(0)}$ and $\varphi_i^{(1)}$, the components of the chemical shift tensors can then be calculated as simple expectation values. If one has chosen a common gauge origin (e.g., the position of the nucleus for an atom), one is dealing with conventional CHF theory.

Remembering that a change of the gauge origin can be achieved by a gauge transformation as in equation (5) one may choose to replace the expectation value in equation (17) by $E = \langle \Phi | \hat{U}^\dagger \hat{\mathcal{H}} \hat{U} | \Phi \rangle$. By choosing $\hat{U}$ according to equation (5) nothing is gained, since a change of the gauge origin can also be formulated directly, just by replacing $\mathbf{R}$ by $\mathbf{R}'$. However, one can use a more general unitary transformation, $\hat{U}$, than that given by equation (6), allowing different gauge origins for different orbitals. Details of such nonlocal gauge transformations can be found elsewhere.^{12,15}

Performing this transformation, we obtain the working equations of the IGLO method for chemical shifts (for the susceptibilities, see e.g. Kutzelnigg et al.⁵)

$$\{(1 - \hat{P}_0)\hat{F}_k^{(1)} - \hat{P}_k^{(1)}\hat{F}^{(0)} + (1 - \hat{P}_0)\hat{F}^{(0)}\}\psi_k^{(1)} = 0 \quad (19)$$

$$\hat{P}^{(0)} = \sum_{j=1}^n |\psi_j^{(0)}\rangle\langle\psi_j^{(0)}| \quad (20)$$

$$\begin{aligned} \hat{P}_k^{(1)} &= \sum_{j=1}^n |\psi_j^{(1)}\rangle\langle\psi_j^{(0)}| - |\psi_j^{(0)}\rangle\langle\psi_j^{(1)}| \\ &+ [|\psi_j^{(0)}\rangle\langle\psi_j^{(0)}|, \Lambda_k - \Lambda_j] \end{aligned} \quad (21)$$

$$\hat{F}_k^{(1)} = \hat{h}_k^{(1)} - \sum_{j=1}^n \hat{K}_j^{(1)} - \sum_{j=1}^n [\hat{K}_j^{(0)}, \Lambda_j - \Lambda_k] \quad (22)$$

$$\Lambda_k(r) = \frac{e}{2c\hbar} (\mathbf{R}_k \times \mathbf{B}) \cdot \mathbf{r} \quad (23)$$

All wavefunctions and operators in these working equations are real. The first-order operators, characterized by a tilde, are then antisymmetric.

After having solved equation (18) and before considering equation (19), one transforms from the canonical orbitals $\varphi_i^{(0)}$ to the localized orbitals $\psi_i^{(0)}$ according to the criterion of Boys. $\hat{P}^{(0)}$ is the projector onto the occupied unperturbed states, $\hat{P}_k^{(1)}$ is a projector involving unperturbed orbitals $\psi_k^{(0)}$ and their first-order corrections $\psi_k^{(1)}$, as well as the commutator of the unperturbed operator with a difference of gauge functions Λ_k . $\hat{F}_k^{(1)}$ is a first-order coupled Fock operator typical of coupled Hartree–Fock theory, and $\hat{K}_j^{(1)}$ is a first-order exchange operator, defined by its matrix elements

$$\langle a | \hat{K}_j^{(1)} | b \rangle = (a\psi_j^{(1)} | \psi_j^{(0)} b) - (a\psi_j^{(0)} | \psi_j^{(1)} b) \quad (24)$$

with the two-electron integrals on the right-hand side in Mulliken notation. $[\hat{A}, \hat{B}]$ always means the commutator $\hat{A}\hat{B} - \hat{B}\hat{A}$. An essential feature of the IGLO equations is that $\hat{F}_k^{(1)}$ contains the one-electron operator $\hat{h}_k^{(1)}$ with the gauge appropriate for the orbital ψ_k :

$$\hat{h}_k^{(1)} = \frac{e}{2mci} \mathbf{B} \times (\mathbf{r} - \mathbf{R}_k) \cdot \hat{\mathbf{p}} \quad (25)$$

The only approximation with respect to the exact IGLO equations is that the commutator in equation (22) is evaluated by means of a completeness insertion. The chemical shifts are evaluated as

$$\sigma = \sigma^d + \sigma^{p0} + \sigma^{p1} \quad (26)$$

$$\sigma^d = 2 \sum_{k=1}^n \langle \psi_k^{(0)} | \hat{h}_{k2}' | \psi_k^{(0)} \rangle \quad (27)$$

$$\sigma^{p0} = -4 \sum_{j,k=1}^n \langle \psi_k^{(0)} | \hat{h}_{01} | \psi_j^{(0)} \rangle \langle \psi_j^{(0)} | \Lambda_j - \Lambda_k | \psi_k^{(0)} \rangle \quad (28)$$

$$\sigma^{p1} = -4 \sum_{k=1}^n \langle \psi_k^{(0)} | \hat{h}_{01} (1 - \hat{P}_0) | \psi_k^{(1)} \rangle \quad (29)$$

$$\hat{h}_{01} = \frac{e}{mci} \boldsymbol{\mu} \times (\mathbf{r} - \mathbf{Q}) \cdot \hat{\mathbf{p}} \quad (30)$$

$$\hat{h}_{k2}' = \frac{e^2}{2mc^2} \frac{\{\mathbf{B} \times (\mathbf{r} - \mathbf{R}_k)\} \cdot \{\boldsymbol{\mu} \times (\mathbf{r} - \mathbf{Q})\}}{|\mathbf{r} - \mathbf{Q}|^3} \quad (31)$$

In fact, equations (26)–(29) refer to each tensor component of σ . Formally, one repeats the calculation for both $\mathbf{B}$ and $\boldsymbol{\mu}$ in the direction of the three Cartesian axes.

Unlike in the case of a theory with a common gauge origin, σ consists of not only a diamagnetic and a paramagnetic term—there are in fact three terms. The first, σ^d , is easily identified as a local diamagnetic term, since it involves

the $\psi_k^{(0)}$ and a second-order operator, the third, equation (29), is clearly paramagnetic, since it involves a first-order perturbation $\psi_k^{(1)}$ of an orbital, and a first-order operator $\hat{h}_{01}$. The second term, equation (28), which vanishes for a common gauge origin, i.e., if $\Lambda_j = \Lambda_k$, shares with the genuine paramagnetic term σ^{p1} the fact that it involves only $\hat{h}_{01}$, but with a diamagnetic term that is completely expressible in terms of the unperturbed orbitals $\psi_k^{(0)}$.

We have usually regarded σ^{p0} as a local paramagnetic contribution and have defined

$$\sigma^p = \sigma^{p0} + \sigma^{p1} \quad (32)$$

but this is not compulsory. Anyhow, the contributions to σ are not observables—they are only useful for interpretative purposes.

5 DIGLO AND MC-IGLO

Direct IGLO or DIGLO²⁴ is related to ordinary IGLO in the same sense as ‘direct SCF’ is to ordinary SCF. While in ordinary IGLO, all two-electron integrals that are needed are evaluated at the beginning and stored on peripheral memory, in direct IGLO (based on the semidirect SCF of the TURBOMOLE package²⁵), most integrals are calculated whenever they are needed, and only a small number of (expensive) integrals are stored. In using DIGLO, one achieves independence of the size of available disk space, and the number of basis functions, related to the size of the molecule, is only limited by the available computer time.

MC-IGLO^{26,27} differs from IGLO insofar as it takes care of so-called *nondynamic* correlation effects. The variational wavefunction is no longer a single Slater determinant, but a linear combination of Slater determinants with both the orbitals and the expansion coefficients being varied. The standard option for MC-IGLO is the full-valence CAS (CAS = ‘complete active space’), but other choices of the active space are possible. MC-IGLO has to be applied whenever the state to be considered is not well described by a single Slater determinant reference function.

6 SOME RESULTS AND APPLICATIONS

Results of IGLO calculations and applications to the elucidation of molecular structures or to the assignment of tensor components have been published in many original papers, and have been documented in reviews,^{5,12} which contain a lot of material not published before. Here, we shall not discuss results that have been reviewed before, unless we regard them as particularly illustrative. In giving examples, we go from light to heavy nuclei as in Kutzelnigg et al.⁵ We start with proton shifts.

It has often been conjectured that ¹H chemical shifts in OH groups correlate with atomic charges or even with local acidities. In a detailed study²⁸ it was shown that generally such a relation does not hold, but that it can be justified if one considers only a limited class of closely related molecules—in this context, to surface hydroxyls that are bounded to B, Al, Si, or P and are completely coordinated by O atoms as in zeolites.

In the field of boron hydrides, the combination of NMR measurements and IGLO calculations has turned out to be particularly fruitful for the elucidation of structures and to be a serious alternative to classical X-ray methods.⁷ The ¹⁰B or ¹¹B shifts are very useful in this context, since IGLO calculations for $\sigma(B)$ are rather accurate even with small basis sets. This is, in part, related to the absence of lone pairs.

Table 1 shows the correlation coefficients and standard deviations of a linear regression between measured and calculated values of $\sigma(B)$ for a large number of boron hydrides for various choices of structures. Although the correlation is quite good for the experimental structures, it is significantly improved if one uses *ab initio* optimized structures, and its quality rises with the level of the *ab initio* method. A final slight improvement is achieved if one does the IGLO calculation with a larger basis. The message is that the theoretical structures are more accurate than those from experiment (X-ray or electron diffraction). In some cases (e.g., B₅H₁₁), too high a degree of symmetry had been assumed in the *experimental structure*. An analogous correlation for some carboranes was poorer unless two *critical* molecules were left out. For one of these (1,5-C₂B₃H₅), it was found that electron correlation effects are non-negligible (see Section 7); for the other critical molecule (1,2-C₂B₃H₇), the (rather old) NMR spectrum was erroneous.

For ¹³C shifts of neutral molecules, there has been increased interest in recent years in theoretical studies of the conformational dependence of $\sigma(C)$. An investigation by Barfield on the γ -*gauche* effect²⁹ can be mentioned here. In polymers such as poly(isobutene) the chemical shifts depend on whether the polymer is isotactic, syndiotactic, or amorphous. For an amorphous polymer, the distribution of various conformations gives rise to broad, unresolved resonances in the ¹³C NMR. These can be simulated (and analyzed) by IGLO calculations on conformations of model oligomers.³⁰

The existence of ring currents in benzene and similar molecules has been a controversial subject for some time. A few definite statements can now be made.³¹ The high-frequency shift of $\sigma(H)$ in olefins has a different origin to the additional high-frequency shift in benzene and other aromatic compounds. This extra shift is due to the ring current in the π system, which deshields the out-of-plane component σ_{zz} by a few ppm with respect to nonaromatic systems, of which only about 1 ppm remains in the isotropic shift. In neutral idealized Hückel annulenes, one finds a ring current contribution to $\sigma(H)$ that is roughly proportional to the number of π electrons.¹²

The most spectacular applications of IGLO calculations to ¹³C shifts are probably those in carbocations. It has been verified⁵ that the 2-norbornyl cation is non-classic, that in the norbornadienyl cation there is a three-center rather than a five-center bond, and that the cyclobutadiene dication C₄H₄²⁺ has a nonplanar equilibrium structure.

After ¹H, ¹³C, and ¹⁹F, one of the most widely studied nuclei is ³¹P. A systematic collection of IGLO results for $\sigma(P)$ has been published,^{5,32} and more work is in progress. Recently, the synthesis of PS₃[−] has been claimed;³³ however, the reported ³¹P shift³³ of 52.3 ppm is inconsistent with that computed for PS₃[−] (*D*_{3h}, basis II), namely 436 ppm. It would fit better with P₂S₆^{2−}, for which the IGLO value is 77 ppm.

While cubic P₈ does not exist (the equilibrium structure of P₈ is less symmetric³⁴), some cubic systems derived formally

Table 1 Statistical Analysis^a of the Performance of IGLO Calculations⁷

IGLO basis (geometry)	Slope	Correlation coefficient	Deviation (ppm)	
			Largest	Standard
DZ (experiment)	1.08	0.984	18.5	5.3
DZ (3-21G)	1.02	0.990	10.4	5.5

^bR = H.

^cR = *t*-C₄H₉.

from P₈ have been synthesized, namely, (RCP)₄ and (RSiP)₄. The measured and computed shifts are compared in Table 2.³⁵ The poorer agreement for δ(C) and δ(Si) is in part due to the difference of R in experiment and theory.

An important feature of theoretical studies, such as IGLO calculations, is that information about principal values and the orientation of principal axis systems are directly available, since the full shielding tensor is calculated. Thus, interesting comparisons with results from solid state NMR can be made. Quite often, these data, especially those on the orientation of principal axis systems, are not available from experiment. The calculations then give additional and complementary information. The phosphorus shielding tensors in dithiadiphosphetanes³⁶ and iminophosphanes³⁷ have been studied.

In a cooperation with M. Jansen et al., the chemical shift tensors of molecules of the type P₄O₆S_x, *x* = 0, . . . 4, have been calculated and compared with the experimental counterparts.³⁸ The results are shown in Table 3. The agreement between theory and experiment for the isotropic shifts is usually satisfactory. It is also not unexpected that the agreement is usually better for the formally five-valent than for the three-valent P, because the former has no lone pairs. While there is fair agreement between experimental and theoretical tensor components for four of the five molecules, in one case, namely, P₄O₆S, a large discrepancy appears for P(III). However, this discrepancy can be completely removed if one assumes that in the crystal there is free rotation around the threefold axis going through the PS bond. Transformation of the shift tensors to the new reference frame reestablishes the consistency between theory and experiment.

Rather little has been published on IGLO calculations involving nuclei of atoms of the fourth and higher rows. Some results for Ge and Se are displayed in Table 4. To give an example of a fifth-row atom, we mention some recent calculations on Xe. It has been observed that Xe adsorbed in an Na⁺-containing zeolite shows a downfield shift

(+60 ppm with respect to free Xe), while Xe adsorbed in an Ag⁺-containing zeolite exhibits an upfield shift (−70 ppm).³⁹ Model calculations on Na⁺Xe and Ag⁺Xe at the respective equilibrium distances (5.5*a*₀ and 6.0*a*₀, respectively) led to shifts of +61 and −66 ppm.⁴⁰

7 CORRELATION AND RELATIVISTIC EFFECTS

Since IGLO is a method based on a single Slater determinant wavefunction, i.e., one in which effects of electron correlation are ignored, it is surprising that it works so well in many cases, while for many other properties electron correlation cannot generally be ignored. A partial answer lies in the fact that the chemical shift is a one-electron property (as is the magnetic susceptibility). Two-electron properties are usually much more sensitive to electron correlation.

If one distinguishes between dynamic correlation and nondynamic correlation, in the sense that the former is related to the short-range electron interaction, and the latter to near degeneracy or avoided crossing (i.e., the presence of low-lying excited states), then one expects that only nondynamic correlation will have a *strong* effect on one-electron properties. While the treatment of dynamic correlation requires long expansions in Slater determinants (configuration interaction, CI)—or, at a low level of approximation, Møller–Plesset perturbation theory—the method of choice for the treatment of nondynamic correlation is a multiconfiguration SCF (MC-SCF) approach, as implemented in MC-IGLO²⁶ or, more recently, MC-GIAO.⁴¹

In those cases where SCF-IGLO (or GIAO) is a good starting approximation, the results can be somewhat improved by means of Møller–Plesset perturbation theory, for example, the GIAO-MP2 method of Gauss.⁴² MP2 is not very helpful for those cases where nondynamic correlation matters, like for O₃.

How can one know when strong correlation effects are to be expected? This is usually the case if strong paramagnetic (deshielding) contributions are present. Their existence is also related to the presence of low-lying excited states. While local diamagnetic contributions are well reproduced on an SCF level, paramagnetic ones are usually overestimated (in absolute value). For example, the ¹⁷O chemical shieldings in ozone are much too paramagnetic at the SCF level (about −3000 ppm), and an MC-IGLO calculation yields about −1200 ppm for the terminal and about −700 ppm for the central oxygen atom, in accordance with experimental values.¹² In fact, the shieldings in ozone are extremely paramagnetic (strongly deshielded), but this effect is greatly overestimated at the SCF level.

^aChemical shifts in ppm with respect to GeH₄ and Se(CH₃)₂; the shieldings $\sigma_{\text{Ge}}(\text{GeH}_4)$ and $\sigma_{\text{Se}}[\text{Se}(\text{CH}_3)_2]$ are 1738.0 and 1860.6.^bData for two different geometries.

Although this is a general trend, there are notable exceptions: in F₂, which is also strongly deshielded, the SCF result is too diamagnetic by about 30 ppm, while MC-IGLO gives a reasonable value. This tendency to *underestimate* the paramagnetic contribution can be observed with some other ¹⁹F shieldings as well. As an aside, the rovibronic corrections in F₂ are exceptionally large (−40 ppm), which has to be taken into account when comparing theory and experiment.

An interesting example concerns the ¹⁵N shieldings in the dinitrogen oxides. These molecules have low-lying excited states due to the weak (and long) N–N bond. At the SCF level, $\sigma(\text{N})$ is predicted to be much too diamagnetic in N₂O₂ and too paramagnetic in N₂O₄. The MC-IGLO values compare much better with experiment (see Table 5). N₂O₃ is somewhere in between. The experimental values of these shieldings were difficult to obtain, and are possibly not very accurate.⁴³

For organic molecules, there is a rule of thumb that correlation effects are non-negligible if both π bonds and lone pairs are present, giving rise to low-lying $n \rightarrow \pi^*$ transitions.

Since none of the available methods so far allows the treatment of relativistic effects, one can draw conclusions regarding these only indirectly (or by means of semiempirical methods). A detailed IGLO study of HX and CH_nX_{4−n}, with X = F, Cl, Br, I, revealed that relativistic effects are rather small for X = F, Cl, non-negligible for X = Br, but very large for X = I. The so-called heavy-atom effect, i.e., an increased shielding of H or C if a heavy atom is a neighbor, has largely, but not entirely, a relativistic origin.¹²

1 INTRODUCTION

The LORG (localized orbital–local origin) approach to the calculation of nuclear magnetic shieldings^{1–4} is a variant of coupled Hartree–Fock (CHF) theory⁵ where local gauge origins are associated with localized molecular orbitals. In SOLO (second-order LORG),^{4,6} the approach is extended to second order in electron correlation.⁷ For general surveys of theoretical approaches, see *Shielding: Overview of Theoretical Methods*.

The LORG and SOLO approaches are formulated and presently implemented⁸ as post-Hartree–Fock methods allowing several choices of localization schemes and gauge options, as described in Section 3, and allowing analyses of relationships between shielding properties and geometric as well as electronic molecular structure features, as described in Section 4. Section 4 also surveys representative applications, while relationships to other approaches using local gauge origins are included in Section 5.

2 THEORY

2.1 LORG

The LORG approach was first derived¹ from Ramsey’s expression⁹ for the shielding tensor by identifying the matrix elements and energy differences in the paramagnetic contributions as the transition moments and energies in a localized molecular orbital version of the random phase approximation (RPA).⁷ Local gauge origins were assigned to each occupied localized orbital, and orthogonality and completeness properties of the RPA provided the following expression for a Cartesian component of the shielding tensor:¹

$$\begin{aligned} \sigma_{ij}(\text{LORG}) &= \sigma_{ij}^d(\text{LORG}, 1) + \sigma_{ij}^d(\text{LORG}, 2) + \sigma_{ij}^p(\text{LORG}) \\ &= c^{-2} \sum_{\alpha} \langle \alpha | \{ (\mathbf{r} - \mathbf{R}_{\alpha}) \cdot \mathbf{r} \delta_{ij} - [\mathbf{u}_i \cdot (\mathbf{r} - \mathbf{R}_{\alpha})](\mathbf{u}_j \cdot \mathbf{r}) \} / r^3 | \alpha \rangle \\ &\quad + ic^{-2} \sum_{\alpha} \sum_{\beta} (\mathbf{u}_i \cdot \langle \alpha | \hat{\ell} / r^3 | \beta \rangle) [\mathbf{u}_j \cdot (\mathbf{R}_{\alpha} - \mathbf{R}_{\beta}) \times \langle \beta | \mathbf{r} | \alpha \rangle] \\ &\quad - 2c^{-2} \sum_{\alpha m} \sum_{\beta n} (\mathbf{u}_i \cdot \langle \alpha | \hat{\ell} / r^3 | m \rangle) \Omega_{\alpha m, \beta n} (\mathbf{u}_j \cdot \langle n | \hat{\ell}^{(\alpha)} | \beta \rangle) \end{aligned} \quad (1)$$

in atomic units. The localized orbitals α and β are doubly occupied in the Hartree–Fock ground state $|\Delta_0\rangle$, and m and n are virtual orbitals. The quantities $\mathbf{u}_i$ and $\mathbf{u}_j$ are Cartesian unit vectors, the angular momentum operator $\hat{\ell}$ and position vectors $\mathbf{r}$ are referred to the magnetic nucleus, and $\mathbf{R}_{\alpha}$ is a local origin assigned to orbital α , so that $\hat{\ell}^{(\alpha)} \equiv (\mathbf{r} - \mathbf{R}_{\alpha}) \times \hat{\mathbf{p}}$ is the angular momentum relative to this origin. Ω is an inverse energy matrix

$$\Omega = (\mathbf{A} - \mathbf{B})^{-1}, \quad \begin{cases} A_{\alpha m, \beta n} = \langle \alpha \rightarrow m | \hat{\mathcal{H}} - E_0 | \beta \rightarrow n \rangle \\ B_{\alpha m, \beta n} = \langle \alpha \rightarrow m, \beta \rightarrow n | \hat{\mathcal{T}} | \Delta_0 \rangle \end{cases} \quad (2)$$

where E_0 is the energy of $|\Delta_0\rangle$. Expressions for the matrix elements $A_{\alpha m, \beta n}$ and $B_{\alpha m, \beta n}$ have been given previously.^{1,3} In equation (1) all references to a common origin are replaced by internal distance vectors, cf. equations (8)–(12) in *Shielding: Overview of Theoretical Methods*. However, the conventional distinctions⁹ between dia- and paramagnetic terms no longer apply; in particular σ_{ij}^d (LORG, 2) mixes erstwhile dia- and paramagnetic terms. Diamagnetic labels, d, now imply that these terms are computed solely from occupied orbitals, and the paramagnetic label, p, implies contributions involving the virtual orbital space.

Explicit evaluation of σ_{ij}^p (LORG) is time-consuming and impractical, unless analysis into individual excitations $\alpha \rightarrow m$ is exploited. Introducing instead the linear equations²

$$\sum_{\alpha, m} (\mathbf{A} - \mathbf{B})_{\beta n, \alpha m} \langle \alpha | \hat{\mathbf{p}} | m \rangle = i \langle \beta | \hat{\mathbf{p}} | n \rangle \quad (3)$$

$$\sum_{\alpha, m} (\mathbf{A} - \mathbf{B})_{\beta n, \alpha m} \langle \alpha | \hat{\eta} | m \rangle = i \langle \beta | \hat{\eta} | n \rangle \quad (4)$$

which can be solved iteratively for the implied matrix elements $\langle \alpha | \hat{\eta} | m \rangle$, the paramagnetic term becomes²

$$\begin{aligned} \sigma_{ij}^p(\text{LORG}) &= \sum_{\alpha} \sigma_{ij}^p(\text{LORG}, \alpha) \\ &\equiv -2ic^{-2} \sum_{\alpha} \sum_m (\mathbf{u}_i \cdot \langle \alpha | \hat{\ell} / r^3 | m \rangle) [\mathbf{u}_j \cdot (\langle m | \hat{\eta} | \alpha \rangle - \mathbf{R}_{\alpha} \times \langle m | \hat{\mathbf{p}} | \alpha \rangle)] \end{aligned} \quad (5)$$

which is now a sum of bond contributions. The diamagnetic terms can similarly be condensed to bond contributions

$$\sigma_{ij}^d(\text{LORG}, 1) + \sigma_{ij}^d(\text{LORG}, 2) \equiv \sum_{\alpha} \sigma_{ij}^d(\text{LORG}, \alpha) \quad (6)$$

For simplicity the term ‘bond’ includes cores and lone pairs.

The original derivation¹ represented a reduction of RPA to its static limit, identical to coupled Hartree–Fock (CHF) theory.⁵ A later derivation¹⁰ established the connection to CHF theory, and showed that equation (1) can be rewritten as:

$$\begin{aligned} \sigma_{ij}(\text{LORG}) &= \sigma_{ij}(\text{CHF}, \mathbf{R} = 0) \\ &\quad - c^{-2} \sum_{\alpha} \langle \alpha | [\mathbf{R}_{\alpha} \cdot \mathbf{r} \delta_{ij} - (\mathbf{u}_i \cdot \mathbf{R}_{\alpha})(\mathbf{u}_j \cdot \mathbf{r})] / r^3 | \alpha \rangle \\ &\quad + ic^{-2} \sum_{\alpha} \sum_{\beta} (\mathbf{u}_i \cdot \langle \alpha | \hat{\ell} / r^3 | \beta \rangle) [\mathbf{u}_j \cdot (\mathbf{R}_{\alpha} - \mathbf{R}_{\beta}) \times \langle \beta | \mathbf{r} | \alpha \rangle] \\ &\quad - 2ic^{-2} \sum_{\alpha} \sum_m (\mathbf{u}_i \cdot \langle \alpha | \hat{\ell} / r^3 | m \rangle) [\mathbf{u}_j \cdot (\mathbf{R}_{\alpha} \times \langle m | \hat{\mathbf{p}} | \alpha \rangle)] \end{aligned} \quad (7)$$

where $\sigma_{ij}(\text{CHF}, \mathbf{R} = 0)$ is the CHF result using a common origin at the magnetic nucleus.⁵ In the Hartree–Fock limit

Figure 1 LORG isotropic ^{13}C shieldings in 2-norbornenone² versus experimental values. (Reproduced from Jameson¹¹ by permission of the Royal Society of Chemistry)

$\langle m|\hat{\rho}|\alpha\rangle = \langle m|\mathbf{r}|\alpha\rangle$,¹ and orbital completeness then makes the correction terms on the right-hand side of equation (7) cancel identically. CHF and LORG hence converge in the Hartree–Fock limit,^{1,10} by the same token demonstrating the origin independence of CHF theory in this limit.

It was noted already by Ramsey⁹ that severe numerical problems arise in inexact, i.e. finite basis, calculations of chemical shielding because of improper balancing of long range dia- and paramagnetic terms. It follows from equation (7) that the computationally important aspect of local origins in fact lies in the damping of such unbalanced long range terms, as has been shown explicitly in Table I and Appendix C of Hansen and Bouman.¹

In many practical applications only the isotropic part of the shielding tensor

$$\bar{\sigma}(\text{LORG}) = (1/3) \sum_i \sigma_{ii}(\text{LORG}) \quad (8)$$

is of interest, and the overall performance of LORG for the ^{13}C isotropic shieldings in 2-norbornenone² using a small atomic basis set ([3s2p/2s]) is illustrated in Figure 1; experimentally computed agreements are within ± 10 ppm over a total range of about 200 ppm.

2.2 SOLO

Equations (1), (2) and (7) are consistent through first order in the fluctuation potential relative to $|\Delta_0\rangle$.⁷ LORG, and CHF in general, can hence be considered consistent through first order in electron correlation. To extend the LORG approach to second order in electron correlation,⁶ we utilized the second-order polarization propagator (SOPPA) approach of Oddershede et al.,^{7,12} and to establish contact with this

approach we rewrite the paramagnetic contribution in equation (1) as follows:

$$\sigma_{ij}^p(\text{LORG}) = -2c^{-2} \sum_{\alpha m} \sum_{\beta n} t[\mathbf{u}_i \cdot \hat{\mathbf{l}}/r^3]_{\alpha m}^{(1)} \Omega_{\alpha m, \beta n}^{(1)} t[\mathbf{u}_j \cdot \hat{\mathbf{l}}^{(\omega)}]_{n\beta}^{(1)} \quad (9)$$

where superscripts indicate evaluation to first order in electron correlation and $[\Omega^{(1)}]^{-1} = [\mathbf{A}^{(1)} - \mathbf{B}^{(1)}]$ can be identified with the principal propagator $\mathbf{P}(E=0)$ to first order.^{7,12} The terms $t[\mathbf{u}_i \cdot \hat{\mathbf{l}}/r^3]_{\alpha m}$ and $t[\mathbf{u}_j \cdot \hat{\mathbf{l}}^{(\alpha)}]_{n\beta}$ represent transition moments.

Following this line of approach we defined^{4,6} the working second-order LORG (SOLO) expression for an element of the shielding tensor as follows:

$$\begin{aligned} \sigma_{ij}(\text{SOLO}) &\equiv \sigma_{ij}^d(\text{LORG}, 1) + \sigma_{ij}^d(\text{LORG}, 2) + \sigma_{ij}^p(\text{SOLO}) \\ &= c^{-2} \sum_{\alpha} \langle \alpha | \{ (\mathbf{r} - \mathbf{R}_{\alpha}) \cdot \mathbf{r} \delta_{ij} - [\mathbf{u}_i \cdot (\mathbf{r} - \mathbf{R}_{\alpha})] (\mathbf{u}_j \cdot \mathbf{r}) \} / r^3 | \alpha \rangle \\ &\quad + i c^{-2} \sum_{\alpha} \sum_{\beta} (\mathbf{u}_i \cdot \langle \alpha | \hat{\mathbf{l}} / r^3 | \beta \rangle) \{ \mathbf{u}_j \cdot [(\mathbf{R}_{\alpha} - \mathbf{R}_{\beta}) \times \langle \beta | \mathbf{r} | \alpha \rangle] \} \\ &\quad - 2c^{-2} \sum_{\alpha m} \sum_{\beta n} t[\mathbf{u}_i \cdot \hat{\mathbf{l}}/r^3]_{\alpha m}^{(2)} \Omega_{\alpha m, \beta n}^{(2)} t[\mathbf{u}_j \cdot \hat{\mathbf{l}}^{(\alpha)}]_{n\beta}^{(2)} \end{aligned} \quad (10)$$

This differs from equation (1) only in the last term, where the transition moments now include second-order corrections, and where $[\Omega^{(2)}]^{-1}$ is the principal propagator $\mathbf{P}(E=0)$ to second order. We have followed Paidarova et al.¹² in assuming that diamagnetic terms can be evaluated directly from the Hartree–Fock ground state, and explicit expressions for the required second-order expansions are available elsewhere.⁷ An iterative second-order method, mutatis mutandis equations (3) and (4), has been implemented,⁸ and the terms in equation (10) can hence be written as sums of bond contributions, mutatis mutandis equations (5) and (6).

To illustrate the performance of SOLO, Figure 2 compares LORG, SOLO, and experimental results for the ^{15}N isotropic shielding in pyridine and the *n*-azines using a [3s3p1d/2s] atomic basis.¹³ Here the isotropic shieldings change by up to about 50 ppm on going from LORG to SOLO, generally improving the agreements with experiments.

3 OPTIONS

LORG and SOLO calculations require a choice of localization scheme and of local origins, as discussed in Sections 3.1 and 3.2. In addition, LORG and SOLO share with other ab initio methods the chore of choosing an atomic orbital basis. In Section 3.3 we comment on computational strategies and discuss the interplay between localization, local origin, and basis set.

3.1 Localization Schemes

As presently implemented,⁸ LORG and SOLO assume that the occupied orbitals are localized by the Foster–Boys procedure which maximizes the quantity $\sum_{\alpha, \beta} |\mathbf{R}_{\alpha} - \mathbf{R}_{\beta}|^2$, where

$$\mathbf{R}_{\alpha} \equiv \langle \alpha | \mathbf{r} | \alpha \rangle \quad (11)$$

Figure 2 Absolute nitrogen shieldings in azines. Calculated versus experimental isotropic shieldings for the nitrogen atoms at both first-order (LORG) and second-order (SOLO) levels of electron correlation; (□) LORG; (▲) SOLO. (Reproduced from Bouman and Hansen¹³ by permission of *Chemical Physics Letters*)

is the centroid of the localized orbital α .¹⁴ The separation of the centroids is hence maximized, and the immediate results of this procedure are localized core orbitals and essentially spheroidal localized σ orbitals in typical single bonds, while multiple bonds will be represented by τ ('banana') orbitals. Hence, conjugated hydrocarbons and simple aromatics will show structures with alternating single bonds and τ bonds, while heteroatomic compounds (in particular those with multiple bonds and lone pairs) can exhibit complicated patterns that do not lend themselves easily to structural interpretations.

For many purposes the actual orbital pattern is of no interest or consequence, and LORG and SOLO calculations can proceed directly from localized orbitals resulting from the above procedures. However, for structural interpretations of the results, e.g. in order to extract σ and π contributions, or to ensure proper representation of symmetry, it may be advantageous to design the localization procedure. In its simplest form this is done by diagonalization of the Fock matrix within a subset of localized orbitals,¹⁵ transforming two-center τ orbitals into σ and π orbitals, or a pair of sp^2 -type lone-pair orbitals into conventional nonbonding and σ -type lone-pair orbitals. More generally, groups of orbitals, e.g. core, σ , and π orbitals in planar unsaturated or aromatic systems, can be localized separately with the additional option of leaving a group such as the π orbitals delocalized. The localizations amount to different unitary transformations within the occupied orbital space, and leave the Hartree–Fock ground state and the RPA invariant.¹⁵ However, different localizations lead to different sets of local origins, and in small basis sets the LORG shieldings are somewhat sensitive to the choice of localization.

The local origins refer to occupied orbitals only and localization of the virtual orbitals is normally immaterial, but

can be introduced¹⁵ if analysis of the paramagnetic terms into localized orbital excitations is desired.

3.2 Local Origins

Since equations (1) and (7) converge to common as well as local origin independence in the Hartree–Fock limit, the choice of a set of R_α can be viewed as a means of accelerating convergence to the Hartree–Fock limit for a given atomic orbital basis set and localization scheme. Conversely, the choice becomes less critical as the basis set is improved. We have identified¹ two standard origin options,

$$\text{FULL LORG/SOLO: } R_\alpha \equiv \mathcal{R}_\alpha \equiv \langle \alpha | \mathbf{r} | \alpha \rangle \quad \text{for all } \alpha \quad (12)$$

and

$$\text{LORG/SOLO: } R_\alpha \equiv 0 \quad \text{for } \mathcal{R}_\alpha / R_{\min} \quad (13a)$$

$$R_\alpha \equiv \mathcal{R}_\alpha \equiv \langle \alpha | \mathbf{r} | \alpha \rangle \quad \text{for } \mathcal{R}_\alpha / R_{\min} \quad (13b)$$

where equation (13a) colloquially speaking selects the orbitals that are bonded to the magnetic nucleus. LORG is hence a compromise between a local common origin CHF and FULL LORG, and Table 1 of Hansen and Bouman¹ provided the initial rationale for such a compromise for the calculation of ^{13}C shieldings. The quantity $R_{\min}$ will normally be chosen to be smaller than a typical bond distance, and is often quite uncritical. However for molecules with polarized bonds experimentation may be required, as discussed in a recent study of shieldings in the peptide unit.¹⁶ The respective merits of the FULL LORG and LORG options are discussed below.

3.3 Strategies, Choice of Options

Since the LORG and SOLO approaches are formulated and presently implemented⁸ as post-Hartree–Fock methods, these calculations presuppose an SCF calculation generating canonical molecular orbitals and two-electron integrals in atomic or molecular orbital bases; in the former case the integrals are subsequently transformed to molecular orbital basis.¹⁵ The advantage of a post-Hartree–Fock strategy is that experimentation with the various options is quite fast and inexpensive once the molecular orbital and two-electron integral files are available for a given molecule and a given atomic orbital basis.

The interplay between options can be illustrated for ^1H and ^{13}C in benzene.¹⁷ Figures 3(a) and (b) show the isotropic shielding in four atomic basis sets for FULL LORG and LORG using two different localization schemes, viz. a Kekulé-type structure with alternating single and σ , π double bonds, and a structure generated by separate localization of core and σ orbitals leaving π orbitals delocalized (canonical). Basis A is double-zeta [3s2p/2s],¹⁸ basis B is [3s2p/2s1p] where the polarization function on H is a 50–50 contraction of Gaussians ($\alpha_1 = 0.50$, $\alpha_2 = 1.50$), basis C is [3s3p1d/2s],³ and basis D is [3s3p1d/2s1p]. Similarly, Figures 4(a) and (b) show the *span*,¹⁹ i.e. $\Omega = \sigma_{33} - \sigma_{11}$, where $\sigma_{33} \geq \sigma_{22} \geq \sigma_{11}$ are principal shieldings. The figures include estimated Hartree–Fock limits²⁰ and experimental results.^{21,22}

For the isotropic shieldings, Figures 1(a) and (b), the FULL LORG–LORG distinction is more critical than localization

4 SHIELDING CALCULATIONS: LORG AND SOLO APPROACHES

Table 1 Bond Decomposition of Isotropic LORG Shieldings^a for ¹³C in 2-Norbornenone (in ppm)

Bond/Nucleus	C-1	C-2	C-3	C-4	C-5	C-6	C-7

Total	148	-29	161	164	36	46	150

^aShieldings are obtained in basis A (see text) and contributions smaller than 1 ppm are neglected. The 1s(C) contributions are for the carbon nucleus given at the top of the particular column.

choice in the smaller basis sets. LORG is quite stable with respect to basis set for ¹³C in accord with previous findings,¹¹ while for ¹H FULL LORG is the more stable option. A ‘locally dense basis set’ effect²³ can be detected, since increasing the basis on ¹H (basis B) and ¹³C (basis C) selectively improves FULL LORG–LORG agreements for the respective nuclei. Full use of the ‘locally dense basis set’ concept²³ within the LORG approach is reported elsewhere.²⁴ For tensorial shielding properties, Figures 2(a) and (b) suggest, not unexpectedly, that basis sets of less than triple-zeta polarized quality, i.e. [3s3p1d/2s1p], are computationally unsafe.

4 APPLICATIONS

4.1 Bond and Symmetry Analyses

Equations (5) and (6) allow decomposition of the shieldings into bond contributions,¹ and Table 1 shows the contributions to the ¹³C isotropic shielding in 2-norbornenone¹⁷ for which the overall results are shown in Figure 1. Contributions from orbitals directly bonded to the respective nuclei are shown in bold face, and the orbital labeled O (lone pair) is directed along the C=O bond. The local nature of the shielding is quite apparent, as is the difference in local σ and π double bond contributions.

A different type of analysis obtains by exploitation of symmetry, since the paramagnetic terms can be built up one symmetry block at a time^{1,25} utilizing the fact that in canonical bases the $(\mathbf{A} - \mathbf{B})$ matrix, equation (2), and hence equations (3) and (4) are block diagonal with respect to molecular

point group symmetry. Equations (3) and (4) can accordingly be solved separately within irreducible representations before being transformed to localized basis. In Table 2 we illustrate this for the Cartesian elements of the shielding tensor of a ¹H nucleus in benzene calculated¹⁷ in basis D of Figures 3 and 4, using in-plane x and y axes, along and perpendicular to the C-¹H bond, respectively. In the present case only the C_h subgroup symmetry is exploited, and the table shows the individual paramagnetic contributions from $\sigma \rightarrow \sigma^*$ (¹A'), $\pi \rightarrow \pi^*$ (¹A'), $\sigma \rightarrow \pi^*$ (¹A''), and $\pi \rightarrow \sigma^*$ (¹A'') excitations. Paramagnetic contributions from excitations out of C(1s) orbitals are neglected, while their minuscule diamagnetic contributions are included in the σ (sigma) terms. As indicated, the orbital excitations transform pairwise as the same irreducible representation; this feature persists in full D_{6h} symmetry. For the sake of the analysis, the tensors in the upper part of Table 2 hence neglect $(\mathbf{A} - \mathbf{B})$ matrix elements coupling excitations within the pairs. The agreement with the results of the complete calculation reported in the lower part of Table 2 indicates that such couplings are indeed small in the present case. Point group selection rules for the tensor elements and the relative importance of the various orbital contributions are clearly demonstrated in the table. We note in particular the small, but unique, *negative* π contribution to σ_{zz} , ascribed to the ‘ring current effect’ in common NMR lore.²⁶ A LORG study of the ring current model is reported elsewhere.²⁷

4.2 Representative Applications

LORG and SOLO calculations have been performed almost exclusively ab initio and have been based, again almost

exclusively, on the RPAC implementation,⁸ although an application based on equation (7) has also been reported.²⁸ A study²⁹ employing a semiempirical approach concluded that the parameterization cannot adequately overcome the problems inherent in the use of a minimal basis set for shielding calculations.

Representative applications utilizing features of the LORG approach include molecular symmetry analyses of nonsymmetric shielding tensors,^{4,25} a study of the importance of solvation³⁰ and molecular embedding³¹ for deuterium isotope effects, and a study of point charge and dipolar perturbations on the shielding of the heavy atoms in the peptide unit.¹⁶ A study of the ring current model for proton shieldings in aromatic molecules²⁷ is mentioned above, and a novel approach for the visual display of shielding tensors^{3,25,27} has been proposed. The study of solvation effects in isotope effects³⁰ is based on the calculation of shielding surfaces involving hydrogen bonding; see also Orendt et al.³² for a LORG study of hydrogen bonding effects for ^{17}O shielding tensors in larger molecules. Other LORG studies of shielding surfaces include

Figure 4 (a) Span, $\Omega = \sigma_{33} - \sigma_{11}$ for ^{13}C in benzene (in ppm). (b) Span, $\Omega = \sigma_{33} - \sigma_{11}$ for ^1H in benzene (in ppm). applications to intramolecular modes in small hydrides,^{33,34} in the PHO_3^{2-} ion,³⁵ and LORG³⁶ and SOLO³⁷ studies of weakly bound systems. LORG calculations of ligand and central atom shifts in transition metal complexes have been reported,^{38,39} however as pointed out by Ellis et al.³⁹ calculations at the CHF level neglecting spin–orbit effects cannot be expected to be quantitatively adequate for the shielding of transition metal nuclei. Of course, an important function of theoretical shielding calculations lies in the analysis and assignment of experimental data; examples are LORG⁴⁰ and SOLO⁴¹ assisted studies of ^{15}N shielding tensors. See also *Shielding Tensor Calculations*.

5 CONCLUDING REMARKS

The LORG and SOLO approaches belong to a family of methods that use local origins to ensure gauge origin independence and to increase convergence towards complete basis results. The latter feature, which results from a damping

of unbalanced long range shielding contributions as discussed in Section 2.1, is essential for the comparison of shieldings between molecules of very different size, i.e. for a faithful representation of chemical shifts.¹

The use of local origins can be traced to Kirkwood's theory^{42,43} of optical rotatory power, where magnetic dipole transition moments are expanded relative to local origins, and to London's theory⁴⁴ of diamagnetic susceptibilities, where complex local gauge factors are introduced in the atomic orbital basis. LORG and SOLO took the Kirkwood approach as the point of departure,¹ and grew out of a localized orbital RPA approach to calculating and analyzing electronic spectra and circular dichroism of chiral molecules.^{8,43} London's approach formed the basis for the GIAO⁴⁵ method (Gauge Invariant/Including Atomic Orbitals), see **Shielding Theory: GIAO Method**; a perhaps more appropriate acronym is LAO (London Atomic Orbitals).⁴⁶ The IGLO⁴⁷ method (Individual Gauge for Localized Orbitals) method introduces local gauge factors in a localized molecular orbital basis, see **Shielding Calculations: IGLO Method**. An IGAIM (Individual Gauges for Atoms in Molecules) has also been proposed,⁴⁸ and a gauge approach based on a propagator formulation of the diamagnetic shielding contribution has been explored, see Sauer et al.⁴⁹ and discussion therein. At the CHF level all these approaches converge to the same results in the Hartree–Fock limit;¹⁰ in particular the difference between LORG and IGLO can be viewed as a difference in the evaluation of the last term in equation (7).¹⁰

Extensions of the above methods to electron correlation levels beyond CHF include SOLO (second-order LORG) described in Section 2.2, and a second-order Møller–Plesset (MP2) version of GIAO.⁵⁰ Although consistent through second order, these two methods are distinctly different and the relationship between SOPPA/SOLO and MP2-GIAO is being investigated.⁵¹ Multiconfigurational versions of the GIAO/LAO method (MC-LAO⁵²) and of IGLO (MC-IGLO⁵³) have also been developed. At present, the merits and limitations of these post-CHF approaches cannot be considered fully explored.

1 INTRODUCTION

Perhaps the most important discovery after the successful detection of the NMR signal has been the observation that the nuclear resonance frequencies depend on the chemical or electronic environment of the nuclei,^{1,2} or, as Norman Ramsey states in his landmark papers of 1950:^{3,4} ‘In measurements of nuclear magnetic moments, a correction must be made for the magnetic field arising from the motions of the molecular electrons which are induced by the externally applied field.’ Ramsey realized that corrections using only Lamb’s diamagnetic theory were inadequate for molecules, because in molecules there are additional shielding contributions arising from the second-order paramagnetism. To address this problem, he developed the necessary theoretical framework to explain and eventually to calculate the ‘chemical effect’ that would become the chemical shift nowadays commonly used for structural elucidation. The calculation of the second-order paramagnetic contribution using perturbation theory has been a challenge to theoreticians for more than 40 years. In this article, we present a detailed discussion of the perturbative schemes that can be used in the calculation of chemical shieldings. In addition, we have included a small amount of material describing the symmetry properties of shielding tensors, some references to more comprehensive derivations of the Hamiltonian describing the magnetic shielding constants, and a detailed discussion of the gauge dependence of the chemical shielding. Practical implementations of the theories described here and their applications to solve chemical problems are presented elsewhere in this Encyclopedia, see Related Articles.

2 SYMMETRY PROPERTIES OF THE SHIELDING TENSOR

The formal definition of the components of the chemical shielding tensor is

$$\sigma_{\alpha\beta} = \frac{\partial^2 E}{\partial \mu_\alpha \partial B_\beta} \quad (1)$$

where E is the total electronic energy of the molecule, $\mathbf{B}$ is the external magnetic field, and $\boldsymbol{\mu}$ is the magnetic moment of the nucleus of interest. There are two important observations that can be made from equation (1)

1. The chemical shielding tensor is an antisymmetric tensor because

$$\sigma_{\alpha\beta} = \frac{\partial^2 E}{\partial \mu_\alpha \partial B_\beta} = \frac{\partial^2 E}{\partial B_\beta \partial \mu_\alpha} \neq \frac{\partial^2 E}{\partial \mu_\beta \partial B_\alpha} = \sigma_{\beta\alpha} \quad (2)$$

This property of the tensor should not be confused with the fact that the first-order response function (the NMR spectrum) is sensitive only to the symmetric part of the tensor and that the antisymmetric components contribute only to the second-order response, i.e., the relaxation of the spin magnetization.^{5,6}

2. When using perturbation theory, the chemical shielding tensor components can be identified as the coefficients in the expansion of the electronic energy that correspond to bilinear terms in the nuclear magnetic moment and the external magnetic field.

The chemical shielding tensor has nine independent components, the number of which may be reduced by molecular symmetry. The independent components of the chemical shielding tensor for different molecular symmetries are given in Table 1.⁷ Note that the diamagnetic contribution to the chemical shielding tensor is a symmetric quantity—this will become apparent when we develop the perturbation expansions for the shielding tensors.

3 EXACT PERTURBATION THEORY

In order to obtain the exact expressions, using the nonrelativistic Born–Oppenheimer approximation, for the calculation of the chemical shieldings, it is necessary to include in the electronic Hamiltonian the vector potential representing the external magnetic field and the dipolar field originated in the magnetic moment of the nucleus.^{8–10} In the Coulomb gauge, the vector potential defining these fields at the position of electron k can be written as

$$\mathbf{A}_k(\mathbf{r}) = \frac{1}{2} \mathbf{B} \times \mathbf{r}_k + \frac{\boldsymbol{\mu}_N \times \mathbf{r}_{Nk}}{r_{Nk}^3} \quad (3)$$

where we follow the standard notation used in this Encyclopedia. The origin of the vector potential is at the position O and $\mathbf{r}_k$ and $\mathbf{r}_{Nk}$ are defined according to Figure 1. Note that, for simplicity, we are assuming that only one nucleus in the molecule has a nonzero magnetic moment. $\mathbf{r}_k$ is the position of electron k measured from the origin of the coordinate system, and $\mathbf{r}_{Nk}$ is the position of electron k measured from the nucleus N . Following the standard procedures for the inclusion of magnetic interactions in the electronic Hamiltonian, the full electronic Hamiltonian in the presence of the two magnetic fields becomes

$$\hat{\mathcal{H}} = \frac{1}{2} \sum_k \left[\frac{1}{i} \nabla_k - \frac{1}{c} \mathbf{A}_k(\mathbf{r}) \right]^2 + V(\mathbf{r}) \quad (4)$$

Using the properties of the Coulomb gauge, i.e. $\nabla \cdot \mathbf{A} = 0$, the expansion of this Hamiltonian leads to six terms, only three of which are relevant to the calculation of chemical shieldings. These are

$$\hat{\mathcal{H}}_\alpha^{(1,0)} = \frac{-i}{2c} \sum_k (\hat{\mathbf{L}}_k)_\alpha = \frac{-i}{2c} \sum_k (\mathbf{r}_k \times \nabla_k)_\alpha \quad (5)$$

2 SHIELDING CALCULATIONS: PERTURBATION METHODS

Table 1 Nonvanishing Components of the Chemical Shielding Tensor for Different Point Groups (Reproduced by Permission of Taylor and Francis, from A. D. Buckingham and S. M. Malm, *Mol. Phys.*, 1971, **22**, 1127)

Point group appropriate to the shielded nucleus	Number of independent components		Nonvanishing components for the symmetric(s) and antisymmetric(a) components
	$\sigma_{\alpha\beta}^d$	$\sigma_{\alpha\beta}^p$	
C_1, C_i	6	9	$\sigma_{zz}, \sigma_{xx}, \sigma_{yy}, \sigma_{xy}^s, \sigma_{xz}^s, \sigma_{yz}^s;$ $\sigma_{xy}^a, \sigma_{xz}^a, \sigma_{yz}^a$
C_2, C_s, C_{2h}	4	5	$\sigma_{zz}, \sigma_{xx}, \sigma_{yy}, \sigma_{xy}^s; \sigma_{xy}^a$
C_{2v}, D_2, D_{2h}	3	3	$\sigma_{zz}, \sigma_{xx}, \sigma_{yy}$
C_4, S_4, C_{4h}	2	3	$\sigma_{zz}, \sigma_{xx}, \sigma_{yy}; \sigma_{xy}^a$
$C_3, S_6, C_{3h}, C_6, C_{6h}$	2	3	$\sigma_{zz}, \sigma_{xx} = \sigma_{yy}; \sigma_{xy}^a$
$C_{4v}, D_{2d}, D_4, D_{4h}, C_{3v},$ $D_3, D_{3d}, D_{3h}, D_{4h}, D_{3h},$ C_{6v}, D_6, D_{6h}	2	2	$\sigma_{zz}, \sigma_{xx} = \sigma_{yy}; \sigma_{xy}^a$
$C_{\infty v}, D_{\infty h}$	2	1	$\sigma_{zz}, \sigma_{xx} = \sigma_{yy} (\sigma_{zz}^p = 0)$

$$\hat{\mathcal{H}}_{\alpha}^{(0,1)} = \frac{-i}{c} \sum_k \frac{(\hat{\mathbf{L}}_{Nk})_{\alpha}}{r_{Nk}^3} = \frac{-i}{2c} \sum_k \frac{(\mathbf{r}_{Nk} \times \nabla_k)_{\alpha}}{r_{Nk}^3} \quad (6)$$

$$\hat{\mathcal{H}}_{\alpha\beta}^{(1,1)} = \frac{1}{c^2} \sum_k \frac{\mathbf{r}_k \cdot \mathbf{r}_{Nk} \delta_{\alpha\beta} - (\mathbf{r}_k)_{\alpha} (\mathbf{r}_{Nk})_{\beta}}{r_{Nk}^3} \quad (7)$$

where the superscripts indicate the order in the external magnetic field, $\mathbf{B}$, and in the nuclear magnetic moment, $\boldsymbol{\mu}$, respectively. If we restrict our analysis to closed shell molecules, for which the electronic ground state is of the Σ type, $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$ give no contribution to the energy at first-order in Raleigh–Schrödinger (RS) perturbation theory. The third term, $\hat{\mathcal{H}}^{(1,1)}$, gives at first order a nonzero contribution that is proportional to $1/c^2$; the other contribution of order $1/c^2$ can be obtained from the second-order cross term between $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$. Using the definition of chemical shielding given by equation (1), we can define the diamagnetic and paramagnetic contributions to the chemical shielding as the first- and second-order terms in the energy expansion that are bilinear in the external magnetic field and the nuclear magnetic moment, respectively. The final expressions for the diamagnetic and paramagnetic contributions are

$$\sigma_{\alpha\beta}^d(O) = \frac{1}{2c^2} \langle \psi_0 | [\mathbf{r}_k \cdot \mathbf{r}_{Nk} \delta_{\alpha\beta} - (\mathbf{r}_k)_{\alpha} (\mathbf{r}_{Nk})_{\beta}] r_{Nk}^{-3} | \psi_0 \rangle \quad (8)$$

$$\sigma_{\alpha\beta}^p(O) = \frac{-1}{2c^2} \sum_n \frac{1}{E_n - E_0} \langle \psi_0 | (\hat{\mathbf{L}}_k)_{\alpha} | \psi_n \rangle \langle \psi_n | (\hat{\mathbf{L}}_{Nk})_{\beta} r_{Nk}^{-3} | \psi_0 \rangle + \text{c.c.} \quad (9)$$

where we have indicated explicitly that equations (8) and (9) are valid when the origin of the vector potential is at the position O . The sum in equation (9) is over all the excited states of the molecule. Before discussing the methods for practical evaluation of equations (8) and (9), it is important to understand the behavior of the diamagnetic and paramagnetic terms under translations of the origin of the coordinate system.

Figure 1 Coordinate system used to illustrate the gauge origin dependence of the diamagnetic and paramagnetic contributions of the chemical shielding

4 GAUGE ORIGIN DEPENDENCE OF THE CHEMICAL SHIELDING

Using the notation of Figure 1, we can calculate the effect of a translation of the origin of coordinates on the diamagnetic and paramagnetic contribution by using the replacements

$$\left. \begin{aligned} \mathbf{r}_{Nk} &= \mathbf{r}'_{Nk} \\ \mathbf{r}_k &= \mathbf{r}'_k + \mathbf{R}_{O'} \end{aligned} \right\} \quad (10)$$

in equations (8) and (9) to obtain the expressions for σ^d and σ^p in the new coordinate system with origin at O' . For the diamagnetic components, we obtain

$$\sigma_{\alpha\beta}^d(O) = \frac{1}{2c^2} \langle \psi_0 | [\mathbf{r}'_k \cdot \mathbf{r}_{Nk} \delta_{\alpha\beta} + \mathbf{R}_{O'} \cdot \mathbf{r}_{Nk} \delta_{\alpha\beta} - (\mathbf{r}'_k)_{\alpha} (\mathbf{r}_{Nk})_{\beta} - (\mathbf{R}_{O'})_{\alpha} (\mathbf{r}_{Nk})_{\beta}] r_{Nk}^{-3} | \psi_0 \rangle \quad (11)$$

which becomes

$$\sigma_{\alpha\beta}^d(O) = \sigma_{\alpha\beta}^d(O') + \frac{\mathbf{R}_{O'}}{2c^2} \cdot \langle \psi_0 | \frac{\mathbf{r}_{Nk}}{r_{Nk}^3} | \psi_0 \rangle \delta_{\alpha\beta} - (\mathbf{R}_{O'})_{\alpha} \langle \psi_0 | \frac{(\mathbf{r}_{Nk})_{\beta}}{r_{Nk}^3} | \psi_0 \rangle \quad (12)$$

The same replacements can be made for the paramagnetic contribution

$$\sigma_{\alpha\beta}^p(O) = \frac{-1}{2c^2} \sum_n \frac{1}{E_n - E_0} \langle \psi_0 | [(\mathbf{r}'_k + \mathbf{R}_{O'}) \times \nabla]_\alpha | \psi_n \rangle \times \langle \psi_n | (\mathbf{L}_{Nk})_\beta r_{Nk}^{-3} | \psi_0 \rangle + \text{c.c.} \quad (13)$$

which becomes

$$\sigma_{\alpha\beta}^p(O) = \sigma_{\alpha\beta}^p(O') + \left[\frac{-1}{2c^2} \sum_n \frac{1}{E_n - E_0} \langle \psi_0 | (\mathbf{R}_{O'} \times \nabla)_\alpha | \psi_n \rangle \times \langle \psi_n | (\mathbf{r}_{Nk} \times \nabla)_\beta r_{Nk}^{-3} | \psi_0 \rangle + \text{c.c.} \right] \quad (14)$$

At this point of the derivation, it is crucial to assume that we are working with the exact solution of the Schrödinger equation; therefore the $|\psi_n\rangle$ form a complete set, for which the virial relationship

$$(E_n - E_0) \langle \psi_0 | \mathbf{r} | \psi_n \rangle = \langle \psi_0 | \nabla | \psi_n \rangle \quad (15)$$

holds exactly. Note that this relationship is also true for any variational solution of the Schrödinger equation in a complete Hilbert space. This, as we shall see later, makes the chemical shielding calculations gauge-invariant for any variational wavefunction in a complete Hilbert space.

Using equation (15), it is possible to eliminate the energy denominator in equation (14):

$$\sigma_{\alpha\beta}^p(O) = \sigma_{\alpha\beta}^p(O') + \left[\frac{-1}{2c^2} \sum_n (\mathbf{R}_{O'} \times \langle \psi_0 | \mathbf{r}_{Nk} | \psi_n \rangle)_\alpha \times \langle \psi_n | (\mathbf{r}_{Nk} \times \nabla)_\beta r_{Nk}^{-3} | \psi_0 \rangle + \text{c.c.} \right] \quad (16)$$

which, making use of the closure relationship $\sum_n |\psi_n\rangle \langle \psi_n| = \hat{1}$ and the commutator $[\mathbf{r}, \nabla] = -1$, can be written as

$$\sigma_{\alpha\beta}^p(O) = \sigma_{\alpha\beta}^p(O') - \frac{\mathbf{R}_{O'}}{2c^2} \cdot \langle \psi_0 | \frac{\mathbf{r}_{Nk}}{r_{Nk}^3} | \psi_0 \rangle \delta_{\alpha\beta} + (\mathbf{R}_{O'})_\alpha \langle \psi_0 | \frac{(\mathbf{r}_{Nk})_\beta}{r_{Nk}^3} | \psi_0 \rangle \quad (17)$$

There are several important observations that can be derived from equations (12) and (17).

1. The total chemical shielding, i.e., the sum of the paramagnetic and diamagnetic parts, is invariant under changes of the origin of the coordinate system. Note that all the terms in equations (12) and (17) that depend on $\mathbf{R}_{O'}$ cancel each other in the sum of the two expressions. In the language of electromagnetic interactions, this is equivalent to saying that the chemical shielding tensor is invariant under gauge transformations that preserve $\nabla \cdot \mathbf{A} = 0$, i.e., the Coulomb gauge. For calculations of the chemical shieldings in other gauges, see the work by Ferarro et al.¹¹
2. The diamagnetic and paramagnetic components depend on the origin of the coordinate system, and their values can be changed at will by changing the relative position of the nucleus with respect to the origin. The origin-dependent contributions to the diamagnetic and paramagnetic terms are linear in the distance between the nucleus and the origin.

3. For exact wavefunctions—actually for any variational approximation of the wavefunction in a complete Hilbert space—the selection of the origin of the coordinate system is inconsequential, because the origin-dependent terms in the diamagnetic and paramagnetic contributions are calculated exactly, and they cancel each other.
4. For atomic systems, there is a natural choice for the origin of the vector potential, namely, the position of the nucleus. For this choice, using equations (12) and (17), it is straightforward to prove that the paramagnetic contribution is identically zero, and therefore the shielding is totally diamagnetic (Lamb’s diamagnetic theory).
5. For approximate wavefunctions, i.e., any calculation that we can do, the selection of the origin of the gauge is a serious problem, because the origin-dependent terms, which cancel each other in exact theories, are calculated using different approximations with different errors, and they do not cancel each other. Note that the diamagnetic contributions are calculated using the more accurate zeroth-order perturbation theory, while the paramagnetic contributions are calculated using second-order perturbation theory, which is much more sensitive to truncation errors in the sum over the excited states. Numerical examples of the effect of changing the gauge origin in shielding calculations abound in the literature,¹² and later in this article we discuss several strategies that have been proposed to minimize the gauge problem.
6. There is one particular selection of the origin of the gauge that deserves special mention. If one chooses the origin of the vector potential at the center of mass of the molecule, it is possible to prove that the paramagnetic contribution at the center of mass is proportional to the spin–rotation constant, which can be measured by microwave spectroscopy.¹³ By measuring the spin–rotation constant and calculating the diamagnetic contribution to the shielding at the center of mass, it is possible to obtain very accurate determinations of the absolute shieldings of the nuclei in small molecules, which can be used to establish absolute chemical shielding scales. These scales are critical for comparing calculated chemical shieldings with their corresponding shift values (see also **Chemical Shift Scales on an Absolute Basis**).
7. For molecules with C_∞ symmetry, if we choose the origin of the coordinate system on the C_∞ axis, the component of the paramagnetic contribution along the axis is identically zero, and therefore the shielding along the C_∞ axis is totally diamagnetic.¹⁴
8. Practical experience as well as theoretical derivations have demonstrated that the best results can be obtained when the gauge origin is located at the center of the electronic distribution of the molecule. This choice produces the best overall selection when the chemical shieldings of all the nuclei in the molecule are computed from one single calculation; when only the shielding of one nucleus is required, the best choice for the origin of the vector potential is the nucleus under consideration.

5 RELATIVISTIC EFFECTS AND I - S COUPLING

In the derivations presented in the previous section, we have assumed that there is no coupling between the molecular angular momentum $\mathbf{L}$ and the electronic spin $\mathbf{S}$, retaining only

terms of order $1/c^2$ in the Hamiltonian. This is equivalent to saying that equations (8) and (9) do not include any relativistic effects. Limitations of space preclude a complete discussion of the problem of relativistic effects on chemical shieldings, but it is worth mentioning that several authors have discussed this problem—at least from a formal point of view. Numerical estimations of the $\mathbf{L}\cdot\mathbf{S}$ coupling and relativistic effects on chemical shieldings are still poorly documented. The interested reader can find derivations of the relativistic theory of magnetic shielding in the literature.^{5,15} A very detailed derivation of the hyperfine Hamiltonians relevant to molecular magnetic interactions has been presented by Michelot.¹⁶

The effect of the $\mathbf{L}\cdot\mathbf{S}$ coupling on the chemical shieldings has been studied by adding to the Hamiltonian given by equation (4) the $\mathbf{L}\cdot\mathbf{S}$ coupling and the interaction between the electronic spin and the external and nuclear moment magnetic fields.^{17,18} Within this approximation, the molecular Hamiltonian becomes

$$\hat{\mathcal{H}} = \frac{1}{2} \sum_k \left\{ \left[\frac{1}{i} \nabla_k - \frac{1}{c} \mathbf{A}_k(\mathbf{r}) \right]^2 + 2\beta \hat{\mathbf{S}}_k \cdot [\nabla_k \times \mathbf{A}_k(\mathbf{r})] + \lambda \hat{\mathbf{L}}_k \cdot \hat{\mathbf{S}}_k \right\} + V(\mathbf{r}) \quad (18)$$

where λ is the coupling energy between the spin and the angular momentum and β is the Bohr magneton. The perturbational treatment of this Hamiltonian leads to the usual diamagnetic and paramagnetic terms discussed above, plus several terms bilinear in the external magnetic field and the nuclear magnetic moment, which represent the $\mathbf{L}\cdot\mathbf{S}$ contribution to the magnetic shielding. The additional terms can be evaluated using third-order perturbation theory, but only limited calculations of this effect have been presented.^{17,18}

6 PERTURBATION SCHEMES

In this section, we describe different perturbation schemes that can be used in practical calculations of chemical shieldings. To avoid unnecessary complications with the gauge problem discussed above, we shall discuss the perturbation schemes assuming that we are using a complete basis set. Schemes to alleviate the gauge problem are discussed at the end of this article and elsewhere in the Encyclopedia (see ‘Related Articles’). To simplify our expressions, we have chosen the position of the nucleus under consideration as the origin of the vector potential. The expressions for the diamagnetic and paramagnetic parts become

$$\sigma_{\alpha\beta}^d(N) = \frac{1}{2c^2} \langle \psi_0 | [r_{Nk}^2 \delta_{\alpha\beta} - (\mathbf{r}_{Nk})_\alpha (\mathbf{r}_{Nk})_\beta] r_{Nk}^{-3} | \psi_0 \rangle \quad (19)$$

$$\sigma_{\alpha\beta}^p(N) = \frac{-1}{2c^2} \sum_n \frac{1}{E_n - E_0} \langle \psi_0 | (\hat{\mathbf{L}}_{Nk})_\alpha | \psi_n \rangle \langle \psi_n | (\hat{\mathbf{L}}_{Nk})_\beta r_{Nk}^{-3} | \psi_0 \rangle + \text{c.c.} \quad (20)$$

The calculation of the diamagnetic part presents no complications, and can be evaluated for any kind of wavefunction, requiring only the evaluation of one-electron integrals of the type $1/r$, $1/r^3$, and xy/r^3 , which are readily available in most quantum mechanical codes. The calculation of the diamagnetic term is computationally simple, requiring a negligible amount of effort after the calculation of the zeroth-order approximation

to the wavefunction. Moreover, because the ground electronic state is less sensitive to the approximations used in the calculation, it is possible to calculate the diamagnetic contribution accurately, even when using modest approximations to the wavefunction.

The more complicated paramagnetic term requires, in principle, knowledge of all the excited electronic states of the molecule, in which case the direct evaluation of equation (20) would be immediate. Unfortunately, this is not the case, and a great deal of effort is necessary to obtain reliable results for the paramagnetic contribution. It is always important, if possible, to calculate the paramagnetic contribution with the same accuracy as the diamagnetic contribution in order to achieve as high a degree as possible of gauge invariance of the numerical results. Unfortunately, this may increase the computational complexity beyond practical limits, and the evaluation of the paramagnetic contribution has always been the limiting factor in the theoretical calculation of chemical shieldings. Historically, better and better approximations have been feasible owing to advances in computational sciences as well as a better understanding of perturbation theory in many-electron systems. In the following subsections, we review the most common approximations to calculate the paramagnetic contribution to the chemical shieldings.

6.1 Coupled Hartree–Fock Perturbation Theory

While most of the early work in the calculation of chemical shieldings was based on very simple approximations, it is convenient for pedagogical reasons to develop the exact coupled Hartree–Fock (CHF) theory of the chemical shielding and then to simplify the expressions to obtain less complex approximations. In this way, we hope that the reader will be able to understand the physical assumptions made for the different approximations.

Using the Hartree–Fock approximation and standard notation¹⁹ the second-order change in the molecular electronic energy for a singlet perturbation $\hat{\mathcal{H}}_1$ is

$$E^{(2)} = \sum_{i,a} [c_{ia}^2 (\epsilon_a - \epsilon_i + \langle ia|ia \rangle) + 2c_{ia} \langle i|\hat{\mathcal{H}}_1|a \rangle] + 2 \sum_{i,a \neq j,b} c_{ia} c_{jb} (4\langle ia|jb \rangle - \langle ab|ij \rangle - \langle ja|ib \rangle) \quad (21)$$

where the c_{ia} are the coefficients corresponding to the excited state determinants, in which we have expanded the perturbed wavefunction as

$$|\psi\rangle = |\psi_0\rangle + \sum_{i,a} c_{ia} |\psi_{i \rightarrow a}\rangle + \sum_{i,a} \sum_{j,b} c_{ia} c_{jb} |\psi_{i \rightarrow a, j \rightarrow b}\rangle + \dots \quad (22)$$

The Hartree–Fock solution for the ground state corresponds to the single determinant wavefunction that minimizes the electronic energy of the system. Therefore, to be consistent with this definition, we shall require that the second-order energy $E^{(2)}$ be a minimum with respect to changes in the expansion coefficients c_{ia} . Using this condition, $\delta E^{(2)}/\delta c_{ia} = 0$, in equation (21), we obtain the following system of linear equations to calculate the coefficients c_{ia} :

$$c_{ia} (\epsilon_a - \epsilon_i + \langle ia|ia \rangle) + \langle i|\hat{\mathcal{H}}_1|a \rangle + 2 \sum_{j,b \neq i,a} c_{jb} (4\langle ia|jb \rangle - \langle ab|ij \rangle - \langle ja|ib \rangle) = 0 \quad (23)$$

The second-order Hartree–Fock energy can be calculated by replacing the coefficients c_{ia} determined from the system of linear equations, given by equation (23) into equation (21).

Several schemes have been developed to solve exactly or approximately the system of linear equations given by equation (23). The simplest approximation is to neglect all of the two-electron integrals in equation (23); this leads to a very simple expression for the second-order energy:

$$E^{(2)} = \sum_{i,a} \frac{\langle i|\hat{\mathcal{H}}_1|a\rangle\langle a|\hat{\mathcal{H}}_1|i\rangle}{\varepsilon_i - \varepsilon_a} \quad (24)$$

Direct use of equation (24) is problematic, because the Hartree–Fock orbital energies for the unoccupied orbitals are always too high; therefore, even when using uncoupled schemes, it is necessary to take into account the repulsion integrals $\langle ia|ia\rangle$ to correct for this deficiency in the orbital energies of the unoccupied orbitals. With this addition, equation (24) becomes

$$E^{(2)} = \sum_{i,a} \frac{\langle i|\hat{\mathcal{H}}_1|a\rangle\langle a|\hat{\mathcal{H}}_1|i\rangle}{\varepsilon_i - \varepsilon_a + \langle ia|ia\rangle} \quad (25)$$

Practical application of equation (24) or equation (25) to the calculation of the paramagnetic contribution of the chemical shielding is immediate, replacing $\hat{\mathcal{H}}_1$ by the appropriate operators given by equations (5) and (6) and by expanding the molecular orbitals $|i\rangle$ in a linear combination of atomic orbitals. In general, the uncoupled approaches have been less than successful, but many semiempirical theories of chemical shieldings have been developed by further simplification of equation (25). In these theories, which assume that only the first term in the sum in equation (25) makes a significant contribution to the chemical shielding, the sum over the excited states is replaced by a quantity solely dependent on the electronic ground state and an average excitation energy, which are usually treated as semiempirical parameters. By eliminating the sum over states, they provide very compact expressions for the semiquantitative analysis of the chemical shieldings.²⁰ Note that the uncoupled approach is physically equivalent to the assumption that the external perturbation does not change the average Hartree–Fock potential in which the molecular electrons move.

The next step in complexity for the calculation of chemical shieldings is to solve the system of equations given by equation (23), including all the coupling terms. This takes into account the change in the average Hartree–Fock potential induced by the external perturbation and the consequent change in the electronic distribution. This physical interpretation has been used as a reason for solving equation (23) in an iterative fashion, solving first the uncoupled problem, using its solution to calculate the correction terms in equation (23) and iterating thereafter this procedure until convergence. This procedure is commonly called a coupled Hartree–Fock (CHF) calculation, and the working equations are

$$c_{ia}^{(n+1)} = \frac{-\langle i|\hat{\mathcal{H}}_1|a\rangle}{\varepsilon_a - \varepsilon_i} - \frac{1}{\varepsilon_a - \varepsilon_i} \sum_{jb} S_{ia,jb} c_{jb}^{(n)} \quad (26)$$

where n indicates the order of the iteration and $S_{ia,jb}$ is given by:

$$S_{ia,jb} = 4\langle ia|jb\rangle - \langle ab|ij\rangle - \langle ja|ib\rangle \quad (27)$$

Note that $S_{ia,jb}$ is independent of the perturbation, and depends only on the properties of the Hartree–Fock electronic ground state. The iterative procedure prescribed by equation (26) converges if all the eigenvalues of $S_{ia,jb}$ are smaller than one in absolute value. In contrast with the serious problems encountered in solving these equations for the calculation of J couplings,²¹ the convergence of the CHF equations for chemical shielding calculations is satisfactory.

It is also possible to express the CHF equations in the language of the polarization propagator approach or linear response theory²² by introducing the inverse of the polarization propagator $\mathbf{P}$:

$$(\mathbf{P}^{-1})_{ia,jb} = (\varepsilon_a - \varepsilon_i)\delta_{ij}\delta_{ab} + 4\langle ia|jb\rangle - \langle ab|ij\rangle - \langle ja|ib\rangle \quad (28)$$

Using this definition of $\mathbf{P}^{-1}$, it is possible to express the second-order contribution to the electronic energy as

$$E^{(2)} = \sum_{ia,jb} \langle i|\hat{\mathcal{H}}_1|a\rangle P_{ia,jb} \langle b|\hat{\mathcal{H}}_1|j\rangle \quad (29)$$

There are several relevant features of equation (29) that are important to discuss:

1. The propagator $\mathbf{P}$ depends only on quantities that are known from the Hartree–Fock calculations [see equation (28)].
2. Once the polarization propagator $\mathbf{P}$ has been calculated by inverting $\mathbf{P}^{-1}$, it is possible to calculate any second-order property depending on it by using equation (29). It should be noted that the calculation of $\mathbf{P}^{-1}$ and its inversion are computationally very expensive, while the evaluation of equation (29) represents a trivial amount of computational effort.
3. An alternative solution of equation (29), commonly named SOS/2 (for sum over states/2), consists in expressing the second-order energy as an explicit sum over states similar to the exact expression given by RS perturbation theory. Within this approach, $\mathbf{P}^{-1}$ is constructed according to equation (28), but it is diagonalized instead of inverted. In the new basis, in which $\mathbf{P}^{-1}$ is diagonal, it is possible to express the second-order energy as

$$E^{(2)} = \sum \frac{\langle i'|\hat{\mathcal{H}}_1|a'\rangle\langle a'|\hat{\mathcal{H}}_1|i'\rangle}{E_{i'} - E_{a'}} \quad (30)$$

where $|i'\rangle$ are the eigenvectors of $\mathbf{P}^{-1}$ and E its eigenvalues. This formulation is totally equivalent to equation (29), but can be used explicitly to analyze the contributions of different orbitals to the chemical shielding.

For simplicity, all the equations discussed above have been expressed in terms of molecular orbitals (MO), but the reader should keep in mind that the actual calculation of the shielding constants normally requires one to rewrite the equations in the atomic orbital (AO) basis or to transform the necessary two-electron integrals from the AO basis into the MO basis. This transformation is the most demanding part of the chemical shielding calculations in terms of CPU, storage and memory requirements. Direct methods for the solution of equation (29), which avoid the two-electron integral bottleneck, promise great advances in our ability to compute chemical shieldings in the future.²³

6.2 Finite Perturbation Theory

The perturbation schemes described in the previous section were based on approximations to the exact perturbation theory; the notion of finite perturbation theory (FPT) or finite field perturbation theory (FFPT) is based on the direct use of equation (1) to calculate chemical shieldings. In the FPT approach, the electronic energy of the system is calculated with and without the magnetic fields derived from the vector potential given by equation (3), and the derivatives of the energy with respect to the magnetic fields are estimated numerically by finite differences:

$$\sigma_{\alpha\beta} = \frac{\partial^2 E}{\partial \mu_\alpha \partial B_\beta} \bigg|_{B_\beta = \mu_\alpha = 0} \approx \frac{E(\Delta\mu_\alpha, \Delta B_\beta) - E(0, 0)}{\Delta\mu_\alpha \Delta B_\beta} \quad (31)$$

In equation (31), the values of ΔB_β and $\Delta\mu_\alpha$ are selected in such way that they produce a large enough change in the electronic energy of the system to calculate the denominator with the desired precision without introducing higher-order terms in the derivatives. Normally, it is necessary to calibrate these increments for each MO method, but this does not represent a significant problem for the application of equation (31) to calculate chemical shieldings. The FPT method can be easily programmed; therefore it can be used to calculate the chemical shielding for any high-order approximation to the electronic wavefunction without major modifications of the necessary computer programs. Its most serious disadvantage is the need for a complete SCF energy calculation for each component of each of the shielding tensors in the molecule. The FPT method is useful for highly correlated methods for which the algebraic expressions for the second-order energy are not readily available.

6.3 Perturbation Theory Including Correlation Effects

When appropriate techniques to mitigate gauge origin problems are used, the Hartree–Fock level calculations of chemical shieldings have been very successful—even when relatively modest basis sets were used. For instance, the chemical shift tensors in sucrose, calculated using the GIAO method, agree with their experimental measurements with standard marginal deviations of 4.6 and 2.7 ppm when using the STO-3G and 3-21G basis sets, respectively (see Figure 2).²⁴ But many cases have also been documented in the literature in which the Hartree–Fock calculations produce fairly poor results, even in the limit of very large basis sets: examples of this behavior can be found for CO²⁵ and in the systematic overestimation of the δ_{11} principal components of the ^{13}C chemical shift tensors for olefinic and aromatic carbons.²⁶

To correct these deficiencies, several attempts have been made to include dynamic electronic correlation in calculations of chemical shieldings. One important consideration in including electron correlation in the calculation of chemical shieldings is to preserve the gauge invariance of the total shielding. As we discussed above, only the exact wavefunction and its variational approximations preserve the gauge invariance of the chemical shieldings in the limit of complete basis sets. This is a severe restriction, because many methods commonly used to include correlation effects in quantum mechanical calculations do not satisfy this requirement. In these cases, numerical

Figure 2 Comparison between the GIAO calculated chemical shift values, in the icosahedral representation, and their experimental values. Reproduced by permission of Kluwer Academic Publishers from D. M. Grant, J. C. Facelli, D. W. Alderman, and M. H. Sherwood, in 'Nuclear Magnetic Shielding and Structure', eds. J. A. Tossell, Kluwer, Dordrecht, 1993, p. 367

experiments are necessary to evaluate the sensitivity of the results with respect to changes in the origin of the vector potential. It has been established that the correlation effects are very sensitive to the basis set used in the calculations; therefore correlation effects calculated with unsaturated basis sets may be misleading.²⁵

In Table 2, we have given a number of numerical examples of electronic correlation effects on calculated chemical shieldings. Note that these are probably the most accurate calculations of chemical shieldings available today; in most cases the results have been obtained using extended basis sets near the Hartree–Fock limit. It is apparent from these results that the importance of correlation effects is strongly dependent on the bonding situation of the nucleus. For a singly bonded nucleus, correlation effects are extremely small—to the degree that it is not possible to assess their impact in improving agreement with the experimental data without taking into account vibrational, medium, and temperature corrections to chemical shieldings. Correlation effects are much more important for nuclei in multiply bonded situations, in which case the agreement between experimental and calculated values shows a significant improvement.

7 LONDON ORBITALS AND GAUGE-INDEPENDENT THEORIES OF CHEMICAL SHIELDING

In practical applications, the gauge origin dependence of chemical shieldings is a significant problem, because in most cases it is not possible to use large basis sets to achieve or even to be near the Hartree–Fock limit. Several methods have been proposed to eliminate this problem by making the results formally gauge-invariant even for incomplete basis sets. The most common methods—GIAO, IGLO, and LORG—are described in detail elsewhere in this Encyclopedia (see 'Related Articles'), but the reader should realize that all of them are based on the use of the same kind of explicit gauge-dependent functions for the atomic (GIAO), or molecular, (IGLO and LORG) orbitals.

The exact wavefunctions transform as

$$\psi(A') = e^{-i\Delta} \psi(A) \quad (32)$$

Table 2 Calculated Effects of Electron Correlation on Chemical Shifts Using Different Methods (All Values in ppm in Absolute Shieldings)

	MC/IGLO		MP2/GIAO		SOLO/LORG		Exp.
	SCF	MC	SCF	MP2	SCF	SOLO	
H ₂ O, ¹⁷ O	321.39	323.04	323.18	339.79	377.94	379.79	344.0
CO, ¹³ C	-23.40	13.39	-29.2	11.1	-17.42	-1.50	3.0
¹⁷ O	-83.86	-36.66	-113.47	-54.06	-87.77	-60.37	-36.7
CH ₄ , ¹³ C	193.82	198.39	195.7	201.5	198.71	200.36	200.36
C ₂ H ₆ , ¹³ C	—	—	184.0	188.0	184.78	184.69	180.9
C ₂ H ₄ , ¹³ C	—	—	59.9	71.2	64.41	72.07	64.5

under a gauge transformation given by

$$A(\mathbf{r}) \rightarrow A(\mathbf{r}') = A(\mathbf{r}) + \nabla\lambda(\mathbf{r}) \quad (33)$$

where

$$\Delta = c^{-1} \sum_i \lambda(\mathbf{r}_i) \quad (34)$$

For complete variational sets equation (32) is automatically satisfied, the energy of the system is gauge-invariant, and the electronic current derived from the wavefunctions is conserved, i.e., $\nabla \cdot \mathbf{j} = 0$.^{27,28} An approximate wavefunction can be forced to satisfy equation (32) by expanding it in the so-called London orbitals or GIAOs given by

$$\chi_p(\mathbf{r}, \mathbf{A}) = \chi_p(\mathbf{r}) \exp \left[-\frac{i}{c} \mathbf{A}(\mathbf{R}_p) \cdot \mathbf{r} \right] \quad (35)$$

where the $\chi_p(\mathbf{r})$ are real atomic orbitals (Slaters, Gaussians, etc.) and $\mathbf{R}_p$ is the position of the center of the $\chi_p(\mathbf{r})$. When the wavefunction is optimized within the space expanded by orbitals of the type given in equation (35), the explicit field dependence of the AOs constrains the search in such a way that only wavefunctions satisfying equation (32) are taken into account. That is to say, the set of trial functions change from one gauge to another in such a way that the energy is invariant. Unfortunately, the use of GIAOs does not guarantee the conservation of the electronic current.²⁷ It is also important to realize that, a priori, there is no reason to expect better results when using this enforced gauge invariance of the energy, but, because the GIAOs are the first-order solutions for the one-electron, one-center, uniform magnetic field problem when $\chi_p(\mathbf{r})$ is the solution of the problem for $\mathbf{B} = 0$, they do provide a more flexible basis for expanding the wavefunction in the presence of a magnetic field. As a consequence, in practical applications, calculations using GIAOs produce better results.

The above discussion was based on using GIAOs for the atomic basis set in the expansion of the wavefunctions. The IGLO and LORG methods avoid the use of GIAOs in the calculation of the zeroth-order wavefunctions, but they expand the first-order perturbation of the wavefunction in a set of localized molecular orbitals with individual gauge origins, producing a similar effect. For a detailed discussion of the differences between the IGLO and LORG methods, the reader can consult the literature.²⁹ Finally, it is important to cite the work by Helgaker and Jørgensen³⁰ showing that it is possible to use London orbitals in the calculation of chemical shieldings employing the techniques developed to calculate polarization propagators for MCSF wavefunctions.

8 ORIGIN-INDEPENDENT FORMULATION OF CHEMICAL SHIELDING

The approaches described above to mitigate the gauge origin problem are all based on the idea of shifting the phase of either atomic or molecular orbitals to compensate for the changes in the origin of the coordinate system. All of them can be characterized by an enforced gauge invariance of the electronic energy by restricting the trial functions to those satisfying equation (32). In contrast to this approach Geertsen³¹ and Sauer and Oddershede²⁵ have expressed the diamagnetic contribution as a second-order property using the polarization propagator formalism. In this formalism, both the paramagnetic and diamagnetic contributions are calculated as second-order properties, and the cancelation of errors discussed above is no longer present, because both contributions are calculated with the same degree of accuracy. Unfortunately, this approach does not provide any practical advantages, because it requires large basis sets to calculate the diamagnetic contributions.

1 INTRODUCTION

Since the publication of the *Encyclopedia of NMR*¹ there has been a significant increase in our ability to calculate shielding tensors. These increased capabilities have originated in new theoretical developments, advances in the algorithms used in quantum mechanical software and great improvements in the performance of computer hardware. This article gives a general overview of these developments and illustrates the use of NMR shielding calculations as a tool for solving common problems in structural chemistry and NMR spectroscopy.

Several methods to calculate shielding constants were described in the original volumes of the *Encyclopedia of Nuclear Magnetic Resonance*.^{2–6} The methods described in the encyclopedia plus other methods, such as IGAIM (individual gauges for atoms in molecules)⁷ and CSGT (continuous gauge transformation),⁸ have become part of the standard toolkit of structural chemists. The implementation of routines to calculate NMR shieldings in popular quantum chemical packages, such as the Gaussian series of programs,⁹ has provided the greatest impetus for the routine use of NMR shielding calculations in structural chemistry.

In this article we discuss significant advances in the calculation of NMR shielding constants reported since the publication of the *Encyclopedia of NMR* in 1996. The material included in this article is by no means comprehensive and it is intended for physical or biological science researchers who are not specialists in the field of NMR. Comprehensive reviews in the field can be found in the accounts published annually by Jamenson and more recently by de Dios and Jameson.¹⁰ Additional reviews on shielding calculations that have been published since the publication of the *Encyclopedia of NMR*, are: Fukui's review,¹¹ Fleischer et al. article in the *Encyclopedia of Computational Chemistry*,¹² and Chestnut's review in *Reviews in Computational Chemistry*.¹³ Also the proceedings of two international meetings^{14,15} provide a

good overview of the state of the art developments in this field.

In Section 2 of this article we discuss the development of distributed gauge methods and the use of modern density functional theory (DFT) to calculate shielding constants. The section ends with a brief discussion of the open problems in the field of shielding calculations. In Section 3 we give a short account of the software available to perform shielding calculations and the hardware necessary for this task. Section 4 presents selected examples of state of the art shielding calculations from the author's work. Finally, the reader is advised that the references presented in Section 8 are by no means comprehensive, representing just a small sample of the work reported in the field in the last five years.

2 DEVELOPMENTS LEADING TO THE MODERN METHODS TO CALCULATE SHIELDING CONSTANTS

The state of the art in the calculation of NMR shielding constants has changed dramatically since the publication of the *Encyclopedia of NMR* in 1996. At that time the calculation of NMR shieldings was a highly specialized field, with a relative modest number of practitioners. While other computational modeling techniques were already highly developed and popular among non-specialists, the calculation of NMR shielding constants was still in its developmental stages. The principal reasons for this state of affairs were the complications associated with the so-called "gauge" problem and the well-known need to include electronic correlation effects in the calculation of NMR shielding constants.

Both problems were particularly severe for calculations in large molecules of practical interest. In these systems the need for large basis sets required to eliminate gauge invariance problems and the steep scaling with the size of the system, which is characteristic of electron structure methods that include electronic correlation effects, made the calculations unfeasible. In the next two subsections we describe new computational techniques that can be used to alleviate these problems, making calculations of shielding constants in large molecules possible.

2.1 Distributed Gauge Origin Methods

The so called "gauge" problem in shielding calculations or more precisely the lack of gauge invariance of the calculated shielding constants is a consequence of using a finite basis in the expansion of the wave function or electron density. Facelli has reviewed the gauge problem in detail in the *Encyclopedia of NMR*,² and another recent treatment of this problem can be found in Fukui's review.¹¹ It has been known for many years that this problem can be eliminated by using complex functions to expand the wave function. In spite of this theoretical understanding, it has taken a long time to derive practical and efficient formulations from this principle. It can be shown that the use of complex functions in the expansion of the wave function is equivalent to using different gauge origins for different regions of the electron density, therefore these methods to calculate shielding constants using complex expansions of the wave function have been designated as

distributed gauge origin methods. Many of the distributed gauge origin methods, like individual gauge for localized orbitals (IGLO),⁵ localized orbitals local origin (LORG),⁶ gauge including atomic orbital (GIAO),⁴ individual gauges for atoms in molecules (IGAIM)⁷ and continuous gauge transformation (CSGT),⁸ have been efficiently implemented (see below) in common chemical modeling packages making possible for non-specialists to calculate shieldings routinely.

The distributed gauge methods can be classified into several different classes, those that use individual gauges for localized orbitals (LORG and IGLO); those that use a formulation based on the current of the electron density and the Bader's topological atom in a molecule description (IGAIM) or an empirical function for the continuous transformation of the gauge origin (CSGT) and finally, the GIAO method, which accomplishes the invariance of the results by using individual gauge origins for each atomic function in the basis set. For practical applications the selection of a method to calculate shielding is quite arbitrary, depending on such practical factors as software availability, cost and/or familiarity of the user with a particular method, hardware compatibility, etc. Methods using a localized orbital description, such as LORG and IGLO, can provide a somehow intuitive decomposition of the shielding into contributions arising from different localized orbitals, a feature quite appealing to chemists. The IGAIM method provides a decomposition of the shielding constants into contributions arising from the electronic density of each atomic basin, as defined by Bader's topological atom in a molecule description.⁷ These types of decompositions are not available when using the GIAO or the CSGT methods, but the later provides an accurate three-dimensional representation of the distribution of induced electron current. Finally,

it is interesting to mention Geertsen's method,¹⁶ which gives a gauge origin independent formulation of the shielding constants by using second order perturbation theory to calculate its diamagnetic part. Unfortunately, while quite elegant, this formulation has not lead to practical applications due to the difficulties associated with the calculation of second order properties.

While all the methods discussed above take different approaches to mitigate the gauge problem, all of them are exact and converge to the same shielding values in the limit of very large basis. Of course, the converged values are identical to those obtained with the common origin method when the same extended basis is used in the calculations. In Figure 1 we present the basis set dependence of the calculated chemical shifts in glycine for different distributed gauge methods compared with the results obtained using the common origin method. The calculations were done using the Gaussian98 system,⁹ the basis sets used correspond to the Dunning's correlation consistent basis, which includes polarization functions,¹⁷ and the standard STO-3G from Pople et al.¹⁸ It is apparent from the Figure that for the very small basis set, STO-3G, none of the methods is able to recover a significant fraction of the infinite basis limit; but significant improvements are observed when using the double zeta (DZ) basis set. Finally, the calculated values for all the methods consider here are almost identical when the quadruple zeta (QZ) basis set is used. While in some of the graphs of Figure 1 the IGAIM method appears to converge faster than the GIAO method, to the author's knowledge this is not a general conclusion, for instance the opposite results have been reported by Cheesman.¹⁹

Figure 1 Basis set dependence of the shieldings in Glycine with different distributed gauge methods. All the values are in ppm referenced to the bare nucleus. The asterisk indicates the nucleus for which the shielding was calculated

2.2 Density Functional Theory Methods

The second important improvement in the calculation of shielding tensors, has been the development of generalized gradient approximations (GGAs) for the exchange-correlation functional in the density functional theory (DFT). While this theory, DFT, has been known for many years the development of GGAs and hybrid exchange-correlation functionals has increased the accuracy of the DFT to the point of making it suitable for shielding calculations.²⁰ Previous DFT theories, based on the local density approximation (LDA), did not have the accuracy necessary to provide the detailed description of the molecular electronic density needed to reproduce shielding constants quantitatively.¹⁹

The importance of the electron correlation effects in the calculation of shielding constants has been known for long time. Calculations at the Hartree–Fock level, while useful, were not as precise as needed for solving structural or assignment problems. Methods including contributions of the electronic correlation in the calculation of shielding constants also have been known for quite some time, for instance calculations using highly correlated Coupled Cluster methods have been published recently.²¹ Unfortunately these methods, even at the MP2 level, do not provide a practical alternative to calculate shielding constants in large molecules because they scale as N^5 to N^7 , depending of the approximation, with the size of the system. The development of effective DFT theories, which include electronic correlation effects, has proven a revolutionary tool in the field of shielding calculations. Using the DFT theory, which scales as N^2 , it is possible to calculate shielding constants in molecular systems of practical interest including electronic correlation effects. Moreover, new DFT methods with quasi-linear scaling are becoming available and certainly they will be applied to the calculation of shielding constants in the near future.

Modern DFT theories are based on different approximations to calculate the exchange-correlation functional. Two fundamental approaches have been taken to establish this functional, one is based on pure mathematical considerations and the other based on empirical correlations that may include a portion of the Hartree–Fock exchange. Numerous shielding calculations, using a myriad of different functionals, have been reported. Many of these studies claim, depending of the set of molecules studied, to have found the best functional to calculate shielding constants. Careful evaluation of the literature would indicate that, except for the LDA approximation that does not include any gradient correction, all the modern exchange-correlation functionals give shielding constants of similar quality. It has become apparent that the shielding constants are much less sensitive to the selection of the exchange-correlation functional than other molecular properties.²²

In Table 1 we compare the RMS between experimental and calculated ^{13}C and ^{15}N NMR chemical shifts for different exchange-correlation functionals for the compounds studied by Cheesman.¹⁹ It is apparent that except for the calculations done using the LDA approximation, the DFT calculations are much better than the Hartree–Fock estimates and close to the values obtained for MP2 calculations. Two important observations can be derived from the table: (i) the calculations are not very sensitive to the exchange-correlation functional used, except for the LDA approximation; (ii) DFT methods recover a significant portion of the electronic correlation effect and provide a viable alternative to calculate chemical shifts with accuracies close to those obtained with the much more expensive MP2 method.

2.3 Limitations of the Current Methods

In spite of the great success of shielding calculations, there are several limitations in the current methods that should be taken into account. These limitations can be broadly classified as those inherent to the approximations used in the calculations and those due to the lack of knowledge of the molecular or crystalline structure.

In the first category the greatest deficiency of the current methods is the neglect of relativistic corrections. This is of minor consequence when dealing with molecules including first or second row atoms, but becomes a significant problem when the molecule includes atoms beyond the third row of the periodic table. There is a great deal of literature dealing with relativistic effects on shielding calculations,^{14,15} but there are no well-established methods that can be used routinely. Moreover, most of the common approximations to take into account these effects have not been implemented in the most popular software used for shielding calculations. The calculation of shielding constants in molecules containing heavy atoms remains the realm of very specialized research groups.

The second methodological challenge in the calculation of NMR shielding is associated with the uncertainties in the molecular or crystalline geometry and the effects that the lattice may have on the NMR shielding constants. The first problem is a consequence of the great sensitivity of the shielding constants to the molecular geometry, a fact that has been known for some time.²³ While this sensitivity has been instrumental for using NMR chemical shift information to elucidate structural problems,²⁴ at the same time it can lead to unacceptably large errors in the calculated shielding constants due to the uncertainties in the position of hydrogen atoms observed in common structural methods such as X-ray. It has become common practice to optimize the position of the hydrogens atoms, determined by X-ray structures, before

Table 1 RMS error between calculated and experimental chemical shifts for different exchange correlation functionals^a

RMS	HF	LSDA	BPW91	BLYP	B3PW91	B3LYP	MP2
^{13}C	11.5	16.1	7.7	9.2	8.7	9.5	2.3

^aAll values are in ppm from Ref.¹⁹, calculated using the GIAO method with a qz2p basis set and MP2/tz2p geometries.

Table 2 Standard deviation between the experimental and Dunning D95 and D95** calculated ^{13}C chemical shifts in Methyl Bacteriopheophorbide^a

Geometry	D95		D95**	
	Exp.	Exp. (NA)	Exp.	Exp. (NA)
X-ray	14.7	8.1	–	–
H-optimized	12.8	4.0	13.0	4.0
Crystal Optimized	12.8	4.0	13.0	4.0
Molecular Optimized	12.9	4.1	13.1	4.0

^aValues in ppm from Ref.³⁴.

performing shielding calculations. The dramatic effect of this practice can be observed in the results presented in Table 2, the RMS between the calculated and experimental ^{13}C chemical shifts in methyl bacteriopheophorbide *a* decrease by a factor two, when the H-optimized structure is used in the shielding calculations.

Unfortunately, the practice of using optimized or partially optimized structures to calculate NMR shielding constants leads also to significant questions about possible cancellation of errors between the method used to optimize the geometry and the one used to calculate the NMR shielding constants. When using only the agreement between experimental and calculated NMR shielding constants as criteria for success, it is conceivable that good agreement could be achieved due to the use of a optimized geometry that underestimates the inter atomic bond distances, in conjunction with a method to calculate NMR shielding constants that also underestimates the shieldings or vice versa. Note that almost always $\partial\sigma/\partial r \leq 0$.²⁵ Comprehensive studies, including intermolecular effects (see below) and vibrational corrections, are needed to fully understand the interplay between geometry optimization and shielding calculations.

The inclusion of intermolecular effects in the calculation of shielding constants has attracted a great deal of attention over the years,²⁶ but no off the shelf methods are available to take into account these effects in the calculations. Unfortunately, in many cases the intermolecular interactions cannot be neglected without losing the quantitative agreement between experimental and calculated results (see below). In these situations it is necessary to exercise care and complement the standard methods available to calculate shielding constants with appropriate ways to take into account the intermolecular effects. A number of modern methods to address this issue are discussed in Section 4.4.

3 SOFTWARE AVAILABLE AND HARDWARE NEEDED FOR SHIELDING CALCULATIONS

Significant shielding calculations can be done using hardware and software commonly available in most structural chemical labs. With this in mind, it is important to provide a short account of the software available and the hardware necessary for NMR shielding calculations. In the next subsections we describe several of the most common software packages that can be used to calculate shielding constants and the typical hardware requirements for these calculations. The reader should notice that the software list is not comprehensive and that due to the rapidly evolving nature of the field it may become outdated shortly.

3.1 Gaussian98 Software

In terms of making shielding calculations available to a larger community of researchers, the most significant development has been the work by Cheesman et al.¹⁹ Using the framework of the CDFT (Coupled DFT) perturbation theory they implemented the calculation of shielding tensors in the popular Gaussian suite of programs.⁹ This implementation makes use of the techniques previously developed by Pulay and co-workers,⁴ to efficiently calculate the complex two electron integrals necessary to implement the GIAO formulation. This method has become the most popular tool to calculate shielding constants. A number of additional methods to calculate shielding constants have also been implemented in the Gaussian suite of programs. These include HF, DFT and MP2 electronic approximations as well as single origin, GIAO, IGAIM and CSGT methods to deal with the gauge origin problem.

3.2 Other Commonly Used Programs

In addition to the popular Gaussian suite of programs several well known programs provide capabilities to calculate shielding constants using different approximations. Some of common programs available for shielding calculations are:

ACESII (<http://www.qtp.ufl.edu/Aces2/>).²⁷ Analytically evaluated NMR shielding tensors are available at the SCF and MBPT(2) levels using gauge-including atomic orbitals (GIAOs) to ensure exact gauge-invariance.

CADPAC (<http://ket.ch.cam.ac.uk/software/cadpac.html>).²⁸ NMR shielding constants can be calculated using the LORG algorithm for the DFT and HF electronic approximations.

deMon (<http://www.sims.nrc.ca/sims/deMon/>).^{29,30} NMR shielding calculations using the DFT approximation within the SOS scheme described by Malkin.³⁰

NWChem (<http://www.emsl.pnl.gov:2080/docs/nwchem/nwchem.html>).³¹ Calculation of NMR shielding (GIAO method) for the HF electronic approximation using the coupled Hartree–Fock scheme. The implementation of these calculations using the DFT electronic approximation has been announced for a future release of this program.

It is important to realize that this is only a partial listing of computer programs capable of calculating NMR shielding constants. There are numerous other programs in many research groups with similar capabilities, but these tend to be

less supported and more difficult to use than those listed above. Also the reader should keep in mind that this field is changing rapidly and that the capability to calculate NMR shielding constants is becoming a standard feature of most molecular modeling software packages.

3.3 Hardware Necessary for Shielding Calculations

Modest shielding calculations, up to 10–20 non-hydrogen atoms, with a few hundreds of basis functions can be done in reasonable time using typical desktop computers. While these calculations cannot be done in an interactive fashion, overnight turn around for each shielding calculation is a reasonable expectation. If a geometry optimization of the system is necessary before performing the shielding calculation, this time may increase significantly depending on the quality and magnitude of the geometry optimization needed. Much larger calculations, involving of the order of 100 non-hydrogen atoms and more than one thousand basis functions are more suitable for large SMP (symmetric multi processors), Beowulf clusters or other parallel supercomputer systems. In general the software available for shielding calculations runs in parallel mode, but does not scale well with the number of processors. Very seldom more than 8–10 processors can be used effectively with the existing software. The better scalability performance of NWChem³² provides hope for improved scalability of shielding calculations when the DFT approach is implemented in this package.

4 CHEMICAL AND STRUCTURAL RESEARCH USING MODERN METHODS

This section gives a few examples of the author's work in which calculations of NMR shielding constants were used to address common problems in NMR spectroscopy and structural chemistry. It is important to realize that this is not a comprehensive review of this topic. There is considerably more work reported in this area than it is possible or even desirable to include in an encyclopedia article. Readers interested in specific applications and/or in gaining a detailed understanding of the field should consult the important reviews published in this field. These references are given in the introductory section of this article.

In Section 4.1 we discuss the issues associated with comparing calculated shielding constants with measured chemical shifts. In Section 4.2 we show an example on how to use shielding calculations to improve the experimental assignment of ¹³C resonances in methyl bacteriopheophorbide *a*. In Section 4.3 we show how modern techniques to calculate NMR shielding constants can be used to produce relatively large and consistent data sets of chemical shifts and how they can be used to gain insight into their classification. Finally in Section 4.4 we discuss some of the methods than can be used to take into account intermolecular/crystalline interactions.

4.1 Transforming Shieldings into Shifts

A significant complication to assess the quality of calculated shielding constants is the need for a reliable method to compare calculated and experimental values. NMR experiments provide

chemical shifts, i.e., the position of a resonance frequency with respect to the resonance frequency of an established standard. The quantum chemical calculations provide absolute shielding constants, i.e., the relative shift of the resonance with respect to the resonance frequency of the bare nucleus. In principle, if the absolute shielding is known for the standard used in the experimental determination of the shift, the calculated shielding constants can be compared with the experimental chemical shifts using the following equation:

$$\delta(\text{shift}) = -\sigma(\text{shielding}) + \sigma_{\text{Ref}}(\text{shielding}) \quad (1)$$

Note that in equation (1) there is an additional minus sign that has been introduced between the shift scale and the shielding scale. This change of sign is introduced to take into account that the chemical shift increases as the nucleus becomes more de-shielded, while the shielding decreases.

Unfortunately, the use of equation (1) is complicated by the lack of precise values for σ_{Ref} (shielding). Absolute values of the shielding of the most common standards have been determined using Flygare's³³ relationship between the spin-rotational constant and the paramagnetic contribution to the shielding calculated at the center of mass. Unfortunately, these values do not take into account the effects that thermal averaging and/or solvent (in liquids) or crystal lattice (in solids) interactions may have on the chemical shifts of the standards. Precise studies of chemical shifts associated with thermal averaging and lattice effects are only known for very few standards.

To address these referencing difficulties it is quite common to correlate the calculated shielding constants with the experimental shift values using a linear regression of the type

$$\delta^{\text{exp}}(\text{shift}) = -A\sigma^{\text{calc}}(\text{shielding}) + B \quad (2)$$

where *A* and *B* are constants determined by linear regression. The deviations of *A* from unity and *B* from the absolute value of the shielding of the reference standard give an indication of overall systematic errors in the calculations. Typically the deviations in *A* are an indication of the under or over estimation of the electronic correlation effects on the calculated shielding constants, while those in *B* are an indication of the uncertainties in the referencing process associated with thermal averaging and lattice effects.

4.2 Chemical Shifts Assignments

The assignment of NMR resonances has always been problematic and in spite of the great progress in using two-dimensional techniques for assignment purposes, these problems are still serious, particularly in solid state NMR. Calculations of shielding constants can provide additional information that can help in the assignment of experimental spectra.

A good example on how to use shielding calculations in aid to solve assignment problems was recently presented by Facelli in his study of methyl bacteriopheophorbide *a*.³⁴ The calculated chemical shift values, using the Dunning D95** basis set and the H-optimized geometry, are compared with the experimental values in Table 2 and their linear relationship plotted in Figure 2. A careful comparison between the calculated and experimental results shows that when

Figure 2 Correlation between the calculated and experimental ^{13}C chemical shifts in Methyl Bacteriopheophorbide *a*. Original assignments (a) and revised ones (b). All values are in ppm. (Reproduced with permission from Ref.³⁴)

Figure 3 Linear relationship between experimental (shifts) and calculated (shieldings) ^{13}C chemical shifts principal values in PAHs. All values are in ppm. (Reproduced with permission from Ref.³⁵)

using the literature assignments of the carbon resonances, the residuals for C_{11} , C_{13} , C_{12} , C_{14} , C_1 , C_5 , C_{17} and C_{16} are at least two times larger than the standard deviation of the linear fit. Moreover, these large residuals appear in pairs (see Figure 2) suggesting that the experimental values may have been incorrectly assigned. If these assignments are exchanged the standard deviation between the calculated and experimental values drops by a factor close to two for the optimized structures. From Table 2 it is also apparent that the improvement in the correlation is independent of the geometry and basis used in the calculations. This dramatic improvement,

observed when exchanging the experimental assignments for C_{11} , C_{13} , C_{12} , C_{14} , C_1 , C_5 , C_{17} and C_{16} , is depicted in the graph at the bottom of Figure 2, where it is shown that all the outliers in the correlation are eliminated when the new assignments are used.

4.3 Large Collections of Shielding Tensors: Hierarchical Cluster Analysis

The developments of the calculation of shielding constants described above allow researchers to tackle problems in novel

ways. For instance, an important problem in using chemical shift information to study complex substances, such as coals and soots, has been the lack of information on the amount of homogeneous broadening expected in the solid state spectra of these materials. It has been known for a long time that a carbon nucleus in a particular chemical environment has a chemical shift tensor with characteristic principal values, but very little quantitative information exists on how much variability exists in these values or how much overlap exists between the characteristic ranges for different chemical environments. Shielding calculations can help to address this problem by providing a practical method to assemble larger collections of data than those available from experiments.

A hierarchical cluster analysis of the principal values of ^{13}C chemical shift tensors encountered in polycyclic aromatic hydrocarbons (PAHs) has been done recently using calculated chemical shifts.³⁵ The analysis was performed using chemical

shift tensors calculated using the DFT (B3PW91) GIAO method, with a D95 basis set on optimized geometries obtained using the CVFF force field and the DISCOVER routine in MSI's InsightII package. The good correlation observed (see Figure 3) between the calculated and experimental values, when available, supports the use of the calculated values in the hierarchical cluster analysis. This analysis was performed for two data sets of increasing size and the classification was found independent of the size of the sample, leading to the conclusion that the results presented here are valid for all PAHs.

The classification of the tensors using the hierarchical cluster analysis produces classes of chemical shift principal values that can be associated with the intuitive classification of chemical types of carbons present in PAHs. Figure 4 presents the results of the hierarchical cluster analysis of all the ^{13}C chemical shift principal values included in the smaller data set (150 different sets of three chemical shift principal values).

Figure 4 Hierarchical cluster analysis of the ^{13}C chemical shift tensor principal values of PAHs. The hierarchy includes classifications using from one to seven clusters. The number in square brackets after the principal values is the standard deviation. Seven clusters is the number of significant clusters given by the “best cut” procedure. The seven classes can be associated with the following types of carbons: (I) C–H aromatic carbons, (II) C–H aromatic carbons that are subject to steric strain, (III) C–C_a aromatic carbons where C_a is an aliphatic carbon in a planar configuration, (IV) C–C_a aromatic carbons where C_a is an aliphatic carbon in a non-planar configuration, (V) bridgehead aromatic carbons attached to two six member rings and one five member ring (this is always a non-planar configuration), (VI) bridgehead aromatic carbons attached to three six member rings in a planar configuration, (VII) bridgehead aromatic carbons attached to three six member rings in a non-planar configuration. All values are in ppm. (Reproduced with permission from Ref.³⁵)

Figure 5 SSNMR ^{15}N Spectra of benzamide. Comparison with the experimental spectra of different simulations performed using ^{15}N chemical shifts calculated with different molecular models. This figure shows the dramatic effects of the HB interactions in the ^{15}N chemical shift tensor principal values

The figure presents the results for classifications including one to seven clusters, which is the maximum allowable number of clusters using the “best cut” method. The classification scheme also provides standard deviations within each class; these can be used as a measure of the inhomogeneous broadening expected for each characteristic NMR signal in complex mixtures of PAHs.

4.4 Intermolecular/Crystalline Effects

An active area of research in the theory of shielding calculations is the development of new methods to take into account intermolecular effects. While there is a long history of including these effects in NMR shielding calculations,³⁶ with the advent of new powerful computational methods for shielding calculations and new data from solid state NMR there has been an increased interest of reproducing the so called solid state effects. These effects, which originate in intermolecular interactions, are observed as changes in the resonance frequencies in the solid from those observed in liquids, as well as by duplication of spectral lines due to magnetic non-equivalences in the crystallographic cell. These magnetic non-equivalences are averaged, by molecular tumbling in liquid and gas phases,

and therefore not observed in the corresponding NMR spectra. Solid state effects have been observed and modeled in both ^{13}C and ^{15}N chemical shifts.^{37–40} For instance Figure 5 depicts the effects of including intermolecular effects, using the cluster method, in the calculation of the ^{15}N chemical shifts of benzamide.⁴⁰ It is apparent that the spectrum simulated using the ^{15}N chemical shift principal values calculated without including the intermolecular effects does not even resemble the experimental one. This is immediately corrected once these interactions are included in the calculations.

Crystalline effects are implicitly included in the calculation of molecular properties when the calculations are done using a formulation that includes periodic boundary conditions, the most common example of this technique can be found in the CRYSTAL98 program.⁴¹ Recently Mauri et al.^{42,43} have introduced a method to calculate NMR shielding constants in periodic systems, which of course includes implicitly all the intermolecular interactions. Unfortunately, this method has been implemented using the LDA approximation,²⁰ which reproduces chemical shifts with much less accuracy than hybrid functionals.¹⁹ To the author’s knowledge there has not been any implementation of a method to calculate shielding constants using periodic boundary conditions in a general

molecular simulation program like CRYSTAL98.⁴¹ Therefore, intermolecular effects must be explicitly modeled when using hybrid exchange correlation functionals in the calculation of chemical shifts.

Many approximate methods have been used to include these effects in *ab initio* molecular calculations. Currently, there are two general schemes to model intermolecular effects: (i) the cluster models and (ii) the charge point models. A detailed discussion of both schemes is available elsewhere.³⁶ The cluster model explicitly includes in the calculation of the shielding constants the neighboring molecules or some of their *significant fragments*.⁴⁴ The difficulties associated with this method arise from the selection of the *significant fragments*, which is somehow arbitrary, and the considerable increase in the computational resources needed when large fragments are added to the calculations. Charge models, which describe the intermolecular effects by a discrete distribution of point charges, are very attractive because they derive from a very simple idea: the crystalline electrostatic potential can be represented by a finite distribution of point charges. The great advantage of these models is that the cost of shielding calculations does not significantly increase when a distribution of point charges is added to the system. Note also, that most of the existing programs to calculate NMR shielding constants have build-in capabilities to include a distribution of point charges in their calculation. The charges used in the calculations can be derived from simple population analysis methods⁴⁵ or from more elaborate methods that may adjust them to electrostatic potentials that mimic either the molecular or crystalline (Madelung) electrostatic potentials. In general the methods that attempt to use charges derived from electrostatic potentials obtained by *ab initio* calculations produce better results.⁴⁶ For instance, Facelli and Ferraro have used Troung's surface charge representation of the electrostatic embedding potential (SCREEP) method,⁴⁷ which attempts to reproduce the Madelung potential by a charge distribution on a van der Waals surface surrounding the molecule of interest. Grant and co-workers⁴⁸ have used a similar approach to calculate ¹³C chemical shifts in thiocarbonates using the method proposed by Derenzo et al.⁴⁹ to calculate the Madelung potential.

In liquids intermolecular effects have been taken into account by using continuous models,⁵⁰ molecular dynamics simulations⁵¹ and thermo dynamical averaging techniques.⁵²

5 CONCLUSIONS

This article shows that by using tools, hardware and software, typically available to most researchers in the areas of NMR spectroscopy and/or structural chemistry it is possible to perform meaningful calculations of NMR shielding constants. While there are still unresolved problems with these calculations, like relativistic effects in molecules containing heavy nuclei and systematic treatments of intermolecular effects, there is a large number of systems in which these calculations can be used routinely to solve important structural problems or to elucidate issues of molecular electronic structure.

Several examples of the use of calculated shielding constants in aid to solve common problems encountered in NMR spectroscopy and structural chemistry were used to illustrate how useful these calculations can be.

1 INTRODUCTION

Powerful ad hoc computational approaches are available to predict NMR chemical shifts for medium and large molecules (see *Shielding Calculations: LORG and SOLO Approaches*; *Shielding Calculations: IGLO Method*, and Pulay et al.¹). These methods yield theoretical estimates in reasonably good agreement with experiment, and are useful to rationalize trends, to check the reliability of measured values, etc. The aims of calculations on small molecules, based upon general quantum mechanical procedures, are somewhat different: the main emphasis is placed in understanding physical facts and determining, fully a priori, the exact value of absolute quantities, namely, nuclear magnetic shieldings; the quality of the theoretical predictions is not established by mere comparison with corresponding experimental data, which might be misleading in a number of cases. More exactly, yardsticks of accuracy are sought as by-products of the calculation, by evaluating related properties, namely magnetic susceptibility, quantum mechanical sum rules and constraints, upper and lower bounds, limiting values of the computational scheme based on a given approximation (e.g., the Hartree–Fock method), etc. In this article, after a short overview showing the limits of a classical approach to the shielding mechanism, we shall examine fully theoretical procedures enabling us to assess the accuracy of nuclear magnetic shielding predicted via approximate wavefunctions, independently of comparison with experimental values. The tests of accuracy rely on conditions for origin independence or, more generally, invariance under a gauge transformation of the electromagnetic potentials and associated canonical transformations of the electronic Hamiltonian, conditions for charge conservation, hypervirial theorems, etc. Although the main interest lies in theoretical determination of nuclear shieldings for a molecule in a spatially uniform and time-independent magnetic field, the more general case of a molecule responding linearly to harmonic perturbations is also examined, by introducing the Bloch gauge and the magnetic multipole Hamiltonian.^{2,3}

The methods described in this article provide rigorous constraints and severe tests of quality for electronic wavefunctions. Although they are based on very general relationships,

valid for any quantum mechanical system, practical applications are presently restricted to small molecules, for which accurate variational wavefunctions are available.

1.1 Magnetic Shielding in Classical Electrodynamics

Let us consider an electrically neutral molecule with N nuclei and an even number n of electrons, with mass m_e , smeared out with charge density $\rho(\mathbf{r}) = -e\gamma(\mathbf{r})$, a function of position $\mathbf{r}$ within the molecular domain. Systems of this type are symmetric under time reversal, and, except a few cases, diamagnetic: an external magnetic field $\mathbf{B}$, supposed, for simplicity, static and homogeneous, induces within the electron cloud an average orbital magnetic moment with a component $\langle \mathbf{m} \rangle$ antiparallel to $\mathbf{B}$. According to the Ampère and Larmor theorems of classical electrodynamics, this orbital moment arises from an induced electronic current density (in agreement with the Lenz law, the electron flow is in a direction such as to oppose the external field)

$$\mathbf{J}_L^B(\mathbf{r}) = -\frac{e^2}{m_e c} \gamma(\mathbf{r}) \mathbf{A}(\mathbf{r}) \quad (1)$$

where $\mathbf{A}$ is the vector potential associated with $\mathbf{B}$, in the Coulomb gauge,

$$\mathbf{B} = \nabla \times \mathbf{A}, \quad \nabla \cdot \mathbf{A} = 0, \quad \mathbf{A} = \frac{1}{2} \mathbf{B} \times \mathbf{r} \quad (2)$$

The stationary field generated at a point $\mathbf{r}_0$ by the Larmor precession is given by the Biot–Savart law

$$\mathbf{B}_L(\mathbf{r}_0) = \frac{1}{c} \int d^3r \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|^3} \times \mathbf{J}_L^B(\mathbf{r}) = -\sigma_L(\mathbf{r}_0) \cdot \mathbf{B} \quad (3)$$

where $\mathbf{r}$ is the distance of the volume element $d\mathbf{r}$ from the origin, so that the local effective field is

$$\mathbf{B}(\mathbf{r}_0) = \mathbf{B} + \mathbf{B}_L(\mathbf{r}_0) = [\mathbf{1} - \sigma_L(\mathbf{r}_0)] \cdot \mathbf{B} \quad (4)$$

The magnetic shielding arising at $\mathbf{r}_0$, from the electron circulation is described by the tensor

$$\sigma_L(\mathbf{r}_0) = \frac{e^2}{2m_e c^2} \int d^3r \gamma(\mathbf{r}) \left(\mathbf{r} \cdot \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|^3} \mathbf{1} - \mathbf{r} \frac{\mathbf{r} - \mathbf{r}_0}{|\mathbf{r} - \mathbf{r}_0|^3} \right) \quad (5)$$

The average shielding of a point at the origin of coordinates is connected with the scalar potential due to the electron cloud,

$$\frac{1}{3} \text{Tr}[\sigma_L(\mathbf{0})] = -\frac{e}{3m_e c^2} \phi(\mathbf{0}), \quad \phi(\mathbf{0}) = -e \int d^3r \gamma(\mathbf{r}) \frac{1}{r} \quad (6)$$

The first-order magnetic moment arising from the Larmor currents,

$$\langle \mathbf{m}_L \rangle = \frac{1}{2c} \int d^3r \mathbf{r} \times \mathbf{J}_L^B = \chi_L \cdot \mathbf{B} \quad (7)$$

and its second-order interaction energy with the magnetic field,

$$W_L^{BB} = -\frac{1}{2} \langle \mathbf{m}_L \rangle \cdot \mathbf{B} = -\frac{1}{2c} \int d^3r \mathbf{r} \cdot \mathbf{J}_L^B = -\frac{1}{2} \mathbf{B} \cdot \chi_L \cdot \mathbf{B} \quad (8)$$

are expressed via the Langevin magnetic susceptibility

$$\chi_L = -\frac{e^2}{4m_e c^2} \int d^3r \gamma(\mathbf{r}) (r^2 \mathbf{1} - \mathbf{r} \mathbf{r}) \quad (9)$$

2 SHIELDING IN SMALL MOLECULES

Using equation (4), the energy of interaction between an intrinsic magnetic dipole μ_I on nucleus I , at $\mathbf{R}_I$, and the local effective magnetic field is

$$-\mu_I \cdot \mathbf{B}(\mathbf{R}_I) = -\mu_I \cdot \mathbf{B} + \mu_I \cdot \sigma_L^I \cdot \mathbf{B}, \quad \sigma_L^I \equiv \sigma_L(\mathbf{R}_I) \quad (10)$$

where σ_L^I is a tensor describing Larmor shielding of nucleus I . From equation (3) and the expression for the vector potential at $\mathbf{r}$ due to the nuclear dipole,

$$\mathbf{A}^{\mu_I} = \mu_I \times \frac{\mathbf{r} - \mathbf{R}_I}{|\mathbf{r} - \mathbf{R}_I|^3} \quad (11)$$

one obtains the energy of interaction between the nuclear dipole and the local stationary magnetic field arising from the Larmor currents:

$$\mu_I \cdot \sigma_L^I \cdot \mathbf{B} \equiv W_L^{\mu_I B} = -\frac{1}{c} \int d^3r A^{\mu_I} \cdot \mathbf{J}_L^B = -\mu_I \cdot \mathbf{B}_L(\mathbf{R}_I) \quad (12)$$

An obvious ‘interchange theorem’ holds, i.e.,

$$W_L^{\mu_I B} = -\frac{1}{c} \int d^3r A \cdot \mathbf{J}_L^{\mu_I} = -\langle \mathbf{m}_L^I \rangle \cdot \mathbf{B}, \quad \langle \mathbf{m}_L^I \rangle \equiv -\mu_I \cdot \sigma_L^I \quad (13)$$

introducing the Larmor-type current density induced by the nuclear magnetic dipole within the electron distribution:

$$\mathbf{J}_L^{\mu_I}(\mathbf{r}) = -\frac{e^2}{m_e c} \gamma(\mathbf{r}) \mathbf{A}^{\mu_I}(\mathbf{r}) \quad (14)$$

According to an alternative interpretation to that provided by equation (12), this result accounts for the energy of interaction between the external magnetic field and an average orbital magnetic dipole moment induced within the electron cloud by the nuclear moment.

Classical electrodynamics is unable to describe paramagnetic contributions: quantum mechanical methods given below are necessary to understand these.

2 ELECTRONIC HAMILTONIANS FOR A MOLECULE IN AN ELECTROMAGNETIC FIELD

2.1 Gauge Transformations

Let us consider a charge distribution $\rho(\mathbf{r}, t)$, flowing with local velocity $\mathbf{v}(\mathbf{r}, t)$. The condition for charge conservation is, in component form (with $\alpha = 1, 2, 3$),

$$\nabla_\alpha J_\alpha + \frac{\partial \rho}{\partial t} = 0, \quad J_\alpha = \rho v_\alpha \quad (15)$$

Note that here and in what follows, the Einstein summation convention is adopted, i.e., a summation over pairs of repeated indices is implied: $\nabla_\alpha J_\alpha \equiv \sum_{\alpha=1}^3 \nabla_\alpha J_\alpha$. According to the Maxwell equations, the electromagnetic field can be described by introducing scalar and vector potentials $\phi(\mathbf{r}, t)$ and $\mathbf{A}_\alpha(\mathbf{r}, t)$:

$$\mathbf{B}_\alpha = \epsilon_{\alpha\beta\gamma} \nabla_\beta A_\gamma, \quad E_\alpha = -\nabla_\alpha \phi - \frac{1}{c} \frac{\partial A_\alpha}{\partial t} \quad (16)$$

These potentials are defined to within a gauge transformation, leaving the fields and the Maxwell equations invariant, induced

by an arbitrary continuous function $f = f(\mathbf{r}, t)$ tending smoothly to 0 at infinity:

$$A_\alpha \rightarrow A'_\alpha = A_\alpha + \nabla_\alpha f, \quad \phi \rightarrow \phi' = \phi - \frac{1}{c} \frac{\partial f}{\partial t} \quad (17)$$

The classical Lagrangian for one electron in an electromagnetic field is a sum of ‘particle’ and ‘interaction’ terms:

$$L = L_c + L_1, \quad L_c = \frac{1}{2} m_e \dot{\mathbf{r}}^2, \quad L_1 = e\phi(\mathbf{r}, t) - \frac{e}{c} \dot{\mathbf{r}}_\alpha A_\alpha(\mathbf{r}, t) \quad (18)$$

A change of gauge yields an equivalent Lagrangian

$$L \rightarrow L' = L + \frac{dg}{dt}, \quad \frac{dg}{dt} = \dot{\mathbf{r}}_\alpha \nabla_\alpha g + \frac{\partial g}{\partial t}, \quad g = -\frac{e}{c} f \quad (19)$$

but does not affect the Lagrange equation of motion

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{\mathbf{r}}_\alpha} - \frac{\partial L}{\partial \mathbf{r}_\alpha} = 0 \quad (20)$$

Assuming that the electron is spread out with density ρ , and flows with current density $\mathbf{J}_\alpha$,

$$\rho(\mathbf{R}, t) = -e\delta[\mathbf{R} - \mathbf{r}(t)], \quad \mathbf{J}_\alpha(\mathbf{R}, t) = -e\dot{\mathbf{r}}_\alpha(t)\delta[\mathbf{R} - \mathbf{r}(t)] \quad (21)$$

satisfying equation (15), an interaction Lagrangian density can be defined by

$$\mathcal{L}_1 = -\rho(\mathbf{R}, t)\phi(\mathbf{R}, t) + \frac{1}{c} \mathbf{J}_\alpha(\mathbf{R}, t) \mathbf{A}_\alpha(\mathbf{R}, t), \quad L_1 = \int \mathcal{L}_1 d^3R \quad (22)$$

which, under a gauge transformation given by equation (17), where $f = f(\mathbf{R}, t)$, transforms as

$$\begin{aligned} \mathcal{L}_1 \rightarrow \mathcal{L}'_1 &= \mathcal{L}_1 + \frac{1}{c} \left(\rho \frac{\partial f}{\partial t} + \mathbf{J}_\alpha \nabla_\alpha f \right) \\ &= \frac{1}{c} \left[\frac{\partial}{\partial t} (\rho f) + \nabla_\alpha (\mathbf{J}_\alpha f) - f \left(\frac{\partial \rho}{\partial t} + \nabla_\alpha \mathbf{J}_\alpha \right) \right] \end{aligned} \quad (23)$$

where the last contribution vanishes owing to the continuity constraint, equation (15). Integrating over all space, the second contribution, owing to the Gauss theorem, gives a surface integral vanishing for the boundary conditions on $\mathbf{J}_\alpha$ and f , and one is left with a total time derivative, i.e., with an equivalent Lagrangian, equation (19), and the same equation of motion, equation (20): charge-current conservation is a necessary condition for gauge invariance of the equation of motion.

The classical Hamiltonian is defined via the mechanical momentum,

$$h = \dot{\mathbf{r}}_\alpha p_\alpha - L = \frac{1}{2m_e} \pi_\alpha \pi_\alpha - e\phi, \quad \pi_\alpha = p_\alpha + \frac{e}{c} A_\alpha \quad (24)$$

Under a change of gauge, the classical dynamical variables in equation (24) transform as

$$\begin{aligned} p_\alpha &= \frac{\partial L}{\partial \dot{\mathbf{r}}_\alpha} \rightarrow p'_\alpha = \frac{\partial L'}{\partial \dot{\mathbf{r}}_\alpha} = p_\alpha + \nabla_\alpha g \\ h' &= \dot{\mathbf{r}}_\alpha p'_\alpha - L' = h - \frac{\partial g}{\partial t} \end{aligned} \quad (25)$$

2.2 Canonical Transformations

Some problems arise when the Hamiltonian is quantized, since the canonical momentum operator $-i\hbar\nabla_\alpha$ corresponds to different classical variables in unprimed and primed representations: the transformed quantum Hamiltonian is not obtained via equation (25). Therefore let us define ‘particle’ and ‘interaction’ operators

$$\begin{aligned}\hat{h}^{(0)} &= \frac{1}{2m_e} \hat{p}^2 \\ \hat{h}^{(1)} + \frac{1}{2}\hat{h}^{(2)} &= \frac{e}{2m_e c} (A_\alpha \hat{p}_\alpha + \hat{p}_\alpha A_\alpha) + \frac{e^2}{2m_e c^2} A_\alpha A_\alpha - e\phi\end{aligned}\quad (26)$$

Under a change of gauge, the mechanical momentum undergoes a similarity transformation induced by a unitary operator,

$$\hat{\pi}_\alpha \rightarrow \hat{\pi}'_\alpha = \hat{\pi}_\alpha - \nabla_\alpha \hat{g} \equiv \hat{Q} \hat{\pi}_\alpha \hat{Q}^\dagger, \quad \hat{Q} = \exp\left(\frac{i}{\hbar} \hat{g}\right) \quad (27)$$

Owing to the transformations given by equations (17) and (27), different equivalent Hamiltonians can be used for an electron in the electromagnetic field. Allowing for a class of gauge function wider than that retained in equation (19), i.e., $\hat{g} = \hat{g}(\mathbf{r}, \mathbf{p}, \mathbf{A}, \phi)$, a transformed quantum mechanical Hamiltonian will have the general form

$$\hat{h}' = i\hbar \left(\frac{\partial \hat{Q}}{\partial t} \right) \hat{Q}^\dagger + \hat{Q} \hat{h} \hat{Q}^\dagger \quad (28)$$

As the generating function depends on the canonical momentum, the transformation to the new Hamiltonian is not accompanied by a change, equation (19), of the Lagrangian. In addition, the operators $\hat{g}$ and $\partial\hat{g}/\partial t$ do not generally commute (although we shall limit ourselves to transformations where $[\hat{g}, \partial\hat{g}/\partial t] = 0$ hereinafter). Under a transformation, equation (17), changing the one-electron wavefunction consistently with equation (28), the Schrödinger equation is invariant:

$$\psi \rightarrow \psi' = \hat{Q} \psi, \quad \hat{h}' \psi' = i\hbar \frac{\partial}{\partial t} \psi' \quad (29)$$

Using the quantum mechanical definition of total time derivative,

$$\frac{d\hat{g}}{dt} = \frac{i}{\hbar} [\hat{h}^{(0)}, \hat{g}] + \frac{\partial \hat{g}}{\partial t} \quad (30)$$

and the Hausdorff formula, to second order in $\hat{g}$, one obtains

$$\hat{h}' = \hat{h} - \frac{d\hat{g}}{dt} + \frac{i}{\hbar} [\hat{g}, \hat{h}^{(1)}] + \frac{1}{2} \left(\frac{i}{\hbar} \right)^2 [\hat{g}, [\hat{g}, \hat{h}^{(0)}]] \quad (31)$$

An alternative first-order Hamiltonian is obtained by choosing $\hat{g}$ so that

$$\hat{h}^{(1)} = \frac{\partial \hat{g}}{\partial t}, \quad \hat{h}'^{(1)} = \hat{h}^{(1)} - \frac{d\hat{g}}{dt} = -\frac{i}{\hbar} [\hat{h}^{(0)}, \hat{g}] \quad (32)$$

In practice, the gauge transformations that have been studied so far amount merely to a change of origin of the coordinate system for a molecule in the presence of a spatially uniform and time-independent magnetic field:

$$r'_\alpha \rightarrow r''_\alpha = r'_\alpha + d_\alpha, \quad A'_\alpha \rightarrow A''_\alpha = A'_\alpha + d_\beta \nabla_\alpha A'_\beta \quad (33)$$

$$f = -\frac{1}{2} \epsilon_{\alpha\beta\gamma} (r_\alpha - r'_\alpha) B_\beta d_\gamma \equiv A'_\gamma d_\gamma, \quad g \equiv -\frac{e}{c} A'_\alpha d_\alpha \quad (34)$$

Much more general choices for the gauge function f can, of course, be made. Three changes of gauge of the electromagnetic potentials will be outlined here:

1. the Bloch transformation;
2. the Landau transformation;
3. the canonical transformation leading to the torque formalism.

2.3 The Bloch Potentials

The MacLaurin series for the electric and magnetic fields, e.g.,

$$B(\mathbf{r}, t)_\alpha = \sum_{k=0}^{\infty} \frac{1}{k!} r_{\alpha_1} r_{\alpha_2} \cdots r_{\alpha_k} B(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \cdots \alpha_1 \alpha} \quad (35)$$

(where

$$B(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \cdots \alpha_1 \alpha} \equiv \left[\frac{\partial^k B(\mathbf{r}, t)_\alpha}{\partial r_{\alpha_k} \partial r_{\alpha_{k-1}} \cdots \partial r_{\alpha_1}} \right]_{\mathbf{r}=\mathbf{0}} \quad (36)$$

etc. denote the partial derivatives with respect to coordinates, at the origin), are not compatible with the analogous power expansions for vector and scalar potentials, which would not satisfy the equations for the fields, equation (16). Therefore, following Bloch,^{2,3} one carries out a transformation, equation (17), where

$$f^B(\mathbf{r}, t) = - \sum_{k=1}^{\infty} \frac{1}{k!} r_{\alpha_1} r_{\alpha_2} \cdots r_{\alpha_k} A(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \cdots \alpha_1} \quad (37)$$

The new potentials satisfying equation (16) are

$$\begin{aligned}A^B(\mathbf{r}, t)_\alpha &= \sum_{k=0}^{\infty} \frac{k+1}{(k+2)!} \epsilon_{\alpha\beta\gamma} r_\gamma r_{\alpha_1} r_{\alpha_2} \cdots \\ &\quad \times r_{\alpha_k} B(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \cdots \alpha_1 \beta}\end{aligned}\quad (38)$$

$$\phi^B(\mathbf{r}, t) = - \sum_{k=0}^{\infty} \frac{1}{(k+1)!} r_\alpha r_{\alpha_1} r_{\alpha_2} \cdots r_{\alpha_k} E(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \cdots \alpha_1 \alpha} \quad (39)$$

For a static electric field, one has $A^B_{\alpha\alpha} = 0$ cf. the condition defining the Coulomb gauge, $A^C_{\alpha\alpha} = 0 = \phi$, in a static homogeneous magnetic field.

The Bloch gauge is particularly useful, since it leads to a natural definition for the multipolar Hamiltonian adopted hereinafter to describe the properties of a molecule in a nonuniform time-dependent electromagnetic field.³

2.4 The Landau Gauge

Let us denote by A^C_α the vector potential in the Coulomb gauge, equation (2). The divergenceless Landau gauge² is obtained via the transformation

$$A^L_\alpha = A^C_\alpha + \nabla_\alpha f^L = B_\beta r_\gamma, \quad f^L(\mathbf{r}) = \frac{1}{2} (B_x yz + B_y zx + B_z xy) \quad (40)$$

(α , β , and γ are any cyclic permutations of x , y , and z). The one-electron Hamiltonian in the Landau gauge, $\hat{h}_L$, is obtained

with a transformation of the Coulomb Hamiltonian based on equation (40). From equation (26),

$$\hat{h}_C \rightarrow \hat{h}_L = \hat{h}^{(0)} + \hat{h}_L^{(1)} + \frac{1}{2}\hat{h}_L^{(2)} \quad (41)$$

$$\hat{h}_L^{(1)} = \frac{e}{m_e c} A_\alpha^L \hat{p}_\alpha = \frac{e}{m_e c} (B_y z \hat{p}_x + B_z x \hat{p}_y + B_x y \hat{p}_z) \quad (42)$$

$$\hat{h}_L^{(2)} = \frac{e^2}{m_e c^2} A_\alpha^L A_\alpha^L = \frac{e^2}{m_e c^2} (B_x^2 y^2 + B_y^2 x^2 + B_z^2 x^2) \quad (43)$$

A transformation of the origin [cf. equation (33)] can be thought of as a change of gauge of the Landau vector potential:

$$A_\alpha^L \rightarrow A_\alpha'^L = A_\alpha^L + \nabla_\alpha \mathbb{L}, \quad \mathbb{L} = -(B_y d_z x + B_z d_x y + B_x d_y z) \quad (44)$$

2.5 The One-Electron Torque Hamiltonian

Instead of using the potentials ϕ and A_α , one seeks an alternative representation of the electromagnetic field introducing Hertz–Righi polarization potentials.² Adopting the Nisbet gauge² for the electric Hertz vector $\mathbf{Z}$,

$$\phi(\mathbf{r}, t) = -\nabla_\alpha Z_\alpha(\mathbf{r}, t) = 0, \quad A_\alpha(\mathbf{r}, t) = \frac{1}{c} \frac{\partial}{\partial t} Z_\alpha(\mathbf{r}, t) \quad (45)$$

The one-electron Hamiltonian within the torque formalism^{2,4} is obtained according to equation (32). Through first order in the magnetic field,

$$\hat{g}^{(\nabla \times \mathbf{Z})_0} = \frac{e}{2m_e c^2} \epsilon_{\alpha\beta\gamma} \nabla_\beta Z_\gamma(\mathbf{0}, t) \hat{l}_\alpha \quad (46)$$

$$\hat{h}^{(1)} = \frac{e}{2m_e c} B_\alpha(\mathbf{0}, t) \hat{l}_\alpha \equiv \frac{\partial}{\partial t} \hat{g}^{(\nabla \times \mathbf{Z})_0} \quad (47)$$

introducing $\hat{k}_\alpha$, the torque about the origin on the unperturbed electron, and a reduced one-electron operator:

$$\hat{h}_\alpha^{(\nabla \times \mathbf{Z})_0} = -\frac{e}{2m_e c^2} \hat{k}_\alpha, \quad \hat{k}_\alpha = \frac{d\hat{l}_\alpha}{dt} = \frac{i}{\hbar} [\hat{h}^{(0)}, \hat{l}_\alpha] \quad (48)$$

2.6 Electronic Hamiltonians

Let the n electrons in a molecule be assigned coordinate vectors $\mathbf{r}_i$, canonical momenta $\hat{\mathbf{p}}_i = -i\hbar \nabla_i$, and angular momenta $\hat{\mathbf{l}}_i = \mathbf{r}_i \times \hat{\mathbf{p}}_i$ ($i = 1, 2, \dots, n$). The corresponding quantities for the N nuclei are $Z_I e$, M_I , $\mathbf{R}_I$, etc. In the absence of any perturbation, the electronic states of the molecule are the eigenfunctions $|j\rangle$ of the unperturbed Born–Oppenheimer Hamiltonian

$$\hat{H}^{(0)} = \sum_{i=1}^n \left[\frac{\hat{p}_i^2}{2m_e} - \sum_{I=1}^N \frac{Z_I e^2}{|\mathbf{r}_i - \mathbf{R}_I|} + \frac{1}{2} \sum_{j \neq i}^n \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} \right] + \frac{1}{2} \sum_{I=1}^N \sum_{J \neq I}^N \frac{Z_I Z_J e^2}{|\mathbf{R}_I - \mathbf{R}_J|} \quad (49)$$

i.e., $\hat{H}^{(0)}|j\rangle = E_j^{(0)}|j\rangle$. In the presence of an electromagnetic field with potentials $\mathbf{A}_i \equiv \mathbf{A}(\mathbf{r}_i, t)$ and $\phi_i \equiv \phi(\mathbf{r}_i, t)$, the interaction Hamiltonian is

$$\hat{V} = \sum_{i=1}^n \left[\frac{e}{2m_e c} (\mathbf{A}_i \cdot \hat{\mathbf{p}}_i + \hat{\mathbf{p}}_i \cdot \mathbf{A}_i) + \frac{e^2}{2m_e c^2} A_i^2 - e\phi_i \right] \quad (50)$$

In the Bloch gauge, to first order in the fields and their derivatives,³

$$\hat{H}^{(1)} = - \sum_{k=0}^{\infty} [E(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \dots \alpha_1 \alpha} \hat{\mu}_{\alpha \alpha_1 \alpha_2 \dots \alpha_k} + B(\mathbf{0}, t)_{\alpha_k \alpha_{k-1} \dots \alpha_1 \alpha} \hat{m}_{\alpha \alpha_1 \alpha_2 \dots \alpha_k}] \quad (51)$$

where, using Bloch normalization, the unperturbed magnetic multipole operators can be written (omitting contributions from electron spin) as,

$$\hat{m}_{\alpha \alpha_1 \dots \alpha_k} = - \frac{k+1}{(k+2)!} \frac{e}{2m_e c} \times \sum_{i=1}^n (\hat{l}_\alpha r_{\alpha_1} \dots r_{\alpha_k} + r_{\alpha_1} \dots r_{\alpha_k} \hat{l}_\alpha)_i. \quad (52)$$

If two indices are equal, $\hat{m}_{\alpha\alpha} = 0 = \hat{m}_{\alpha\alpha\beta\dots}$, etc. The contributions provided by A_i^2 in equation (50) are accounted for by defining ‘perturbed’ multipoles

$$\hat{m}'_\alpha = \hat{m}_\alpha + \hat{\chi}_{\alpha\beta}^d B(\mathbf{0}, t)_\beta + \hat{\chi}_{\alpha\beta;\gamma}^d B(\mathbf{0}, t)_{\gamma\beta} + \hat{\chi}_{\alpha\beta;\gamma\delta}^d B(\mathbf{0}, t)_{\delta\gamma\beta} + \hat{\chi}_{\alpha\beta;\gamma\delta\epsilon}^d B(\mathbf{0}, t)_{\epsilon\delta\gamma\beta} + \dots \quad (53a)$$

$$\hat{m}'_{\alpha\beta} = \hat{m}_{\alpha\beta} + \hat{\chi}_{\alpha\gamma;\beta}^d B(\mathbf{0}, t)_\gamma + \frac{16}{9} \hat{\chi}_{\alpha\gamma;\beta\delta}^d B(\mathbf{0}, t)_{\delta\gamma} + \frac{5}{2} \hat{\chi}_{\alpha\gamma;\beta\delta\epsilon}^d B(\mathbf{0}, t)_{\epsilon\delta\gamma} + \dots \quad (53b)$$

where the following auxiliary tensors have been introduced:

$$\hat{\chi}_{\alpha\beta}^d = - \frac{e^2}{4m_e c^2} \sum_{i=1}^n (r_v^2 \delta_{\alpha\beta} - r_\alpha r_\beta)_i \quad (54)$$

$$\hat{\chi}_{\alpha\beta;\gamma}^d = - \frac{e^2}{6m_e c^2} \sum_{i=1}^n [(r_v^2 \delta_{\alpha\beta} - r_\alpha r_\beta) r_\gamma]_i \quad (55)$$

$$\hat{\chi}_{\alpha\beta;\gamma\delta}^d = - \frac{e^2}{16m_e c^2} \sum_{i=1}^n [(r_v^2 \delta_{\alpha\beta} - r_\alpha r_\beta) r_\gamma r_\delta]_i \quad (56)$$

etc., (symmetric indices separated by a semicolon can be freely permuted).

The torque formalism [cf. equations (47) and (48)], is easily generalized to define an alternative first-order n -electron Hamiltonian. The operator for the torque exerted by the nuclei on the electrons (about the origin $\mathbf{r}_0$) is

$$\hat{\mathbf{K}}_n^N = \sum_{I=1}^N \sum_{i=1}^n \hat{\mathbf{K}}_i^I, \quad \hat{\mathbf{K}}_i^I(\mathbf{r}_0) = e^2 Z_I \frac{\mathbf{r}_i - \mathbf{R}_I}{|\mathbf{r}_i - \mathbf{R}_I|^3} \times (\mathbf{R}_I - \mathbf{r}_0) \quad (57)$$

and the n -electron ‘reduced Hamiltonian’ [cf. equation (48)], is

$$\sum_{i=1}^n \hat{h}_{i\alpha}^{(\nabla \times \mathbf{Z})_0} = - \frac{e}{2m_e c^2} \hat{\mathbf{K}}_{n\alpha}^N \quad (58)$$

The torque Hamiltonian, equation (47), depends on time: time-dependent perturbation theory must be used to describe the magnetic properties in the torque formalism—even for static fields.

In the presence of a nuclear magnetic dipole $\boldsymbol{\mu}_I$, the terms $-\boldsymbol{\mu}_I \cdot \hat{\mathbf{B}}_{I\alpha}^n$ and

$$\hat{H}^{(11)} = \frac{e^2}{m_e c^2} \sum_{i=1}^n (A_\alpha A_\alpha^{\mu I})_i, \quad A_{i\alpha}^{\mu I} = \frac{1}{e} \epsilon_{\alpha\beta\gamma} \mu_{I\beta} \hat{E}_{I\gamma}^i \quad (59)$$

must be added to the Hamiltonian of equation (50). In equation (59) the vector potential, equation (11), has been expressed via the operator for the electric field of electron i on nucleus I ,

$$\hat{E}_{I\alpha}^i = e \frac{r_{i\alpha} - R_{I\alpha}}{|\mathbf{r}_i - \mathbf{R}_I|^3} \quad (60)$$

and the operator for the magnetic field of the electrons on nucleus I in the absence of an external perturbation is

$$\hat{B}_{I\alpha}^n = -\frac{e}{mc_e} \hat{M}_{I\alpha}^n, \quad \hat{M}_{I\alpha}^n = \frac{1}{e} \epsilon_{\alpha\beta\gamma} \sum_{i=1}^n E_{I\beta}^i \hat{p}_{i\gamma} \quad (61)$$

From equations (38) and (59), in nonuniform fields, the perturbed operator is

$$\begin{aligned} \hat{B}_{I\alpha}^n &= \hat{B}_{I\alpha}^n - \hat{\sigma}_{\alpha,\beta}^{dI} B(\mathbf{0}, t)_\beta - \hat{\sigma}_{\alpha,\beta\gamma}^{dI} B(\mathbf{0}, t)_{\gamma\beta} \\ &\quad - \hat{\sigma}_{\alpha,\beta\gamma\delta}^{dI} B(\mathbf{0}, t)_{\delta\gamma\beta} + \dots \end{aligned} \quad (62)$$

where a comma separates the index for a component of the nuclear magnetic moment and a group of indices relative to the magnetic field and its spatial derivatives. The first two operators for the diamagnetic contributions to nuclear shielding are defined by

$$\hat{\sigma}_{\alpha,\beta}^{dI} = \frac{e}{2m_e c^2} \sum_{i=1}^n (r_{i\lambda} \hat{E}_{I\lambda}^i \delta_{\alpha\beta} - r_{i\alpha} \hat{E}_{I\beta}^i) \quad (63)$$

$$\hat{\sigma}_{\alpha,\beta\gamma}^{dI} = \frac{e}{3m_e c^2} \sum_{i=1}^n (r_{i\lambda} \hat{E}_{I\lambda}^i \delta_{\alpha\beta} - r_{i\alpha} \hat{E}_{I\beta}^i) r_{i\gamma} \quad (64)$$

3 LINEAR RESPONSE IN MAGNETIC FIELDS

We shall be interested in the average values, formally correct to first order in the perturbing field and its spatial derivatives, of the operators in equations (53) and (62), which themselves involve the perturbation, over the time-dependent perturbed state. Representing the external perturbation as a monochromatic plane wave with frequency ω , and denoting the electronic transition (natural) frequencies by $\omega_{ja} = \hbar^{-1}(E_j^{(0)} - E_a^{(0)})$, one obtains a formula for the expectation value² where the first-order Hamiltonian is expressed in an arbitrary formalism: the response properties obtained corresponding to a different $\hat{H}^{(1)}$ will be the same if the kets $|j\rangle$ are exact eigenvectors of the (model) $\hat{H}^{(0)}$. This equivalence can be checked by means of the off-diagonal Ehrenfest, or hypervirial, relations [a consequence of the definition in equation (30)]

$$\langle a | \hat{R}_\alpha | j \rangle = \frac{i}{m_e} \omega_{ja}^{-1} \langle a | \hat{P}_\alpha | j \rangle = -\frac{1}{m_e} \omega_{ja}^{-2} \langle a | \hat{F}_{n\alpha}^N | j \rangle \quad (65)$$

$$\langle a | \hat{L}_\alpha | j \rangle = i \omega_{ja}^{-1} \langle a | \hat{K}_{n\alpha}^N | j \rangle \quad (66)$$

where

$$\begin{aligned} \hat{R}_\alpha &= \sum_{i=1}^n r_{i\alpha}, \quad \hat{P}_\alpha = \sum_{i=1}^n \hat{p}_{i\alpha} \\ \hat{L}_\alpha &= \sum_{i=1}^n \hat{l}_{i\alpha}, \quad \hat{F}_{n\alpha}^N = -\sum_{I=1}^N \sum_{i=1}^n Z_I e \hat{E}_{I\alpha}^i \end{aligned} \quad (67)$$

are the operators for electron centroid, total canonical and angular momentum, and force exerted by the nuclei on the electrons.

3.1 Magnetic Dipole Properties

The frequency-dependent, or dynamic, paramagnetic contributions to the susceptibility and nuclear shielding, in the L formalism, are²

$$\chi_{(LL)\alpha\beta}^p(\omega) = \frac{e^2}{4m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2\omega_{ja}}{\omega_{ja}^2 - \omega^2} \text{Re}(\langle a | \hat{L}_\alpha | j \rangle \langle j | \hat{L}_\beta | a \rangle) \quad (68)$$

$$\sigma_{(L)\alpha\beta}^p(\omega) = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2\omega_{ja}}{\omega_{ja}^2 - \omega^2} \text{Re}(\langle a | \hat{B}_{I\alpha}^n | j \rangle \langle j | \hat{m}_\beta | a \rangle) \quad (69)$$

Using the torque Hamiltonian defined in equations (47), (57), and (58), or the hypervirial relations in equation (66), these properties become, in the KL and K formalisms,

$$\begin{aligned} \chi_{(KL)\alpha\beta}^p(\omega) &= -\frac{e^2}{4m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2 - \omega^2} \\ &\quad \times \text{Im}(\langle a | \hat{K}_{n\alpha}^N | j \rangle \langle j | \hat{L}_\beta | a \rangle) \end{aligned} \quad (70)$$

$$\begin{aligned} \sigma_{(K)\alpha\beta}^p(\omega) &= -\frac{e^2}{2m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2 - \omega^2} \\ &\quad \times \text{Im}(\langle a | \hat{M}_{I\alpha}^n | j \rangle \langle j | \hat{K}_{n\beta}^N | a \rangle) \end{aligned} \quad (71)$$

The paramagnetic susceptibility, in the KK formalism, is

$$\begin{aligned} \chi_{(KK)\alpha\beta}^p(\omega) &= \frac{e^2}{4m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}(\omega_{ja}^2 - \omega^2)} \\ &\quad \times \text{Re}(\langle a | \hat{K}_{n\alpha}^N | j \rangle \langle j | \hat{K}_{n\beta}^N | a \rangle) \end{aligned} \quad (72)$$

If $|a\rangle$ and $|j\rangle$ are exact eigenstates of $\hat{H}^{(0)}$ then

$$\chi_{(KK)}^p \equiv \chi_{(KL)}^p \equiv \chi_{(LL)}^p \equiv \chi^p, \quad \sigma_{(K)}^p \equiv \sigma_{(L)}^p \equiv \sigma^p \quad (73)$$

The diamagnetic contributions (independent of ω) are obtained as expectation values of the operators in equations (54) and (63):

$$\chi_{\alpha\beta}^d = \langle a | \hat{\chi}_{\alpha\beta}^d | a \rangle, \quad \sigma_{\alpha\beta}^{dI} = \langle a | \hat{\sigma}_{\alpha\beta}^{dI} | a \rangle \quad (74)$$

and total magnetic dipole response tensors are

$$\chi_{\alpha\beta}(\omega) = \chi_{\alpha\beta}^p(\omega) + \chi_{\alpha\beta}^d, \quad \sigma_{\alpha\beta}^I(\omega) = \sigma_{\alpha\beta}^{pI}(\omega) + \sigma_{\alpha\beta}^{dI} \quad (75)$$

It is sometimes convenient, for computational purposes, to introduce a perturbation expansion for the electron current density induced by a static external magnetic field and by an intramolecular nuclear magnetic dipole: to first order in B_β and $\mu_{I\beta}$,

$$J(\mathbf{r})_\alpha = J_\alpha^{(0)}(\mathbf{r}) + \mathcal{J}_\alpha^{B_\beta}(\mathbf{r}) B_\beta + \mathcal{J}_\alpha^{\mu_{I\beta}}(\mathbf{r}) \mu_{I\beta} + \dots \quad (76)$$

defining two second-rank current density tensors, $\mathcal{J}_\alpha^{B_\beta}$ and $\mathcal{J}_\alpha^{\mu_{I\beta}}$. The classical ansatz for the interaction energies, equations (8), (12), and (13), can be retained, using the total quantum current density, equation (76). As energies are gauge-invariant, the condition for charge conservation in a static magnetic field [cf. equation (23)], becomes,⁵ using equations (8) and (17) with $f = r_\beta$,

$$\int d^3r J_\alpha = 0 \quad (77)$$

The magnetic susceptibility and the nuclear magnetic shielding of nucleus I , at $\mathbf{R}_I$, can be expressed in terms of the current density, equation (76):

$$\begin{aligned}\chi_{\alpha\delta} &= \frac{1}{2c} \epsilon_{\alpha\beta\gamma} \int d^3r r_\beta \mathcal{J}_\gamma^{B_\delta}(\mathbf{r}) \\ \sigma_{\alpha\delta}^I &= -\frac{1}{c} \epsilon_{\alpha\beta\gamma} \int d^3r \frac{r_\beta - R_{I\beta}}{|\mathbf{r} - \mathbf{R}_I|^3} \mathcal{J}_\gamma^{B_\delta}(\mathbf{r}) \\ &= -\frac{1}{2c} \epsilon_{\beta\gamma\delta} \int d^3r r_\beta \mathcal{J}_\gamma^{\mu_I \alpha}(\mathbf{r})\end{aligned}\quad (78)$$

3.2 Magnetic Multipolar Contributions

Paramagnetic contributions to susceptibility and nuclear shielding in the L formalism, arising from higher magnetic moments, are evaluated using the unperturbed operators of equations (52) and (61). Mixed dipolar–multipolar paramagnetic susceptibilities are

$$\begin{aligned}\chi_{\alpha,\beta\gamma}^p(\omega) &= \frac{1}{\hbar} \sum_{j \neq a} \frac{2\omega_{ja}}{\omega_{ja}^2 - \omega^2} \text{Re}(\langle a | \hat{m}_\alpha | j \rangle \langle j | \hat{m}_{\beta\gamma} | a \rangle) \\ &= \chi_{\beta\gamma,\alpha}^p(\omega)\end{aligned}\quad (80)$$

$$\begin{aligned}\chi_{\alpha\beta,\gamma\delta}^p(\omega) &= \frac{1}{\hbar} \sum_{j \neq a} \frac{2\omega_{ja}}{\omega_{ja}^2 - \omega^2} \text{Re}(\langle a | \hat{m}_{\alpha\beta} | j \rangle \langle j | \hat{m}_{\gamma\delta} | a \rangle) \\ &= \chi_{\gamma\delta,\alpha\beta}^p(\omega)\end{aligned}\quad (81)$$

etc., where tensor indices are divided in groups (separated by a comma) that can be freely permuted, since they refer to different multipoles, equation (52). The contributions to nuclear magnetic shielding from higher magnetic multipoles are

$$\sigma_{\alpha,\beta\gamma}^{pI}(\omega) = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2\omega_{ja}}{\omega_{ja}^2 - \omega^2} \text{Re}(\langle a | \hat{B}_{I\alpha}^n | j \rangle \langle j | \hat{m}_{\beta\gamma} | a \rangle) \quad (82)$$

etc., where a comma separates the index for a component of the nuclear magnetic moment and a group of indices relative to the field gradients. $\chi_{\alpha,\beta\beta}^p(\omega) = 0 = \chi_{\alpha\beta,\gamma\gamma}^p(\omega)$ and $\sigma_{\alpha,\beta\beta}^{pI}(\omega) = 0 = \sigma_{\alpha\beta,\gamma\gamma}^{pI}(\omega)$, etc. The diamagnetic contributions, from equations (55) and (64), are

$$\chi_{\alpha\beta,\gamma}^d = \langle a | \hat{\chi}_{\alpha\beta,\gamma}^d | a \rangle, \quad \chi_{\alpha\beta,\gamma\delta}^d = \langle a | \hat{\chi}_{\alpha\beta,\gamma\delta}^d | a \rangle \quad (83)$$

$$\sigma_{\alpha,\beta\gamma}^{dI} = \langle a | \hat{\sigma}_{\alpha,\beta\gamma}^{dI} | a \rangle, \quad \sigma_{\alpha,\beta\gamma\delta}^{dI} = \langle a | \hat{\sigma}_{\alpha,\beta\gamma\delta}^{dI} | a \rangle \quad (84)$$

etc. Therefore the magnetic moments induced by a nonuniform magnetic field can be written as

$$\begin{aligned}\Delta \langle \hat{m}'_\lambda \rangle &= \chi_{\lambda\alpha} B(\mathbf{0}, t)_\alpha + \chi_{\lambda,\alpha\beta} B(\mathbf{0}, t)_{\beta\alpha} \\ &\quad + \chi_{\lambda,\alpha\beta\gamma} B(\mathbf{0}, t)_{\gamma\beta\alpha} + \dots\end{aligned}\quad (85)$$

$$\begin{aligned}\Delta \langle \hat{m}'_{\lambda\mu} \rangle &= \chi_{\lambda\mu,\alpha} B(\mathbf{0}, t)_\alpha + \chi_{\lambda\mu,\alpha\beta} B(\mathbf{0}, t)_{\beta\alpha} \\ &\quad + \chi_{\lambda\mu,\alpha\beta\gamma} B(\mathbf{0}, t)_{\gamma\beta\alpha} + \dots\end{aligned}\quad (86)$$

etc., where the total dipolar–multipolar susceptibilities are defined, for example, by

$$\chi_{\alpha,\beta\gamma}(\omega) = \chi_{\alpha,\beta\gamma}^p(\omega) + \chi_{\alpha\beta,\gamma}^d \quad (87)$$

$$\chi_{\alpha\beta,\gamma\delta}(\omega) = \chi_{\alpha\beta,\gamma\delta}^p(\omega) + \frac{16}{9} \chi_{\alpha\gamma,\beta\delta}^d = \chi_{\gamma\delta,\alpha\beta}(\omega) \quad (88)$$

The magnetic field induced on nucleus I by the electron cloud perturbed by a nonuniform magnetic field is

$$\begin{aligned}\Delta \langle \hat{B}_{I\alpha}^n \rangle &= -\sigma_{\alpha\beta}^I B(\mathbf{0}, t)_\beta - \sigma_{\alpha,\beta\gamma}^I B(\mathbf{0}, t)_{\gamma\beta} \\ &\quad - \sigma_{\alpha,\beta\gamma\delta}^I B(\mathbf{0}, t)_{\delta\gamma\beta} + \dots\end{aligned}\quad (89)$$

where the multipolar contributions to the total dynamic magnetic shieldings are

$$\sigma_{\alpha,\beta\gamma}^I(\omega) = \sigma_{\alpha,\beta\gamma}^{pI}(\omega) + \sigma_{\alpha,\beta\gamma}^{dI} \quad (90)$$

etc. Magnetic multipolar effects are invoked to rationalize ‘contact shifts’.³

3.3 Magnetic Properties in the Landau Gauge

In this gauge [cf. equations (42) and (43)], the total n electron interaction Hamiltonian contains the terms

$$\hat{H}_L^B = \frac{e}{m_e c} \sum_{i=1}^n (A_\alpha^L \hat{p}_\alpha)_i \quad (91)$$

$$\hat{H}_L^{BB} = \frac{e^2}{m_e c^2} \left(B_x^2 \sum_{i=1}^n y_i^2 + B_y^2 \sum_{i=1}^n z_i^2 + B_z^2 \sum_{i=1}^n x_i^2 \right) \quad (92)$$

In the reference state $|a\rangle$, the diamagnetic contribution to the susceptibility is⁶

$$\chi_{xx}^{\text{dL}} = -\frac{\partial^2}{\partial B_x^2} \langle a | \frac{1}{2} \hat{H}_L^{BB} | a \rangle = -\frac{e^2}{m_e c^2} \langle a | \sum_{i=1}^n y_i^2 | a \rangle \chi_{xy}^{\text{dL}} = 0, \dots \quad (93)$$

(other tensor components are obtained by cyclic permutation of the indices x , y , and z). Off-diagonal diamagnetic components vanish for any coordinate system in the Landau gauge. The paramagnetic contribution is

$$\chi_{xx}^{\text{pL}} = \frac{e^2}{m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \text{Re} \left[\langle a | \sum_{i=1}^n (y p_z)_i | j \rangle \langle j | \sum_{i=1}^n (y p_z)_i | a \rangle \right] \quad (94a)$$

$$\chi_{xy}^{\text{pL}} = \frac{e^2}{m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \text{Re} \left[\langle a | \sum_{i=1}^n (y p_z)_i | j \rangle \langle j | \sum_{i=1}^n (z p_x)_i | a \rangle \right] \quad (94b)$$

etc. It is a symmetric tensor, as in the Coulomb gauge, diagonal only in its principal axis system: the off-diagonal components of total susceptibility are paramagnetic and, remarkably, origin-independent in the Landau gauge for molecular symmetries equal to or larger than c_{2v} .

In the presence of a nuclear magnetic dipole, the interaction Hamiltonian contains the terms $-\mu_{I\alpha} \hat{B}_{I\alpha}^n$ and $\hat{H}_L^{\mu_I B} = (e^2/m_e c) \sum_{i=1}^n (A_\alpha^{\mu_I} A_\alpha^L)_i$. The diamagnetic contribution to the shielding of nucleus I becomes

$$\sigma_{xx}^{\text{dIL}} = \frac{\partial^2}{\partial \mu_{Ix} \partial B_x} \langle a | \hat{H}_L^{\mu_I B} | a \rangle = \frac{e}{m_e c^2} \langle a | \sum_{i=1}^n y_i \hat{E}_{Iy}^i | a \rangle \quad (95a)$$

$$\sigma_{yx}^{\text{dIL}} = \frac{\partial^2}{\partial \mu_{Iy} \partial B_x} \langle a | \hat{H}_L^{\mu_I B} | a \rangle = -\frac{e}{m_e c^2} \langle a | \sum_{i=1}^n y_i \hat{E}_{Ix}^i | a \rangle \quad (95b)$$

etc. For any coordinate system, $\sigma_{xy}^{d/L} = \sigma_{yz}^{d/L} = \sigma_{zx}^{d/L} = 0$, i.e., the diamagnetic contribution to the shielding of nucleus I is a second-rank asymmetric tensor with a maximum of six independent components. The paramagnetic contribution is

$$\sigma_{xx}^{p/L} = -\frac{e^2}{m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \operatorname{Re} \left[\langle a | \hat{M}_{Ix}^n | j \rangle \langle j | \sum_{i=1}^n (y \hat{p}_z)_i | a \rangle \right] \quad (96a)$$

$$\sigma_{xy}^{p/L} = -\frac{e^2}{m_e^2 c^2 \hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \operatorname{Re} \left[\langle a | \hat{M}_{Ix}^n | j \rangle \langle j | \sum_{i=1}^n (z \hat{p}_x)_i | a \rangle \right] \quad (96b)$$

etc. It is an asymmetric tensor with nine independent components in the absence of molecular symmetry; $\sigma_{xy}^{p/L}$, $\sigma_{yz}^{p/L}$, and $\sigma_{zx}^{p/L}$ are paramagnetic and origin-independent.

Diamagnetic contributions in different gauges are related by

$$\chi_{xx}^{dC} = \frac{1}{4}(\chi_{xx}^{dL} + \chi_{yy}^{dL}), \quad \chi_{\alpha\alpha}^{dC} = \frac{1}{2}\chi_{\alpha\alpha}^{dL} \quad (97)$$

$$\sigma_{xx}^{d/C} = \frac{1}{2}(\sigma_{xx}^{d/L} + \sigma_{yy}^{d/L}), \quad \sigma_{yx}^{d/C} = \frac{1}{2}\sigma_{yx}^{d/L}, \quad \sigma_{\alpha\alpha}^{d/C} = \sigma_{\alpha\alpha}^{d/L} \quad (98)$$

From the hypervirial relation

$$\langle a | \sum_{i=1}^n (x \hat{p}_y)_i | j \rangle = \frac{1}{2} \langle a | \hat{L}_z | j \rangle - \frac{1}{2} i m_e \omega_{ja} \langle a | \sum_{i=1}^n (xy)_i | j \rangle \quad (99)$$

the equations connecting the paramagnetic contributions in the Landau and Coulomb gauges are

$$\chi_{xx}^{pL} = \chi_{xx}^{pC} + \frac{1}{4}(\chi_{yy}^{dL} - 3\chi_{xx}^{dL}), \quad \chi_{xy}^{pL} = \chi_{xy}^{pC} \quad (100)$$

$$\sigma_{xx}^{p/L} = \sigma_{xx}^{p/C} + \frac{1}{2}(\sigma_{yy}^{d/L} - \sigma_{xx}^{d/L}), \quad \sigma_{yx}^{p/L} = \sigma_{yx}^{p/C} - \sigma_{yx}^{d/L} \quad (101)$$

In calculations based on the algebraic approximation, equations (97) and (98) are satisfied identically for any basis set. On the other hand, equations (100) and (101) are obeyed if and only if equation (99) is satisfied, for example, if $|a\rangle$ and $|j\rangle$ are exact Hartree–Fock states.² If a finite basis set is employed according to the self-consistent field scheme, the degree to which equations (100) and (101) are fulfilled gives a measure of the accuracy of the calculation, i.e., information on the quality of the basis set and its degree of completeness with respect to the operators involved: total magnetic properties are invariant in a gauge transformation, equation (40), only if the basis set is complete.

3.4 Diamagnetic Contributions in Propagator Form

For one electron, the diamagnetic contributions to magnetic properties arise from

$$A_\alpha A_\alpha = \frac{1}{4} \epsilon_{\alpha\beta\gamma} B_\beta r_\gamma \epsilon_{\alpha\lambda\mu} B_\lambda r_\mu \quad (102)$$

$$A_\alpha A_\alpha^{\mu_I} = \frac{1}{2e} \epsilon_{\alpha\beta\gamma} B_\beta r_\gamma \epsilon_{\alpha\lambda\mu} \mu_{I\lambda} \hat{E}_{I\mu} \quad (103)$$

Using $[\hat{A}, \hat{B}\hat{C}] = [\hat{A}, \hat{B}]\hat{C} + \hat{B}[\hat{A}, \hat{C}]$ in the commutators

$$\frac{i}{\hbar} [r_\beta, \hat{I}_\alpha] = \epsilon_{\alpha\beta\gamma} r_\gamma, \quad \frac{i}{\hbar} [\hat{M}_{I\lambda}, r_\alpha] = \epsilon_{\alpha\lambda\mu} \hat{E}_{I\mu} \quad (103)$$

one obtains the relationships

$$A_\alpha A_\alpha = \frac{i}{4\hbar} B_\gamma B_\delta \epsilon_{\alpha\beta\gamma} [r_\alpha, r_\beta \hat{I}_\delta] \\ = \frac{i}{8\hbar} B_\gamma B_\delta (\epsilon_{\alpha\beta\gamma} [r_\alpha, r_\beta \hat{I}_\delta] + \epsilon_{\alpha\beta\delta} [\hat{I}_\alpha r_\beta, r_\gamma]) \quad (104)$$

$$A_\alpha A_\alpha^{\mu_I} = -\frac{i}{2\hbar} B_\gamma \mu_{I\delta} \epsilon_{\alpha\beta\gamma} [r_\beta \hat{M}_{I\delta}, r_\alpha] \quad (105)$$

For n electrons, using these commutators, the first of equation (65), and the resolution of the identity $\sum_j |j\rangle \langle j| = \hat{1}$, the diamagnetic contributions to susceptibility and nuclear shielding are (cf. similar formulae by Geertsen⁷)
